ABSTRACT

We describe the algorithm that selects the main sample of galaxies for spectroscopy in the Sloan Digital Sky Survey from the photometric data obtained by the imaging survey. Galaxy photometric properties are measured using the Petrosian magnitude system, which measures flux in apertures determined by the shape of the surface brightness profile. The metric aperture used is essentially independent of cosmological surface brightness dimming, foreground extinction, sky brightness, and the galaxy central surface brightness. The main galaxy sample consists of galaxies with r-band Petrosian magnitude $r \leq 17.77$ and r-band Petrosian half-light surface brightness $\mu_{50} \leq 24.5$ magnitudes per square arcsec. These cuts select about 90 galaxy targets per square degree, with a median redshift of 0.104. We carry out a number of tests to show that (a) our star-galaxy separation criterion is effective at eliminating nearly all stellar contamination while removing almost no genuine galaxies, (b) the fraction of galaxies eliminated by our surface brightness cut is very small ($\sim 0.1\%$), (c) the completeness of the sample is high, exceeding 99%, and (d) the reproducibility of target selection based on repeated imaging scans is consistent with the expected random photometric errors. The main cause of incompleteness is blending with saturated stars, which becomes more significant for brighter, larger galaxies. The SDSS spectra are of high enough signal-to-noise ratio ($S/N > 4$ per pixel) that essentially all targeted galaxies (99.9%) yield a reliable redshift (i.e., with statistical error $< 30\,\mathrm{km\,s^{-1}}$). About 6% of galaxies that satisfy the selection criteria are not observed because they have a companion closer than the 55″ minimum separation of spectroscopic fibers, but these galaxies can be accounted for in statistical analyses of clustering or galaxy properties. The uniformity and completeness of the galaxy sample make it ideal for studies of large scale structure and the characteristics of the galaxy population in the local universe.

Subject headings: surveys — galaxies:distances and redshifts — galaxies:photometry

1. Introduction

The Sloan Digital Sky Survey (SDSS; York et al. 2000) is carrying out an imaging survey in five photometric bands of π ster in the north Galactic cap, and a follow-up spectroscopic survey of roughly 10^6 galaxies and 10^5 quasars, complete within precisely defined selection criteria. The main scientific drivers of the SDSS are the large-scale distributions

of galaxies and quasars. In order to carry out precise measurements of galaxy clustering on the largest scales, and to measure the distribution of galaxy properties with the highest possible precision, it is necessary that the sample of galaxies for which spectra are taken be selected in a uniform and objective manner. The northern spectroscopic survey targets two samples of galaxies: a flux-limited sample to $r = 17.77$ (hereafter called the main sample) and a flux- and color-selected sample extending to $r = 19.5$, designed to target luminous red galaxies (LRGs). This paper describes the algorithm used to select the main galaxy sample and presents demonstrations that the algorithm meets the survey goals of uniformity and completeness. A separate paper (Eisenstein et al. 2001) discusses the LRG sample.

1.1. The Sloan Digital Sky Survey

The SDSS hardware, software, and data products are summarized by York et al. (2000) and Stoughton et al. (2002). In brief, the survey is carried out using a dedicated, wide-field 2.5m telescope, a mosaic CCD camera (Gunn et al. 1998), two fiber-fed double spectrographs, and an auxiliary 0.5 m telescope for photometric calibration. The imaging is done in drift scan mode with the 30 photometric CCDs of the mosaic camera imaging ≈ 20 square degrees per hour, in five broad bands, u, g, r, i and z (Fukugita et al. 1996) that cover the entire optical range from the atmospheric ultraviolet cutoff in the blue to the sensitivity limit of silicon CCDs in the red. The imaging data are 95% complete for point sources at $r^* \approx 22.2$, and the photometric calibration is accurate to about 3% in r at this writing (Hogg et al. 2001; Smith et al. 2002). Because this calibration is still preliminary, we will refer to current measurements with the notation u^*, g^*, r^*, i^*, z^*, but we use u, g, r, i, z to refer to the SDSS filter and magnitude system itself.[21] The astrometric calibration (Pier et al. 2002) is done by comparison with the Tycho-2 (Høg et al. 2000) and UCAC (Zacharias et al. 2000) standards, and is accurate to 0.1 arcsec rms per coordinate.

The imaging data are reduced using a series of interlocking pipelines (`photo`; Lupton et al. 2001), which flat-field the data, find all objects, match up detections in the different bands and perform measurements of their properties, and apply the photometric and astrometric calibrations. Spectroscopic targets — the galaxies described in this paper, LRGs (Eisenstein et al. 2001), quasars (Richards et al. 2002), and a variety of other categories of objects (Stoughton et al. 2002), are chosen from the resulting catalog of detected objects.

The spectroscopic component of the survey is carried out using two fiber-fed double

---

[21]This notation is a change from some earlier papers, including Fukugita et al. (1996), which referred to the filter system as u', g', r', i', z'; see the discussion by Stoughton et al. (2002).

spectrographs, covering the wavelength range 3800Å to 9200Å over 4098 pixels. They have a resolution $\lambda/\Delta\lambda$ varying between 1850 and 2200, and together they are fed by 640 fibers, each with an entrance diameter of $3''$. The fibers are manually plugged into plates inserted into the focal plane; the mapping of fibers to plates is carried out by a tiling algorithm (Blanton et al. 2001b) that optimizes observing efficiency in the presence of large-scale structure. The finite diameter of the fiber cladding prevents fibers on any given plate from being placed closer than $55''$ apart.

For any given plate, a series of fifteen-minute exposures is carried out until the mean signal to noise ratio (S/N) per resolution element exceeds 4 for objects with fiber magnitudes (i.e., as measured through the $3''$ aperture of the fiber) brighter than $g^* = 20.2$ and $i^* = 19.9$, as determined by preliminary reductions done at the observing site. Under good conditions (dark, clear skies and good seeing), this typically requires a total of 45 minutes of exposure.

1.2. The Main Galaxy Spectroscopic Sample

The main galaxy spectroscopic survey is fully sampled to its magnitude limit within the survey footprint, which is planned to be an elliptical area of extent $110° \times 130°$, chosen to minimize Galactic extinction and maximize observing efficiency. The median redshift of this sample is $z \approx 0.1$. This large galaxy sample will allow us to measure many independent modes of the density fluctuations on scales comparable to the peak of the galaxy power spectrum, largely free from the aliasing that can affect surveys with at least one narrow dimension (cf., Kaiser & Peacock 1991; Tegmark 1995). For some instrumental set-ups and scientific goals (e.g., low-order measures of large scale clustering), one can gain efficiency by sparse sampling, i.e., by observing only a fraction of the galaxies down to some limiting magnitude (cf., Kaiser 1986). However, sparse sampling adversely affects other kinds of investigation, including group and cluster studies, high-order clustering measures, and recovery of the underlying galaxy density field (see, e.g., Szapudi & Szalay 1996). Moreover, the field of view and number of spectroscopic fibers of the SDSS were chosen to allow simultaneous spectroscopy of essentially *all* the galaxies in a given field to the faintest magnitude for which the 2.5m telescope can measure redshifts in a reasonable amount of time. We have therefore opted for complete sampling in the main galaxy redshift survey.

We wish to select a magnitude-limited galaxy sample. We have carried out the selection in a single observed band for simplicity. We wish the galaxy detection and photometric measurement in that band to be of high S/N, and we prefer a red passband so that K corrections are modest, fluxes are determined mainly by the older stars that dominate the stellar mass, and uncertainties in Galactic reddening make little difference to the inferred

galaxy magnitude. In the SDSS filter system, this implies either the r or i band. We adopt the former because the sky background is brighter and more variable in the i band than in the r band. The use of a red bandpass tilts the sample slightly towards galaxies of earlier morphological type, but at these bright magnitudes, the $g - r$ color distribution of galaxies is quite narrow (Ivezić et al. 2002), and the distribution of galaxy types is not radically different from what we would obtain with g-band selection (see also Fig. 4 of Shimasaku et al. 2001).

Although we will detail a number of subtleties below, the basic procedure that we use to define galaxy magnitudes and select spectroscopic targets can be summarized as follows. Star-galaxy separation is carried out by comparing the exponential or de Vaucouleurs model magnitude of an object to its Point Spread Function (PSF) magnitude. We define the (angular) Petrosian radius θ_P of a galaxy to be the radius at which the local surface brightness in an annulus about θ_P is $1/5$ of the mean surface brightness within θ_P. We define the r-band Petrosian magnitude of a galaxy, r_P, based on the flux within a circular aperture of radius $2\,\theta_P$. In the absence of seeing effects, the Petrosian magnitude measures the light within a well-defined metric aperture on any given galaxy which is independent of its redshift or foreground extinction. We define the half-light surface brightness μ_{50} to be the mean surface brightness within a circular aperture containing half of the Petrosian flux. The main galaxy sample consists of galaxies with $r_P \leq 17.77$ and $\mu_{50} \leq 24.5$ magnitudes per square arcsec, after correcting for Galactic extinction following Schlegel, Finkbeiner, & Davis (1998; hereafter SFD).

The outline of this paper is as follows. In § 2, we describe our goals for the target selection algorithm. We discuss the measurements of Petrosian quantities in detail in § 3 and Appendix A. The target selection algorithm itself is described in § 4. Various tests to show that the algorithm meets the survey requirements are described in § 5. We conclude in § 6.

2. Desired properties of the Selection Algorithm

The SDSS spectroscopic galaxy surface density is roughly 100 galaxies per square degree. From studies of galaxy number counts (Yasuda et al. 2001), a fully sampled magnitude-limited survey reaches this surface density at a magnitude limit of $r \approx 18$. There are several desiderata for a galaxy spectroscopic target selection algorithm:

1. The selection algorithm should allow accurate determination of a selection function, whereby the probability that a galaxy with given properties (magnitude, color, surface

brightness, redshift, position on the sky, presence of neighbors) is targeted can be objectively quantified. To the extent possible, this selection function should depend only on redshift, and should be independent of seeing, stellar contamination, Galactic extinction, and spectroscopic observing conditions.

2. The algorithm should be based on physically meaningful parameters which are tied as closely as possible to the properties of the galaxies. We must be able to measure these parameters accurately for the sample of galaxies whose spectra we plan to obtain.

3. The algorithm should select a uniform sample of galaxies with a wide range of physical properties, without biasing against, for example, galaxies of unusual color or low surface brightness.

4. The algorithm should select galaxies for which we are able to obtain a spectrum of sufficient quality to yield a redshift in the nominal exposure time. One area of concern in this context will be galaxies with low surface brightness, for which the total light down the 3″ entrance aperture of the fiber will be small.

5. Finally, the selection algorithm should be simple, and its behavior should be straightforward and easy to understand. This makes it easier to test the algorithm, and it will facilitate the construction of realistic mock catalogs of the SDSS galaxy redshift survey from numerical simulations of large-scale structure (e.g., Cole et al. 1998; Colley et al. 2000).

These desiderata do not always point in the same direction. For example, one might maximize the redshift success by selecting on the 3″ fiber magnitude. However, this measures a fraction of the galaxy light that is strongly dependent on redshift and the atmospheric seeing during the imaging observations, making it quite difficult to determine a meaningful selection function; moreover, it biases strongly against low-surface brightness galaxies. Similarly, isophotal magnitudes measure a fraction of the total galaxy light that depends on foreground extinction, sky brightness (if the isophotal threshold is set relative to the sky level), and redshift (because of cosmological surface brightness dimming). After weighing a number of options, we have settled on an algorithm that employs a modified form of the Petrosian (1976) magnitude system, with galaxies selected in r-band.

3. Petrosian Quantities

3.1. Definition of Petrosian Quantities

The Petrosian (1976) magnitude is based on the flux within an aperture defined by the ratio of the local surface brightness to the mean interior surface brightness. The size of this aperture depends on the *shape* of the galaxy's radial surface brightness profile but not its amplitude.

Let $I(\theta)$ be the azimuthally averaged surface brightness profile of a galaxy, as a function of angular distance from its center, θ. We define the *Petrosian ratio* as the ratio of the surface brightness in an annulus $0.8\theta - 1.25\theta$ to the mean surface brightness within θ,

$$\mathcal{R}(\theta) = \frac{2\pi \int_{0.8\theta}^{1.25\theta} I(\theta')\theta'd\theta' / \left[\pi\left((1.25\theta)^2 - (0.8\theta)^2\right)\right]}{2\pi \int_0^\theta I(\theta')\theta'd\theta'/(\pi\theta^2)} \ . \tag{1}$$

The use of a fairly thick annulus reduces the sensitivity of $\mathcal{R}(\theta)$ to noise and to small scale fluctuations in $I(\theta)$. We define the Petrosian radius θ_P by the implicit equation

$$\mathcal{R}(\theta_P) = f_1 \ , \tag{2}$$

where f_1 is a constant, which we set to 0.2. The Petrosian *flux* is defined as the flux within a circular aperture of radius f_2 times the Petrosian radius,

$$F_P = 2\pi \int_0^{f_2\theta_P} I(\theta')\theta'd\theta' \ , \tag{3}$$

and we set $f_2 = 2$ (hereafter, we refer to $f_2\theta_P$ as the *Petrosian aperture*). It will also be useful to formally define a total flux, $F_{\rm tot}$, as the result of the integral in equation (3) out to infinity. The choice of f_1 and f_2 is discussed in §3.2 below. Note that equation (2) for the Petrosian radius may have more than one solution; in this case, we take the outermost of the solutions. The technical details of how photo measures all these quantities are given in Appendix A. Note that the images of overlapping galaxies are deblended using a robust code that conserves flux (Lupton et al., in preparation).

The Petrosian magnitude is defined from the Petrosian flux in the usual way, once the conversion between detected counts and calibrated fluxes is determined. Note, however, that this conversion for SDSS photometry is strictly valid only for point sources, for which a proper aperture correction can be quantified; we ignore this complication in what follows. Our magnitude system is based on the AB_{95} system (Fukugita et al. 1996); i.e., the mean flux density over any of the broad pass-bands is $\overline{f} = 3631 \times 10^{-0.4m}$ Jy, to a fair approximation (see the caveats in Stoughton et al. 2002). We use the asinh magnitude definition of Lupton,

Szalay, & Gunn (1999), which behaves well in the regime of low S/N, though for the bright galaxies in the spectroscopic sample the difference between asinh magnitudes and traditional logarithmic magnitudes is negligible. We refer to the r-band Petrosian apparent magnitude as r_P and to PSF and model magnitudes (see §4.2 below) as r_{PSF} and r_{model}.

Our target selection algorithm also requires a measure of surface brightness, for which we want to retain the desirable properties of the Petrosian system. The surface brightness within θ_P is an obvious choice, but it turns out to be rather noisy. Instead, we define the Petrosian half-light radius θ_{50} as that which encloses half the Petrosian flux,

$$\int_0^{\theta_{50}} I(\theta')\theta'd\theta' = 0.5 \int_0^{f_2\theta_P} I(\theta')\theta'd\theta' \ , \qquad (4)$$

and use the mean surface brightness within this radius,

$$\mu_{50} = r_P + 2.5 \log\left[2\,\pi\theta_{50}{}^2\right] . \qquad (5)$$

Because the flux within $2\theta_P$ is insensitive to small errors in θ_P, the quantities θ_{50} and μ_{50} can be robustly measured.

Figure 1 illustrates our definitions for the case of a circular de Vaucouleurs profile (top; $I(\theta) = I_0 \exp[-7.67(\theta/\theta_e)^{-/4}]$) and a face-on exponential disk (bottom; $I(\theta) = I_0 \exp[-1.68\,\theta/\theta_e]$). Dotted, dashed, and solid curves show the surface brightness profile, curve of growth, and Petrosian ratio $\mathcal{R}(\theta)$. Arrows mark the Petrosian half-light radius θ_{50}, the Petrosian radius θ_P at which $\mathcal{R} = f_1 = 0.2$ and the Petrosian aperture at $f_2\theta_P = 2\theta_P$. The Petrosian radius corresponds to 2.1 effective (or half-light) radii (3.5 scale lengths) for an exponential profile and 1.7 effective radii for a de Vaucouleurs profile. The $2\theta_P$ Petrosian aperture encompasses 99% and 82% of the galaxy's total light in the two cases. The Petrosian half-light radius θ_{50} is slightly smaller than the true half-light radius, since the Petrosian flux is less than the total flux.

Note that we use circular apertures rather than elliptical apertures for all measurements. Elliptical apertures are difficult to choose for galaxies whose light distributions are not well described by concentric self-similar ellipses. Moreover, for disk galaxies, the circular-aperture surface brightness profile is also less sensitive to inclination than the elliptical-aperture profile, at least to the extent that internal extinction can be neglected. Because the Petrosian aperture is always large enough to contain most of a galaxy's light, the ratio of the Petrosian flux to total flux is insensitive to inclination (or de Vaucouleurs axis ratio), as shown in Figure 2.

In the absence of noise, the Petrosian aperture is unaffected by foreground extinction or by the cosmological dimming of the surface brightness. Thus, identical galaxies seen at two

different (luminosity) distances have fluxes related exactly as distance^{-2} (in the absence of K corrections). One can therefore determine the maximum distance at which a galaxy would enter a flux-limited sample without knowing the galaxy's surface brightness profile (which would be needed for the equivalent calculation with, e.g., isophotal magnitudes). Moreover, two galaxies that have the same surface brightness profile shape but different central surface brightness have the same fraction of their flux represented in the Petrosian magnitude, so there is no bias against the selection of low surface brightness galaxies of sufficiently bright Petrosian magnitude. In the absence of noise, the Petrosian magnitude is independent of sky brightness, and for the large angular extent of the galaxies of the spectroscopic sample, it is also insensitive to seeing.

3.2. Setting f_1 and f_2

Here we describe the rationale behind our choice for the Petrosian parameters $f_1 = 0.2$ and $f_2 = 2$. Setting f_1 too high would increase our sensitivity to seeing (by making θ_P small), while setting it too low would require measuring the Petrosian ratio at a point that the surface brightness is many magnitudes below that of the sky, making us particularly sensitive to sky subtraction effects. If the Petrosian aperture f_2 is too large, the measurement of the Petrosian flux is badly affected by sky noise and uncertainty in the sky level. If the aperture is too small, on the other hand, then the Petrosian magnitude departs substantially from the theoretical ideal of a total magnitude, and, equally important, it becomes sensitive to seeing and to noise in the measurement of θ_P.

We have carried out extensive simulations of galaxies with realistic distributions of surface brightness and bulge-to-disk ratio (following Fukugita, Hogan, & Peebles 1998), and have processed the resulting images through `photo` with a range of choices for the Petrosian parameters. We find that seeing has an appreciable effect on the Petrosian quantities for galaxies that would be in the spectroscopic sample, when $f_1 \geq 0.25$. In the simulations, only 2% of the galaxies fail to have a Petrosian radius measured (i.e., i.e., the S/N is too low to measure the Petrosian ratio down to f_1) at the spectroscopic limit for $f_1 = 0.2$, but the fraction of such failures becomes appreciable at smaller f_1. See Yagi et al. (2002) for a similar discussion. Note that `photo` still reports a reasonable measure of a "Petrosian" magnitude even if it is unable to measure a Petrosian radius for a given object (Appendix A).

Given a value of f_1, the quantity f_2 sets the Petrosian aperture. Figure 3 shows the fraction of light within the Petrosian aperture for various combinations of f_1 and f_2 (the effect of seeing is not included here, but for a given value of f_1, the dependence of F_P/F_{tot} on seeing is quite weak; see further discussion below). For many reasonable combinations of

Petrosian parameters, one gets almost 100% of the light in the Petrosian aperture for galaxies with exponential profiles. De Vaucouleurs profiles are much more extended, however, and an appreciable fraction of their light lies in the regime in which the S/N per pixel is appreciably below unity. An aperture large enough to enclose, say, 95% of the light of a de Vaucouleurs profile includes many low S/N pixels and thus a substantial amount of sky noise. For $f_1 = 0.2$, the fraction of light included in the Petrosian aperture for a de Vaucouleurs profile rises from 82% to 89% as f_2 ranges from 2 to 3. However, the simulations mentioned above show that the photometric errors in Petrosian magnitudes at the galaxy spectroscopic survey limit increase from 0.03 mag to 0.09 mag over this f_2 range. We have therefore settled on the value $f_2 = 2$, to keep the S/N of Petrosian magnitudes high while still retaining most of the light for de Vaucouleurs galaxies.

For any given morphological type (at least as defined by the surface brightness profile), the correction from a Petrosian to a total magnitude is an additive constant (fixed multiplicative factor for the flux), only weakly dependent upon inclination (Figure 2). Any scientific analysis that uses the redshift survey must consider whether a different fraction of light is included for ellipticals and spirals affects the result. This is important for such analyses as the total luminosity density of the universe (e.g., Yasuda et al. 2001; Blanton et al. 2001a), but it does not enter in calculating the radial selection function for large-scale structure studies (as the fraction of light is independent of redshift). This dependence of the fraction of the light measured on the galaxy light profile is unavoidable for any target selection algorithm.

3.3. Effects of seeing, redshift, and sky background

The effect of seeing on Petrosian quantities is not completely negligible, as is shown by Figures 1 and 2 of Blanton et al. (2001a). For a poorly resolved galaxy, the surface brightness profile approaches that of a PSF, and the ratio of Petrosian flux to total flux approaches 0.95, the value for a PSF. Thus, as the seeing radius approaches the half-light radius, the Petrosian flux of an exponential galaxy is biased downward, and the Petrosian flux of a de Vaucouleurs law galaxy is biased upward. In practice, a galaxy with $\theta_{50} = 2''$ observed in 1.5$''$ seeing will have its Petrosian magnitude biased by 1-3% depending on profile and axis ratio, and these effects are much smaller for larger galaxies (see Blanton et al. 2001a, Fig. 1). Roughly 35% of galaxies in the spectroscopic sample have $\theta_{50} < 2''$. At the spectroscopic magnitude limit, the typical measurement error in Petrosian magnitudes is ~ 0.035 magnitudes (see Figure 12 and the accompanying discussion in §5.4 below), so seeing effects are small compared to photon noise for the great majority of galaxies in the

spectroscopic sample.

A related issue is the scaling of Petrosian magnitudes with redshift. Figure 4 shows the redshift dependence of the measured R_p, the Petrosian radius expressed in h^{-1} kpc, for galaxies in three narrow slices in absolute magnitude from the SDSS redshift survey. In the absence of evolution and seeing effects, there should be no redshift dependence at all. In the middle panel, the redshift dependence causes a 20% increase in the measured Petrosian radius over the redshift range spanned; for a typical galaxy in the SDSS, the last 20% in radius contains about 5% of the galaxy flux, which is thus an upper limit to the expected systematic effects on redshift (Blanton et al., in preparation, conclude that the systematic effects are in fact considerably smaller than this).

Photometry of objects requires a model for the underlying sky brightness over the extent of the object. For objects that have at least one pixel in any band with flux greater than $200\sigma_{sky}$, where σ_{sky} is the rms amplitude of fluctuations in sky level in that band (this corresponds roughly to objects brighter than $r^* = 17.5$), photo measures the magnitudes twice, using two different models for the sky brightness. The first measurement (called the BRIGHT measurement) uses a global sky value determined over an entire frame, and the second uses a model for the local sky estimated by median-smoothing the image on a scale of approximately $100''$, and thus will be biased high by objects of large angular extent. The difference between these two magnitudes of an object is a reasonable estimate of the photometric error arising from uncertainties in determining the sky underneath an object; in particular, one might be concerned that galaxies of large angular extent will artificially raise the estimate of the local sky, therefore biasing their photometry low. Using 210 galaxies with $r^* < 16$ from the SDSS Early Data Release (Stoughton et al. 2002), we found that 90% of the objects lie in the range $-0.020 < r^*(\text{local sky}) - r^*(\text{global sky}) < 0.065$. Of course, all of these galaxies easily pass the magnitude limit, and the difference between local and global sky subtraction is smaller for the (far more numerous) smaller galaxies with $r^* > 16$. We therefore expect negligible systematic bias in target selection associated with sky subtraction, though there remains a small bias in the magnitudes of large galaxies much brighter than the survey limit. For target selection, we adopt the magnitudes of all galaxies measured using the local sky measurement.

4. The Galaxy Spectroscopic Target Selection Algorithm

The galaxy target selection algorithm is shown schematically as a flowchart in Figure 5. The details of this algorithm have been fine-tuned largely from imaging and spectroscopic observations of a 2.5° wide stripe, 91° degrees long, centered on the Celestial Equator in the

Northern Galactic Cap (Runs 752 and 756), observed during the commissioning period of the SDSS (Stoughton et al. 2002). These are the data for which galaxy counts were presented by Yasuda et al. (2001), and the galaxy luminosity function was presented by Blanton et al. (2001a). The distribution on the sky of galaxies selected by the algorithm is shown in Figure 6. Large-scale structure is of course apparent. The SDSS imaging data in this stripe are taken in a series of twelve parallel *scanlines*; note that the edges between scanlines are *not* apparent, which shows qualitatively that the imaging data are calibrated, and galaxy selected, consistently. See Scranton et al. (2002) for a more detailed and quantitative discussion of this important point.

4.1. Magnitude Limit

We select galaxy targets only from those objects that are detected in the r-band images, i.e., which are more than 5σ above the sky after smoothing with a Point Spread Function filter. Before the selection criteria are applied, the photometry is corrected for Galactic extinction, using the reddening maps of SFD. The Petrosian aperture is unaffected by extinction in the absence of noise (§ 3), so the extinction correction is trivial:

$$r_P \to r_P - 2.75 \times E(B - V), \tag{6}$$

where the factor of 2.75 converts from the $E(B-V)$ reddenings reported by SFD to the r filter shape, assuming a $z = 0$ elliptical galaxy spectral energy distribution. Typical extinction values over the SDSS footprint lie in the range $0 \leq 2.75 \times E(B - V) \leq 0.15$. There is an effort within the SDSS collaboration to measure the reddening independently of SFD, using the colors of halo stars, galaxy counts, and galaxy colors. This map will be used *a posteriori* to derive a more accurate angular selection function, but we anticipate that errors in the selection function associated with uncertainties in the SFD map (estimated by SFD to be 15% of the extinction itself) are already very small.

Our goal is to target a mean of 90 galaxies per square degree in the main galaxy sample. This corresponds to a depth at which the variations of galaxy numbers due to large-scale structure are quite substantial on degree scales, as Figure 6 shows. These fluctuations are consistent with the measured angular correlation function of galaxies (Yasuda et al. 2001; Scranton et al. 2002; Connolly et al. 2002). Because of these fluctuations, we need to average over a large area of sky in order to find the magnitude limit that yields 90 galaxies per square degree. We have carried this out over 492 square degrees of SDSS imaging data from a variety of recent SDSS imaging runs. We have decided on a limiting magnitude of $r_P = 17.77$, which yields 92 galaxies per square degree in this region.

Although our selection boundary in apparent magnitude is formally a sharp one, in practice it is blurred (relative to that of a survey with no measurement errors) by uncertainties in the reddening corrections and the inevitable random errors in magnitude determinations (cf., the discussion in Appendix B). These errors need to be taken into account in statistical analyses such as the luminosity function.

4.2. Star-galaxy Separation

Star-galaxy separation in the SDSS is described by Scranton et al. (2002). In brief, photo generates a detailed model of the PSF at each point in each frame in each band; this is used as a template to determine a PSF magnitude in each band, aperture-corrected to an aperture of radius $7.4''$. In addition, each object is fit in two dimensions using a sector fitting technique (Appendix A.1) to a de Vaucouleurs and an exponential profile of arbitrary axis ratio and orientation, each convolved with the PSF, and aperture-corrected so that the model and PSF magnitudes of stars (for which the model scale size will approach zero) are equal in the mean. Each of these fits has a goodness of fit associated with it; the total magnitude associated with the better-fit of the two models is referred to as the "model" magnitude. A galaxy target is defined as an object for which

$$\Delta_{\mathrm{SG}} \equiv r_{\mathrm{PSF}} - r_{\mathrm{model}} \geq 0.3 \; ; \tag{7}$$

note that this separation is done at a somewhat more conservative cut than is done for the star-galaxy separation in photo itself.

Figure 7 shows the distribution of Petrosian magnitude corrected for extinction as a function of the PSF-model magnitude difference for 13772 objects brighter than $r_P^* = 17.8$ over 115 square degrees imaged at seeing better than $1.8''$; the marginal distribution of the magnitude difference is shown as a histogram on the bottom panel. At these relatively bright magnitudes, the distinction between stars and galaxies is very clean, and there is no evidence for a large population of extremely compact galaxies that could masquerade as stars. We discuss the number of stars that masquerade as galaxies in § 5.1.

Photo models the change of the PSF on scales significantly smaller than the frame size of $10' \times 13'$. However, if the seeing changes rapidly enough, photo cannot estimate a sufficiently accurate PSF, and the star-galaxy separation suffers. Such data are declared not to be survey quality, and are not targeted for spectroscopic observations (see the discussion by Stoughton et al. 2002). Any resultant holes larger than one hour in length ($> 15°$) are marked for reobservation. Stretches of poor data quality were not uncommon in early SDSS commissioning data (Stoughton et al. 2002), but recent improvements to the thermal

environment of the survey telescope have made them increasingly rare.

4.3. Photometric Flags

As described in §3.3, objects detected at more than $200\,\sigma_{\mathrm{sky}}$ have two entries in the database. To avoid duplicate targeting of galaxies, target selection therefore rejects one of these two entries, that flagged as BRIGHT. The deblending procedures employed by photo are described briefly by Stoughton et al. (2002); these procedures effectively handle star-galaxy blends and even galaxy-galaxy blends in the great majority of cases. We only target objects that are isolated, or children of deblends, or parents that are not deblended for one reason or another. That is, all objects that are flagged as blended, and whose children are in the catalog, are rejected.

The vast majority of objects that include saturated pixels are stars, even if they satisfy the star-galaxy separation criterion of equation (7). We therefore reject all objects flagged as SATURATED in r. We expect no more than a handful of nearby galaxies, all with bright active nuclei, to have saturated centers in the SDSS data. However, our procedure also rejects a small number of real galaxies that are blended with a saturated star, since the SATURATED flag is passed onto all children of a parent with saturated pixels if the footprint of the child includes the saturated pixels. We show in §5.3 below that the sample incompleteness introduced by blending of galaxies with saturated stars is very small, less than 0.5%.

4.4. Surface Brightness Limits

As noted by Shectman et al. (1996) and others, every redshift survey has at least an implicit surface brightness cut caused by detection limits of the imaging data used to derive the input catalog, and by the limit at which the spectroscopic observations no longer yield reliable redshifts. In order to make this cut simple and deterministic, we explicitly impose a surface brightness cut ourselves. The distribution of objects classified as galaxies in the magnitude-surface brightness plane is shown in Figure 8.

We target all galaxies brighter than our magnitude cut that have half-light surface brightness $\mu_{50} \leq 23.0$ mag arcsec^{-2} in r; visual inspection shows that essentially all objects down to this surface brightness limit are real galaxies. This cut already includes 99% of all galaxies brighter than our magnitude limit. We have visually inspected about 700 lower surface brightness objects in the range $23.0 \leq \mu_{50} \leq 26.0$ distributed over 500 square degrees of imaging data. In the range $23.0 < \mu_{50} < 24.5$, about 65% of these galaxy target candidates

are in fact faint fragments of bright galaxies (usually spiral arms), cluster cores, or diffraction spikes of bright stars, erroneously pulled out by the deblending algorithm. Targeting fragments of bright galaxies does more than waste a spectroscopic fiber; because two fibers cannot be closer than $55''$, it can cause the *nucleus* of the galaxy (which will be a legitimate galaxy target itself) not to be observed. We have found, however, that such spurious galaxy targets have a local sky biased upwards by the parent galaxy, and we can therefore reject them by putting a cut of 0.05 magnitudes on the difference between the local sky and the mean global sky value measured on the frame (cf., the discussion in § 3.3). Thus, objects in this surface brightness range are targeted only if the local and global sky values agree to 0.05 magnitudes per square arcsec. This algorithm rejects most of the contaminants while rejecting very few genuine low surface brightness galaxies (LSBs); the fraction of remaining objects with $23 < \mu_{50} < 24.5$ that are not real LSBs by visual inspection drops to 35%.

At surface brightnesses fainter than $\mu_{50} = 24.5$, we find only 4 real LSBs (out of about 100 candidate objects) distributed over 500 square degrees, with no obvious automatic way to distinguish them from the much more common ghost images arising due to reflections of bright stars inside the camera. Moreover, such objects have fiber magnitudes of order $r_{\mathrm{fiber}} = 21$ or fainter, making it unlikely that we would be able to measure a successful redshift. We therefore do not target these objects. Low surface brightness objects tend to be of low intrinsic luminosity, so they are visible only within a small volume, and their rarity in the sample does not necessarily translate into a small volume density; however, they probably contribute little to the overall luminosity density of the universe (see the discussions by Blanton et al. 2001a; Cross et al. 2001). Since we find only four galaxies with $\mu_{50} > 24.5$ in an area that contains 45,000 main sample galaxies, we estimate that only $\sim 0.01\%$ of galaxies brighter than our magnitude limit are rejected by our surface brightness cut.

For very nearby galaxies ($cz < 10,000\,\mathrm{km\,s^{-1}}$), the Petrosian half-light radius can be quite large, substantially larger than the $3''$ aperture of the fibers. If a low-surface brightness galaxy is strongly nucleated, our surface brightness cut can result in missing a potentially interesting galaxy that would easily yield a redshift. We therefore accept objects of any surface brightness brighter than our Petrosian magnitude limit, if their fiber magnitude in r is brighter than 19.0. In practice, very few objects enter the sample this way; for example, the stripe shown in Figure 6 contains no galaxies targeted in this manner.

There is non-negligible cross-talk between adjacent fibers in the spectrographs, thus overly bright objects make the extraction of the spectra of neighboring faint objects difficult. To avoid this, we reject objects whose fiber magnitude is brighter than 15 in g and r, and 14.5 in i. This criterion rejects about 0.07% of real galaxies that would otherwise be included in the galaxy spectroscopic sample.

Finally, we reject all objects brighter than $r_P = 15.0$ that have $\theta_{50} < 2''$. This cut rejected a small number of bright stars that managed to satisfy equation (7) during the commissioning phase of the survey, when the star-galaxy separation threshold was $\Delta_{SG} = 0.15$. With the final value of the cut at $\Delta_{SG} = 0.3$, there are no objects in Runs 752 and 756 that are rejected by this cut alone. However, we still enforce this criterion, since such small, bright objects will saturate the spectroscopic CCDs and contaminate the spectra of adjacent fibers, and they are in any case more likely to be star-galaxy separation errors than actual galaxies.

4.5. Tiling and Fiber Assignment

Once targets have been selected, they are *tiled*, i.e., assigned to spectroscopic plates in a way that optimizes the observing efficiency (Blanton et al. 2001b). This process leaves essentially no systematic spatial gaps in the distribution of tiled objects, except at the outer boundary of the tiled region (where they will be tiled in a subsequent run based on more imaging data).

However, as mentioned earlier, fibers cannot be placed closer than $55''$, center to center, on a given plate. The tiling algorithm maximizes the number of targeted objects given this restriction. The tiled objects in decreasing order of priority are brown dwarfs and hot standards (both very rare, of order one object per plate), quasar candidates (of order 100 per plate), and finally (at equal priority, and composing the bulk of the objects) the LRGs and main sample galaxies. An object with a higher priority will never lose a fiber in favor of a lower priority object. However, for two objects of equal priority — in particular, for two main sample galaxies — the choice of observed target is made at random. In regions where plates overlap (roughly 30% of the tiled region), both members of a close pair are often observed. Figure 9 shows the measured redshift difference between such pairs (Zehavi et al. 2002); 58% of close pairs have a redshift difference less than 500 km s^{-1} (compared with only 4% of pairs of arbitrary angular separation). We note, however, that pairs in overlap regions may not be representative of the full pair population, since the locations of overlap regions are influenced by the galaxy clustering pattern.

Zehavi et al. (2002) show that for large-scale structure statistics, it is often sufficient to simply double-weight the observed galaxy of a close pair in statistical calculations, or to assign the unobserved galaxy the same redshift as the observed one (which is similar to double weighting but uses the angular position of the unobserved object). Roughly 6% of all galaxy targets are not assigned a fiber due to the $55''$ restriction.

5.   Tests of Algorithm Performance

In this section, we present tests of the target selection algorithm. We first show (§ 5.1) that our star-galaxy separation works well; less than 2% of the galaxy targets turn out to be stars, while less than 0.5% of true galaxies are rejected by our algorithm. This leads into a discussion of the spectroscopic characteristics of the sample, § 5.2. We then carry out various tests of the completeness of the selection (§ 5.3), and find that the sample completeness exceeds 99%, though it becomes somewhat lower for brighter galaxies, which are more likely to be rejected because of blending with saturated stars. Finally, § 5.4 uses repeat scans of an extended area of sky to quantify the reproducibility of the algorithm; the differences in targeted objects are consistent with expectations due to random photometric errors.

The SDSS science requirements for the galaxy sample include completeness of at least 95%, a redshift success rate of at least 95%, stellar contamination of less than 5%, and insensitivity of selection to observing conditions during imaging. The tests below demonstrate that the galaxy sample easily satisfies these requirements.

5.1.   Tests of Star-Galaxy Separation

We select as galaxy targets objects with $\Delta_{SG} \equiv r_{PSF} - r_{model} \geq 0.3$ (§ 4.2). During the commissioning phase of the survey, we selected galaxy targets using a more permissive value of the star-galaxy separation threshold at $\Delta_{SG} = 0.15$. About 3% of roughly 6000 galaxy targets selected from imaging data with seeing better than 1.8″ lie in the range $0.15 < \Delta_{SG} < 0.6$. Of these, only 10% of the targets with $\Delta_{SG} < 0.3$ are actually galaxies from their spectra, while the galaxy fraction rises to 20% for those with $0.3 < \Delta_{SG} < 0.45$ and to 65% for targets with $0.45 < \Delta_{SG} < 0.6$. The major contaminants at lower values of Δ_{SG} are single stars, while the contaminants above $\Delta_{SG} = 0.3$ are mostly double stars too close ($< 3″$) to be deblended into single stars by photo. The stellar contamination to the galaxy sample is quite independent of seeing as long as the seeing full width at half maximum is smaller than 1.8″ and does not change rapidly (i.e., data of survey quality; see § 4.2).

With our final cut of $\Delta_{SG} > 0.3$, slightly under 2% of galaxy targets are single and double stars. A similar fraction of the targets are classified spectroscopically as quasars; these of course are successes of the algorithm, as they are mostly low-redshift AGN. The spectroscopic results from the $\Delta_{SG} = 0.15$ threshold test run imply that only about 0.3% of true galaxies brighter than our magnitude limit are rejected by our star-galaxy separation criterion.

Finally, the SDSS quasar target selection algorithm (Richards et al. 2002) targets stellar objects with colors distinct from those of ordinary stars. As the colors of galaxies are distinct from those of individual stars (Strateva et al. 2001), unresolved galaxies are likely to be selected by that algorithm. As Richards et al. (2002) demonstrate, some star-forming galaxies and E+A galaxies are indeed selected, but only a handful of such objects brighter than $r_P^* = 17.77$ are not already selected by the galaxy target selection algorithm; these objects represent less than 0.1% of the galaxy sample. Of course, unresolved quasars, which are not included in this total, can be brighter than $r_P^* = 17.77$; such objects are explicitly selected by the quasar target selection algorithm.

5.2. Spectroscopic Characteristics

Figure 10 shows representative SDSS spectra of galaxies close to our photometric limit. The S/N values of the spectra are determined by their fiber magnitudes; the r fiber magnitude distribution for the targetted sample is centered at $r_{fiber} = 18.5$; essentially all galaxies have fiber magnitudes brighter than 20 (at which the spectroscopic S/N per pixel is required to be greater than 4; § 1.1). Thus the fraction of galaxy targets whose spectral S/N is not adequate to measure a redshift is less than 0.1% of the total main galaxy targets. The objects in the tail of the fiber magnitude distribution (at $r_{fiber} > 20.5$) are low surface brightness galaxies. The SDSS spectra are consistently of good enough quality to yield reliable redshift measurements (i.e., with statistical error $< 30 \, \mathrm{km \, s^{-1}}$) for galaxies at fiber magnitudes as faint as $r_{fiber} = 20.8$. Thus the impact of spectroscopic observing conditions on sample completeness is essentially negligible.

Figure 11 shows the redshift histogram for 57,366 galaxies observed in 2000 and 2001. The median redshift is 0.104; even with this large number of galaxies, the redshift distribution is not completely smooth, due to large-scale structure fluctuations. A pie diagram of the galaxy distribution in redshift space from the sample is shown by Zehavi et al. (2002).

5.3. Completeness of the galaxy sample

We anticipate the most serious problems with completeness of the galaxy sample at the bright end, where galaxy photometry can be the most problematic; big galaxies often have substructure (bars, spiral arms, dust lanes, HII regions, and so on), which can fool an automated deblender. In this subsection, we compare the SDSS galaxy sample with samples

drawn from the Two Micron All-Sky Survey (2MASS)[22], the Zwicky catalog, and visual inspection of SDSS images, and show that our completeness is of order 99% overall, worsening to 95% for galaxies brighter than $r^* = 15$. Here we define completeness to be the fraction of galaxies satisfying our selection criteria that are in fact identified as spectroscopic targets by the automated algorithm. About 6% of these targets are not observed spectroscopically because of the 55″ fiber separation constraint (see §4.5). However, the locations of these missed galaxies are known, and they can be accounted for in any statistical analysis of the galaxy population, so we do not count them as contributing to incompleteness.

Falco et al. (1999) have compiled accurate astrometry for galaxies in the Zwicky et al. (1961-68) catalog; we have matched this list with the SDSS database. This catalog is limited to $b_{\rm Zwicky} = 15.7$, corresponding roughly to $r^* \approx 15$. Roughly 90% of the 176 Zwicky galaxies in 77 square degrees of sky have a corresponding SDSS main galaxy target within 3″ of the nominal Zwicky position. Visual inspection shows that the galaxy astrometry in the Zwicky catalog is inaccurate enough to cause a mismatch for about 5% of the galaxies; all of these galaxies in fact have an SDSS spectroscopic galaxy target centered at the correct photometric centroid of the galaxy. The remaining 5% of the galaxies in the Zwicky catalog have corresponding SDSS galaxy candidates that are flagged as SATURATED due to overlap with a saturated star (§ 4.3), and hence these galaxies will not be targeted spectroscopically. Thus of order 95% of galaxies in the Zwicky catalog are being targeted spectroscopically. As one goes fainter, the fraction of galaxy targets that are missed due to the SATURATED flag will go down, since the area covered by the galaxies becomes smaller.

Yasuda et al. (2001) visually inspected all objects brighter than $r^* = 16$ in the stripe defined by Runs 752 and 756 (Stoughton et al. 2002), and classified them into stars and galaxies. There are 1743 galaxies in this sample over 200 square degrees of sky, roughly 10% of the full galaxy sample to $r^* = 17.77$ in this region. The galaxy target selection algorithm selects 1701 (97.6%) of these bright galaxies for spectroscopic observations. Of the 42 galaxies that are not targeted, 30 are blended with saturated stars and hence have the SATURATED flag set, while the remaining 12 galaxies are rejected because they have fiber magnitudes brighter than $i^* = 14.5$.

Finlator et al. (2000) discuss the matching of the SDSS photometric catalog with that of 2MASS. Given typical colors of galaxies of $r - K = 3.0$, the SDSS spectroscopic magnitude limit corresponds to $K \approx 14.7$, which is comparable to the photometric limit of 2MASS. Of order 2% of 2MASS point sources in the region of overlap of the two surveys are not found in the SDSS database; of these, 2/3 are asteroids, and the remaining 1/3 do not enter the SDSS

---

[22]http://www.ipac.caltech.edu/2mass/overview/about2mass.html

catalog because they are associated with complicated blends often involving saturated stars or diffraction spikes which are not deblended properly (Ivezić et al. 2001). Assuming that the latter 1/3 of the missing 2MASS sources are real, the lower limit of the completeness of the SDSS galaxy catalog at the spectroscopic limit is 99.3%.

Finally, we performed an end-to-end study of the completeness of the spectroscopic galaxy sample by visually inspecting all objects brighter than $r^* = 18$ and with $r_{\mathrm{PSF}} - r_{\mathrm{model}} \geq 0.1$ (and with no other cuts based on flags) over 22 square degrees of sky. These two limits are more permissive than the corresponding cuts in the galaxy target selection algorithm, thus allowing us to quantify the number of real galaxy targets that we miss by these sharp cuts. Note that this test is complete to the extent that `photo` successfully finds all objects brighter than $r^* = 18$ in the first place. This is more than four magnitudes brighter than the SDSS "plate limit", and indeed, tests of the repeatability of found objects in regions of sky observed by SDSS more than once show that essentially 100% of objects at this brightness are found both times.

There are 3186 unique entries in our visual inspection sample. Of these, 366 are either single or double stars by visual inspection (the vast majority of which do not satisfy our star-galaxy separation criterion, of course). In addition, 464 objects have dereddened Petrosian magnitudes fainter than $r^* = 17.77$. This leaves 2356 unique objects that should have been targeted by the selection algorithm. Of these, we target 2330 (98.9%). We have spectra of 2184 of these; 21 are classified as quasars spectroscopically, 26 as stars (and thus are errors in our visual classification), two were satellite trails in the imaging data, and the remainder are galaxies. Nearly all the 146 objects for which we have not obtained spectra (6%) have companions within 55″. It occasionally happens that a spectroscopic fiber will break or fall out, resulting in the absence of a spectrum despite a hole being drilled for it; there was only a single example of this problem among the 2330 spectroscopic targets in this sample.

The $2356 - 2330 = 26$ objects that we do not target break down as follows. We miss 10 galaxies because they are blended with saturated stars, while another 6 galaxies do not pass our star-galaxy separation criterion. We miss another 10 galaxies due to an error in setting the flags in `photo` (version 5.2 and earlier). This error has been corrected in V5.3 of `photo`, and we expect not to lose these galaxy targets in the future. Thus, this end-to-end test implies that only $10/2356 = 0.4\%$ of galaxies in this 22 square degree area that should be targeted would not be, with the corrected version of `photo`, and that $6/2356 = 0.25\%$ of true galaxies would be rejected by our star-galaxy separation criterion. The intrinsic sample completeness therefore exceeds 99%. The only significant cause of incompleteness that we have identified is blending with saturated stars, affecting only 5% of bright galaxies, and a negligible fraction fainter than $r_P = 16$.

Ten percent of sample galaxies have a neighbor within 55″. The fraction of these missed galaxies that will be recovered in a subsequent observation of an overlapping plate depends to some extent on the size and geometry of regions that are tiled for spectroscopy, but the estimate from this 22 square degree region that $\sim 6\%$ of galaxy targets will ultimately remain unobserved appears reasonable and consistent with our more recent experience.

5.4. Reproducibility

The SDSS scanlines overlap by about 1′ at their edges; moreover, we have several scans that cover the same area of sky. This allows us to test whether we get consistent results of photometry and main galaxy target selection in the overlaps.

We have tested the repeatability of the galaxy target selection algorithm by selecting galaxy targets from repeated scans of the same region of the sky. In particular, the SDSS imaging runs 745 (observed on Mar 19, 1999) and 756 (observed on Mar 21) scanned the same patch of sky ($160.5 < \alpha < 235.5$ on the Celestial equator); the six columns of the two runs spanned the same range in declination.

Figure 12 shows the difference in the r-band Petrosian magnitudes of galaxies in common between these runs brighter than $r^* = 18$. There is no offset in the mean of the two measurements of the Petrosian magnitudes of these galaxies, and the rms differences in the r-band is 0.035 mag, in good agreement with the estimated Petrosian magnitude errors at the sample magnitude limit.

Over a 90 deg² region of repeated imaging data, we select 9159 (9125) galaxy targets from Run 745 (756). Of these, 8652 (94.5%) targets have a corresponding target within 0.7″ in the other run. There are another 57 (0.6%) targets in Run 745 that have a corresponding galaxy target within 3″ in Run 756. Of the remaining 450 targets in Run 745 that are not selected in Run 756, 342 objects (3.7%) have a corresponding object within 0.7″ in Run 756 that is fainter than the magnitude limit. This fraction is comparable to the fraction of galaxies that is expected to cross the magnitude limit in two repeated scans because of random photometric errors, as discussed in Appendix B. Another 78 (0.9%) targets in Run 745 are rejected by the star-galaxy separation algorithm in Run 756, while 30 objects (0.3%) are saturated in the Run 756 images. The discrepancy in star-galaxy separation is significantly worse than we quoted in § 5.1, due to the fact that Run 745 had seeing significantly worse than our criterion for survey-quality data. The fraction of targets selected from Run 756 but not from Run 745 follows similar statistics. Thus the repeatability of the galaxy target selection sample is probably better than 95%, and nearly all of the non-repeatability can be attributed to

expected random photometric errors, which should not introduce any systematic biases in statistical studies.

6. Conclusions

6.1. Summary of the algorithm performance

The main spectroscopic galaxy sample of the SDSS is a reddening-correct r-band magnitude limited sample of galaxies brighter than $r_P = 17.77$, with an estimated surface density of 92 galaxies per square degree. The magnitude is measured within a Petrosian aperture, so as to provide a meaningful measure of a fraction of the total light of the galaxy that is independent of distance to the galaxy, reddening, and sky background. Star-galaxy separation is based on the difference between PSF and galaxy model magnitudes, which effectively quantifies the extension of the source relative to a PSF. We reject objects with Petrosian half-light surface brightness $\mu_{50} > 24.5$, a cut that eliminates $\sim 0.1\%$ of galaxies brighter than the magnitude limit. In the range $23 < \mu_{50} < 24.5$, we use a measure of the difference between local and global sky brightness to increase our efficiency of targeting real galaxies.

We have objectively tested the star-galaxy separation algorithm and the completeness and reproducibility of the spectroscopic sample using imaging and spectroscopic data taken during the commissioning phase of the survey. During commissioning, we refined the criteria in the target selection algorithm to achieve our goals on the completeness and efficiency of the spectroscopic sample. At the time of this writing, we find that the star-galaxy separation is accurate to better than 2%, with the main contaminants being close double stars. The fraction of true galaxies rejected by the star-galaxy separation criterion is only $\sim 0.3\%$.

The completeness of the main galaxy sample is a function of magnitude. At bright magnitudes ($r^* < 15$), we find that we target 95% of the galaxies in the Zwicky catalog, while the remaining 5% are missed because they are blended with saturated stars. From comparison with visual inspection of bright galaxies ($r^* < 16$) over 200 square degrees of sky, we find that the completeness increases to about 97.6%. Finally, from comparison with a visual inspection of all objects brighter than $r^* = 18$ over 22 square degrees of sky, we find that the completeness of the galaxy sample to the magnitude limit is above 99%. The only significant source of incompleteness that we have identified is blending with saturated stars; this incompleteness is higher for brighter galaxies because they subtend more sky.

Essentially all main sample galaxies (99.9%) that are observed spectroscopically yield successful redshifts. About 10% of galaxy targets do not receive a fiber on the first spectroscopic pass because they lie within 55″ of another sample galaxy. Some of these galaxies

lie in regions of plate overlap and are observed subsequently, and the fraction of galaxies that are missed in the end because of the fiber separation constraint is about 6%. These missing galaxies can be accounted for in any statistical analysis by appropriate weighting of the galaxies in close pairs that are observed.

We have tested the reproducibility of the galaxy sample by selecting targets from repeated scans of the same region of the sky. We find that 94.5% of the spectroscopic sample galaxies are selected in both the scans. About 3.7% of galaxies fall out of the sample because they cross the magnitude limit and are replaced by a similar number of galaxies crossing in the other direction; this fraction is consistent with expectations based on random errors in the Petrosian magnitudes. Other galaxies fall out of the sample because of changes in saturation or star-galaxy separation. Reproducibility of target selection is therefore high, and the random photometric errors that lead to non-reproducibility are not expected to cause systematic biases in statistical analyses.

6.2. Scientific applications of the SDSS imaging and spectroscopic data

The imaging data on which we tested and refined the galaxy target selection algorithm, and the resulting galaxy spectroscopic sample have been studied in the context of both large scale structure and properties of galaxies. Extensive tests by Scranton et al. (2001) show that the imaging data obtained by the SDSS are free from internal and external systematic effects that influence angular clustering for galaxies brighter than $r^* = 22$, almost four magnitudes below the limit of the spectroscopic sample. At the bright end, Yasuda et al. (2001) studied the bright galaxy sample in the same data, and showed that the photometric pipeline correctly identifies and deblends blended objects and provides correct photometry for bright ($r^* < 16$) galaxies.

The spectroscopic galaxy sample targeted using development versions of the target selection algorithm during the commissioning phase of the survey has been used to measure the luminosity function of galaxies as a function of surface brightness, color, and morphology (Blanton et al. 2001). A primary goal of the SDSS is to measure the properties of large scale structure as traced by different types of galaxies. Zehavi et al. (2002) used this spectroscopic sample to measure the correlation function and pairwise velocity dispersion of samples defined by luminosity, color, and morphology. Bernardi et al. (2002) used the spectra and photometry to study the correlations of elliptical galaxy observables including the luminosity, effective radius, surface brightness, color, and velocity dispersion. All these studies show that the galaxies targeted spectroscopically by the SDSS constitute a uniformly selected sample spanning a wide range of galaxy types, ideal for analyses of large scale structure and

galaxy properties.

A.   The Calculation of Petrosian Quantities by `Photo`

A.1.   Measuring Surface Brightnesses

The photometric pipeline, `photo`, measures the radial profile of every object by measuring the flux in a set of annuli, spaced approximately exponentially (successive radii are larger by approximately 1.25/0.8); the outer radii and areas are given in Table 7 of Stoughton et al. (2002). Each annulus is divided into twelve 30° *sectors*. For the inner six annuli (to a radius of about 4.6 arcsec) the flux in each sector is calculated by exact integration over the pixel-convolved image; for larger radii the sectors are defined by a list of the pixels that fall within their limits. Usually the straight mean of the pixel values is used, but for sectors with more than 2048 pixels a mild clip is applied (only data from the first percentile to the point 2.3σ above the median are used).

Given a set of sectors, `photo` can measure the radial profile. If the mean fluxes within each of the sectors in an annulus are $M_j(j = 1, \cdots, 12)$, it calculates a point on the profile ('`profMean`') as

$$I_i = \frac{1}{12} \sum_{j=1}^{j=12} M_j \ .$$

The error of this quantity ('`profErr`') is a little trickier. If we knew that the object had

circular symmetry, we would estimate it as the variance of the M_j divided by $\sqrt{12}$. Unfortunately, in general the variation among the M_j is due both to noise and to the radial profile and flattening of the object. To mitigate this problem, we estimate the variance as

$$\text{Var}_I = \frac{4}{9} \times \frac{1}{12} \sum_{j=1}^{j=12} \left[M_j - \frac{1}{2}(M_{j-1} + M_{j+1}) \right]^2 , \tag{A1}$$

where we interpret '$j \pm 1$' modulo 12, and where the factor 4/9 is strictly correct in the limit that all the $\langle M_j \rangle$ are equal. This use of a local mean takes out linear trends in the profile around the annulus, and results in an estimate of the uncertainty in the profile that is a little conservative, but which includes all effects. The error due to photon noise alone, if one needed this, could easily be calculated from the I_i and the known gain of the CCD.

In practice, `photo` doesn't extract the profile beyond the point that the surface brightness within an annulus falls to (or below) zero.

A.2. Measuring the Petrosian Ratio

The I_i measured in the previous subsection represent the surface brightness at some point in the ith annulus, but exactly what point is not clear. Instead of making some assumption about the form of the radial profile, we preferred to work with the cumulative profile, as the I_i (and the known areas of the annuli, A_i) define unambiguous points C_i on the object's curve of growth. By using some smooth interpolation between these points (which, of course, makes an assumption about the form of the radial profile) we can estimate the surface brightness at any desired radius.

The cumulative profile has a very large dynamic range, so in practice we make this interpolation using a cubic spline on the asinh θ vs. asinh C curve[23], where θ is the angular distance from the center of the object. As with any cubic spline, we need to specify two additional constraints to fully determine the curve; we chose to use the 'not-a-knot' condition, i.e. we force the *third* derivative to be continuous at the second and penultimate points. We also used a 'taut' spline, which adds extra knots wherever they are needed to avoid the extraneous inflection points characteristic of splines put through sets of points with sharp changes of gradient (e.g., two straight line segments; de Boor 1978). We explored the use of smoothing splines, but found that they didn't conserve flux — it is important that the curve actually pass through the measured points!

---

[23]We chose asinh rather than a logarithm as it is well behaved near the origin; cf. Lupton, Szalay, & Gunn (1999).

The choice of boundary conditions at the origin is a little tricky. The gradient $d\,\mathrm{asinh}\,C/d\,\mathrm{asinh}\,\theta$ is 0 at the origin — but only *very* close to the origin. For a constant surface brightness source, once $C \gg 1$, the gradient becomes very large, scaling as $\approx 1/\theta$ for $\theta \ll 1$. Experiment showed that the best results were achieved by not imposing any symmetry (and thus gradient) constraints at $\theta = 0$.

With the cumulative profile, expressed as a spline, in hand, the Petrosian ratio is easily calculated, as defined in equation (1). In practice, we evaluate $\mathcal{R}$ at the annular boundaries θ_i (where we know the cumulative profile), and use another taut not-a-knot spline to interpolate $\mathcal{R}$ as a function of $\mathrm{asinh}\,\theta$.

We estimate the uncertainty $\sigma_{\mathcal{R}}$ in $\mathcal{R}$ by propagating errors in equation (1) on the assumption of Poisson noise in the object and sky; we allow for the covariance between the numerator and denominator and only work to quadratic order in the errors. However, if the resulting S/N exceeds that of the measured radial profile at that point (measured as described in eq. A1), the error in $\mathcal{R}$ is set to $\mathcal{R}$ times the error in the radial profile.

A.3. Measuring the Petrosian Flux

The Petrosian radius θ_P is found by solving the equation $\mathcal{R}(\theta_P) = f_1$. We've expressed $\mathcal{R}$ as a cubic spline, so we can piecewise apply the usual analytic formula for the roots of a cubic and find all Petrosian radii (there may indeed be more than one solution; see below). Clearly $\mathcal{R}(0) = 1$, and for most forms of an object's radial profile $\mathcal{R}(\infty) = 0$ (the exception being a power law $P(\theta) \propto \theta^{-\alpha}$, with $\mathcal{R}(\infty) = (\alpha - 2)/\alpha$), so almost all objects will have at least one θ_P.

Even in the absence of noise, some objects may have more than one θ_P; the Petrosian ratio need not be monotonic in θ. For example, a galaxy with an AGN can have one Petrosian radius for the part of the galaxy where its light is dominated by the nucleus and another, larger, θ_P associated with the extended light; in this case we should adopt the *larger* value. On the other hand, a bright star with a much fainter galaxy nearby that has not been properly deblended can have a small θ_P associated with the star, and another much larger value produced by a small rise in the radial profile at the position of the galaxy, at a radius where the *mean* enclosed surface brightness due to the star has fallen to a low value; in this case we should adopt the *smaller* value.

These spurious values of θ_P are found at a point where the surface brightness is very low, so we have adopted the following procedure, setting flags for each object to describe any unusual problems we come across, as described by Stoughton et al. (2002):

- Find all of the object's Petrosian radii, as described above.

- If there is no Petrosian radius, $\mathcal{R}$ must be above f_1 at the last measured point in the profile (remember that $\theta_P(0) \equiv 1$). We thus take θ_P to be the outermost measured point in the profile (this is equivalent to assuming that the surface brightness is exactly zero beyond this point). We then set the NOPETRO and NOPETRO_BIG flags and proceed to measuring other quantities.

- Otherwise, reject all the values of θ_P where the corresponding surface brightness (as estimated by differentiating the spline representation of the cumulative surface brightness) is below $\mu_{\min} = 25 \, \text{mag arcsec}^{-2}$. If any values are rejected, we set the PETROFAINT flag.

- Keep the largest surviving θ_P. If there is more than one, set the MANYPETRO flag.

- If there are no surviving radii, set the NOPETRO flag; set $\theta_P = \theta_{P\min} = 3''$.

Once we know θ_P, we can estimate its error σ_{θ_P}. We find the Petrosian radii (following the above prescription) corresponding to Petrosian ratios $\mathcal{R} + \sigma_{\mathcal{R}}$ and $\mathcal{R} - \sigma_{\mathcal{R}}$. Half the difference between them is the estimated error on θ_P. This simple approach ignores covariances between the estimates, but gives correct errors within 20% as determined from repeat measurements.

The Petrosian flux F_P is defined as the flux within $f_2 \times \theta_P$; in all bands the θ_P used is that measured in the r band. If $f_2 \times \theta_P$ exceeds the last measured point on the profile, the total flux to that point is used (once again, this corresponds to assuming that the surface brightness falls to zero at this point, as this is the only reasonable assumption we could make). This happens for only 2% of galaxies brighter than the spectroscopic limit. The error in the Petrosian flux σ_{F_P} is made up of two terms, added in quadrature: The photon noise within $f_2\theta_P$ due to the object and sky, and a term due to the uncertainty in θ_P. This second term is $0.5\left[C(\theta_P + \sigma_{\theta_P}) - C(\theta_P - \sigma_{\theta_P})\right]$, where C is the cumulative profile as above. We neglect the covariance between these two terms; the contribution to the photon noise from the region between $\theta_P + \sigma_{\theta_P}$ and $\theta_P - \sigma_{\theta_P}$ is negligible; the uncertainty in θ_P is also mostly determined locally, and is thus more-or-less uncorrelated with the Poisson term. Both terms are included in all bands, even though the Petrosian aperture is based on the r band Petrosian radius for all bands. § 5.4 showed that the resulting errors are quite accurate.

We also calculate two concentration parameters θ_{50} and θ_{90}, the radii containing 50% and 90% of the Petrosian flux. Their errors are naïvely estimated as e.g. $0.5(\theta_{50,F_P+\sigma_{F_P}} - \theta_{50,F_P-\sigma_{F_P}})$ where $\theta_{50,F_P+\sigma_{F_P}}$ is the value of θ_{50} that we'd estimate if the Petrosian flux were

$F_P + \sigma_{F_P}$. Repeat measurements show that the errors in θ_{50} are overestimated by a factor of two at $r^* = 18$, while the errors in θ_{90} are correct to 10%.

B. On the fraction of galaxy targets crossing the magnitude limits in repeated scans

The Petrosian magnitudes have finite errors, and thus a sharp cut in *observed* magnitude will be a slightly fuzzy cut in true magnitudes. One effect, as we saw in § 5.4, is that samples defined from repeat imaging scans of the same area of sky will not be identical. We quantify the expected effect here.

The probability that a galaxy with a true magnitude m is observed to be brighter than the magnitude limit m_l in one scan and fainter than the magnitude limit in another scan is given by

$$P(m) = p(m)\left[1 - p(m)\right], \tag{B1}$$

where

$$p(m) = \frac{1}{\sqrt{2\pi}\,\sigma_m} \int_{-\infty}^{m_l} e^{-\frac{(m-m_l)^2}{2\sigma_m^2}} \, dm_l \equiv \frac{1}{2}\mathrm{erfc}\left(\frac{m - m_l}{\sqrt{2}\sigma_m}\right) \tag{B2}$$

is the probability that a galaxy is brighter than the magnitude limit in one scan, and σ_m is the error in photometry (in magnitudes), which we assume is distributed as a Gaussian. Hence, the fraction of galaxy targets that are targeted in one scan but not in the other is

$$F(m_1 < m_l, m_2 > m_l) = \frac{\int_{-\infty}^{\infty} n(m)p(m)\left[1 - p(m)\right]}{\int_{-\infty}^{\infty} n(m)p(m)}, \tag{B3}$$

where $n(m)$ is the differential number counts of galaxies as a function of magnitude.

Yasuda et al. (2001) have found that $n(m) \propto 10^{0.55m}$ near the magnitude limit of $m_l = 17.77$ in the r-band. At this magnitude, $\sigma_m = 0.035$ mag, and equation (B3) predicts that about 3.2% of galaxies to cross the magnitude limit in two repeated scans, due to random photometric errors alone. This predicted fraction is very close to the fraction 3.7% found in the test discussed in §5.4.

Fig. 1.— Illustration of the Petrosian aperture procedure for a de Vaucouleurs profile (top) and an exponential profile (bottom), assuming an axis ratio of one and negligible seeing. In each panel, the dashed curve shows the curve of growth (fraction of total light within radius θ), and the solid curve shows the Petrosian ratio $\mathcal{R}(\theta)$. The dotted curve shows the logarithmic surface brightness profile, using the right-hand axis scale. The central arrow marks the Petrosian radius at $\mathcal{R}(\theta) = 0.2$. Outer and inner arrows represent the radius of the Petrosian aperture ($f_2\theta_P$) and the Petrosian half-light radius θ_{50}, respectively. All radii are scaled to the true half-light radius θ_e, which is 1.678 scale lengths for the exponential profile.
Fig. 2.— Effect of axis ratio on the Petrosian flux, measured using our circular aperture definitions of Petrosian quantities. The dashed line shows the fraction of the total flux within the Petrosian aperture for inclined exponential disks as a function of axis ratio. The solid line shows the same quantity for a de Vaucouleurs law galaxy. The dotted line represents a galaxy with an inclined (exponential) disk and a circular (de Vaucouleurs law) bulge, assuming a 1:1 bulge-to-disk ratio and a bulge half-light radius that is half that of the disk.
Fig. 3.— The fraction of the total light within the Petrosian aperture $f_2\theta_P$ as a function of the value of f_2, for $f_1 = 1/5$ (solid lines), $1/6$ (dotted lines), and $1/4$ (dashed lines). Lower curves correspond to de Vaucouleurs law profiles and upper curves to exponential profiles. Filled circles mark our adopted values $f_1 = 1/5$, $f_2 = 2$. These calculations simulate idealized circular galaxies, and seeing is assumed to be negligible.
Fig. 4.— R_P, the Petrosian radius θ_P multiplied by the angular diameter distance (assuming $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$) as a function of redshift z for several small ranges of absolute magnitude in the main galaxy sample; in each panel, we show a linear regression of R_p along z as the solid line.

Fig. 5.— Schematic flow diagram of the main galaxy target selection algorithm. All quantities are measured in the r band and are corrected for foreground extinction. See the text for a full description of all quantities referred to in this figure.
Fig. 6.— The distribution of objects on the sky targeted by the galaxy target selection algorithm, in a stripe 2.5° wide centered on the Celestial Equator. We have spectra of essentially all these objects. The stripe is 91 degrees long, $145° < \alpha(2000) < 236°$, and is broken into contiguous pieces for the figure.
Fig. 7.— The relationship between Petrosian magnitude corrected for Galactic extinction, and the difference between PSF and model magnitude in the r band, for stars and galaxies in 115 square degrees. The separation between stars and galaxies is apparent with a simple cut in the difference between PSF and model magnitude. The distribution of this difference for objects brighter than $r^* = 17.8$ is shown in the lower panel.
Fig. 8.— The distribution of objects classified as galaxies with $r_P^* \leq 17.77$ in the de-reddened, r-band, Petrosian magnitude-Petrosian surface brightness plane. The cuts at $\mu_{50} = 23.0$ and 24.5 are indicated. The lower panel shows the differential (histogram; left-hand axis) and cumulative (dotted curve; right-hand axis) distribution of surface brightness; of order 1% of galaxies brighter than the magnitude limit have $\mu_{50} > 23.0$.
Fig. 9.— The distribution of redshift differences of pairs of galaxies separated on the sky by less than 55″, as measured from regions in which two or more spectroscopic plates overlap. 58% of pairs have a redshift difference less than 500 km s^{-1}.
Fig. 10.— Representative SDSS spectra of galaxies from the sample, smoothed with a 5-pixel boxcar. These objects are all close to the magnitude limit of $r^*_{Petro} = 17.77$. Shown are two red galaxies, a star-forming galaxy, a starburst galaxy, and a Seyfert 1 galaxy.
Fig. 11.— The redshift histogram of 57,366 galaxies selected by the algorithm; the y-axis is the number of galaxies in bins of 0.01 in redshift. Even this large number of galaxies is not quite enough to average over large-scale structure fluctuations.
Fig. 12.— The difference between the r-band Petrosian magnitudes of the same galaxies measured in two different imaging runs. The dashed line shows the magnitude limit $r_P = 17.77$ of the main galaxy sample.
