Abstract
Intense muon beams have many potential applications, including neutrino factories and muon colliders. However, muons are produced as tertiary beams, resulting in diffuse phase space distributions. To make useful beams, the muons must be rapidly cooled before they decay. An idea conceived recently for the collection and cooling of muon beams, namely, the use of a Quasi-Isochronous Helical Channel (QIHC) to facilitate capture of muons into RF buckets, has been developed further. The resulting distribution could be cooled quickly and coalesced into a single bunch to optimize the luminosity of a muon collider. After a brief elaboration of the QIHC concept, recent developments are described.

INTRODUCTION
A Quasi-Isochronous Helical Channel (QIHC) is being investigated as an alternative to a significant portion of the baseline front end for a neutrino factory or muon collider. The study 2A [1] front end consists of a target solenoid (20 T), a tapered capture solenoid (20 T to 2T, 12 m long), a drift section (99 m), an RF buncher (50 m), an energy-phase rotator (54 m), and a cooling region (80 m). The QIHC might be developed to replace all but the last cooling stage, and this cooling section may be replaced by a Helical Cooling Channel (HCC) [2,3]. The QIHC offers a more natural match into the potentially more efficient HCC.

The QIHC concept takes advantage of the larger RF buckets for particles traveling in nearly isochronous orbits. Critical components of a QIHC system, as presently conceived, include the following: (1) a helical magnetic field that creates helical particle trajectories near a reference orbit of a selected muon momentum, (2) RF cavities that capture particles in stable buckets, and (3) an absorber that reduces the energy of particles that would otherwise be too energetic to be captured. In this paper, we present the analytic theory behind the concept along with simulation results. However, current simulations are not fully exercise all possible parameters; further simulations are to be performed in the near future.

NEARLY ISOCHRONOUS CONDITION
The QIHC aims to take advantage of a larger RF bucket area when operating near transition:

\[
A_{\text{bucket}} = \frac{16}{w_f} \sqrt{\frac{e V'_{\text{max}} \lambda_{\text{RF}} m_\mu c^2}{2\pi |\eta|}} \left[ \frac{1 - \sin(\phi_s)}{1 + \sin(\phi_s)} \right]
\]

where
- the term in brackets is an approximation for the moving-bucket factor
- \(w_f\) is the RF frequency in radians/second
- \(V'_{\text{max}}\) is the maximum E-field voltage gradient
- \(\lambda_{\text{RF}}\) is the RF wavelength
- \(m_\mu\) is the mass of the muon
- \(\phi_s\) is the synchronous particle RF phase, and
- \(\eta\) is the slip factor, derived in [2] for an HCC as:

\[
\eta = \sqrt{1 + \kappa^2} \gamma \frac{\beta - 1}{\gamma^2}
\]

In which
- \(\gamma\) becomes \(\gamma_t\) when \(\eta=0\) and the dispersion factor \(\tilde{D}\) relates to apparatus quantities and design momentum via:

\[
\tilde{D} = \frac{a}{p} \frac{\kappa^2 + (1 - \kappa^2)(B_0^2 + [1 + \kappa^2]/(kb - l)]}{1 + \kappa^2} \frac{(1 + \kappa^2)^{3/2}}{p^2} \frac{\partial b_\rho}{\partial \rho}
\]

in which
- \(p\) is reference momentum; \(a\) is reference radius
- \(\kappa = p_{\text{transverse}}/p_z\) is helix pitch
- \(B\) is the solenoid \(B_z\)
- \(k = 2\pi a / \lambda\) is helix period
- \(\frac{\partial b_\rho}{\partial \rho}\) being the quadrupole component

DESIGN & SIMULATION
Since the HCC is charge specific [2], this paper focuses on capture of \(\mu^+\). Our original intention was to manipulate the parameters that control transition in a HCC after matching into it from a solenoid. However, preliminary studies showed that transition occurs in the match itself for an existing HCC configuration optimized for cooling. Instead of redesigning the match, we decided to start our simulation effort based on an established HCC design and its matching portion [3]. All simulations utilized G4beamline [4].

The cooling HCC has \(B_z\) on the reference of 4.2 T and the acceptance is approximately 150 MeV/c < \(p < 300\) MeV/c. Hence, we modified the portion upstream of the HCC as follows:

1. The tapered solenoid is modified from \(B_z\) with 20 T to \(\sim 2\) T to 20 T \(\rightarrow 4.2\) T. This shortens the tapered solenoid from about 10 m to 4.5 m.
2. In order to maximize the number of muons that fall into the HCC acceptance, we implement two sequential straight sections:
   a. 20 m of RF in vacuum at 5 MV/m to capture \(\mu^+\)’s and \(\pi^+\)’s and allow lower momenta \(\pi^-\)’s to decay into \(\mu^-\).
   b. 20 m of RF in material (Be & 100 atm H\(_2\)) gas at 35 MV/m to enlarge RF bucket size and cause otherwise useless higher energy \(\pi^-\)’s to interact

with material, producing lower energy $\pi$'s that decay into $\mu$'s in the useful momenta range.

After the modified portion upstream of the HCC, we began to use the established match and HCC. The match has added to it RF, H$_2$ gas, and Be windows. The HCC itself also incorporates RF and material, but this is an innovation for the matching section.

Figure 1 and Table 1 show and describe the layout, respectively. Figure 2 shows that muons from a MERIT-like targetry [5] exiting the tapered solenoid peak at around 150 MeV/c in momenta, near the bottom of the HCC acceptance. So, the first 20 m straight is timed to capture 150 MeV/c muons and phased to accelerate them to 162 MeV/c at the end of this first straight, with results shown in Figure 3.

The second straight section introduces a variable amount of Be, totaling half an interaction length for pions, to cause the otherwise useless higher energy pions to interact and create lower energy pions that decay into muons of the right energy for the HCC acceptance. Figure 4 shows the momenta and longitudinal position at creation of muons and pions; pion creation is readily seen at the start of the second straight. The longitudinal dynamics of $\mu$'s and $\pi$'s at the end of the second straight section are displayed in Figure 5.

In this first study, the design philosophy for the match was to keep the RF bucket as large as possible throughout, which translated into keeping a constant momentum of 237 MeV/c. Since the pitch ($\kappa = \frac{P_{\mu\text{trans}}}{P_\gamma}$) of the path grows from 0 to 1, the path length likewise grows per unit of $z$, necessitating a growth in $\phi$, as the $\mu^-$ plows through more material, causing the RF bucket size to shrink due to the factor in square brackets in equation (1). We also extracted $\gamma_r$ from the match via the fastest time of flight between transverse planes, which guided us to know when to jump the phase to maintain stability. Figure 6 shows the accelerating phase, $\phi$, the derived bucket area, and other relevant parameters. Figure 7 contains the final distribution of $\mu^-$s and $\pi^-$s at the end of the match.
