Abstract

The proposed Project X machine at Fermilab must deliver a widely varying bunch pattern to provide beam to several experiments quasi-simultaneously. H-Beam is delivered to the 2.1 MeV Medium Energy Beam Transport (MEBT) section at 162.5 MHz continuous wave (CW) by a radio frequency quadrupole magnet (RFQ). Unnecessary beam bunches will be selectively chopped out in the MEBT by two identical choppers on a bunch-by-bunch basis and stopped by an absorber. The Project X Injector Experiment (PXIE) will be the test bed to demonstrate a chopper's ability to form an arbitrary bunch pattern. Presently two kicker system versions are under development. One proposed version is a 50 Ω planar structure driven by a ±250 V linear amplifier. The second proposed version is a 200 Ω helical, microstrip line structure driven by a 500 V bipolar switch. This paper describes the development status of the 200 Ω version and includes the design concept, comparison of 3D modelling work with prototype measurements, 200 Ω hardware description and progress with the driver.

SYSTEM REQUIREMENTS

The challenge for this application is the bandwidth requirement to chop beam continuously. Beam will be delivered to a number of experiments “at the same time”, so kicking patterns would vary depending upon the needs of the experiments. Thus, the frequency at which bunches change from being kicked in and out will vary from 1 to 35 MHz average and 81.25 MHz peak for about 20 alternating bunches. This 200 Ω chopper offers a design solution by taking advantage of reduced power requirement and includes the development of suitable driver.

Beam beta in the MEBT is .067 at 2.1 MeV, so the kicker can be a traveling wave structure (the “kicker”) to slow down the propagating kicker voltage to match the beam velocity. The chopper consists of two 50 cm long traveling wave kickers parallel to each other on opposite sides of the beam. Applied voltage to the parallel kickers will always be of opposite polarity.

The MEBT's lattice allows for a chopper either to apply a voltage to only kick beam out to the absorber (the unipolar scheme), or to kick beam both in and out with opposite polarity voltages (the bipolar scheme). The unipolar scheme requires applying 0 V and 500 V and the bipolar scheme ±250 V. Voltage tolerance is ±25 V.

SYSTEM DESIGN

Component power dissipation is a big issue, and current flowing in the kicker does nothing to kick beam. These facts made it appealing to design a higher impedance system than 50 Ω. Power delivered to the load is a factor of four lower at 200, the kicker structure’s RF I²R losses in the vacuum are lower by a factor of 16 (all other physical characteristics being the same). The downside is that all system components need to be developed. Fig. 1 is the block diagram of intended system.

Helical kicker

Meander line kickers have been implemented. However, limited power handling but evident pulse distortion suggested considering alternatives. Helical structures have also been built [2]. Constructing a cylindrically helical, 175 Ω microstrip line demonstrated promising results. Subsequent ~200 Ω versions with good mechanical uniformity resulted in good enough performance to proceed with the 200 Ω idea.

The helical wire is #13 flat magnet wire (.105” x .041”) held above a copper ground tube by four ceramic spacers. This wire size was chosen to be stiff to hold its shape yet easy enough to wind tightly on a mandrel by hand. The 2 cm wide electrodes to face the beam are attached to each turn of wire. Beam aperture between the two facing helices is 16 mm. Fig. 2a shows a photograph of a kicker prototype.

The helix electrical characteristics and performance are affected when the two helical are positioned alongside each other, as in Fig. 2a, and driven with opposite polarities. The electrical effects are that impedance is lowered and propagation velocity reduced at the 3-5% level. Also, the helix microstrip line alone exhibits 900 MHz bandwidth but drops by almost 300 MHz due to the second helix’s proximity. Therefore, electrical measurements of a single helix are only valid when a zero voltage plane is installed to effectively electrically mirror the missing helix. A metal surface positioned at beam-centre needs to extend the length of the helix, be parallel to the electrodes and grounded to the copper ground tube at both ends.

Magnetic coupling of the helical microstrip line geometry affects its characteristic impedance. The geometry for this 200 Ω helix would be 140 Ω line if laid out flat.

Estimated RF I²R losses in the wire are about 6 W. However, the design requirements call for handling 40 W of inadvertent beam striking each helix. The ceramic spacers supporting the helix will conduct the heat to the copper ground tube. This nominal 1” diameter copper

tube is to be water cooled. The ceramic chosen is a type of machinable AlN having 50 W/m/K thermal conductivity available from Ceramic Products, Inc. Vacuum compatible epoxy is to be applied between all ceramic to copper surfaces to assist thermal conduction. The wire is estimated to rise <10°C but has yet to be confirmed by testing.

**Chopper driver**

The approach taken for the 200 Ω chopper driver was to develop a bipolar switch, DC coupled to the helix. The required switching rates are those mentioned earlier, and rise/fall times need to be under 2 ns, 5%-95%. Switching losses must be considered for the average rate of 35 MHz and are not trivial. A transistor’s capacitive switching losses are \( CV^2f \) in a bipolar switch topology and amount to 3.5 W switching 100 V but 88 W switching 500 V having 10 pF Coss. The appeal to build a bipolar switch as a chopper driver was: (1) it has the DC coupled advantages; (2) designing a circuit from scratch for 200 Ω is easier than for 50 (at least in principle), and (3) the very low capacitance of available GaN FETs from Polyfet Devices, Inc. There is no single transistor available that can switch 500 V and handle their own capacitive switching losses at 35 MHz; but these FET losses come down with \( V^2 \) when connected in series to share voltage.

Current development effort is on a bipolar driver using cascode switches. Five FETs would be necessary per switch for 500 V with currently suitable and available FETs. The cascode switch is a modular design to allow for a variable number of common gate stages. A bipolar switch assembly is shown in Fig. 3 composed of 3-FET cascode switches.

Fig. 1 shows the driver’s major circuit blocks regardless of the number common gate stages installed cascode. The high-side switch floats with the load, so gate signal isolation must be designed for the ultimate transient immunity of >250 kV/µs—well beyond commercial isolator ICs. (Low jitter fiber optic receivers are too physically large.) Narrow voltage pulses are generated at the ground-level from input rising and falling edges. These pulses set and reset latches on the cascode switch’s control level that, in turn, reconstruct the ground-level chopper signal waveform and preserve timing information. Dead time is a settable parameter necessary to prevent shoot-through current. The cascode control board level includes a discrete GaN FET driver circuit, again, in the absence of any available IC. Not shown in any diagram is a 1 MHz, regulated AC voltage
distribution system that delivers power to every isolated circuit board. Both high and low-side switches are totally isolated from power/ground. Thus, the driver can be biased with bipolar voltages or with a voltage offset from ground.

**Figure 3.** Bipolar switch assembly composed of 3-FET cascode switches mounted to power distribution board.

### 200 Ω Lines, Feed Throughs and Load

This design is sensitive to reflections at impedance discontinuities particularly downstream of the helix. Reflections are re-reflected off the driver because of its very low impedance. Modelling verified a flat 200 Ω microstrip as the best line type to match to the helix. Feed throughs were custom made by MPC Products, Inc., and designed having isolated, cylindrical 200 Ω geometry; see Fig. 2b. Finally, the 200 Ω load was made by Elab, Inc., utilizing commercial attenuators but include an input compensation network to minimize reflection.

**PRELIMINARY RESULTS**

Fig. 4 is the through-voltage measurement observed at the 200 Ω load/attenuator output revealing the degree to which the 200 Ω transmission lines and load are matched to the helix. The major reflections are due to helix end effect not completely eliminated. Fig. 5 is the shows the hardware included in this measurement. A more finalized assembly is currently being constructed that will include the feed throughs.

**Figure 4.** Through-voltage of incident pulse and all reflections. Reflection levels are ±3%.

**Figure 5.** Reflection test setup. Helix is a 26 cm long prototype driven by 100 V (alt. ±50 V) bipolar switch.

Development efforts first investigated whether a cascode switch was feasible at all. A cascode switch using 5 FETs achieved 480 V but had issues. These were addressed and incorporated into the current design that was next assembled to demonstrate switching to at least 100 V bipolar. This circuit (in Fig. 5) dissipates little power at 35 MHz CW and switches at 81 MHz easily for long bursts. Current efforts are with 3-FET cascode switches in a bipolar assembly, but results are two preliminary to report.

**Figure 6.** Helix through-voltage driven 0-100V, at 75 MHz. Bipolar switch driver is composed of 1-FET switches: <2 ns rise time (5-95%), fall time includes 2.4 ns dead time, 2.1 ns flattop.

### SUMMARY

A 200 Ω microstrip line helix has been demonstrated to be a viable kicker option. Reflections are manageable. GaN FETs are choice with which to build a fast switch driver. The status of building a 500 V a bipolar switch driver out of cascode switches is at the 300 V stage of development.
