Abstract

Five mutually exclusive searches for supersymmetry are presented based on events in which b jets and four W bosons are produced in proton-proton collisions at $\sqrt{s} = 8$ TeV. The data, corresponding to an integrated luminosity of 19.5 fb$^{-1}$, were collected with the CMS experiment at the CERN LHC in 2012. The five studies differ in the leptonic signature from the W boson decays, and correspond to all-hadronic, single-lepton, opposite-sign dilepton, same-sign dilepton, and $\geq 3$ lepton final states. The results of the five studies are combined to yield 95% confidence level exclusions of 1280 and 570 GeV for the gluino and bottom-squark masses in the context of gluino and bottom-squark pair production, respectively. These limits are around 50 GeV more stringent than are obtained from any of the individual channels.

Submitted to Physics Letters B
1 Introduction

The standard model (SM) of particle physics provides an accurate description of known particle properties and interactions. The discovery of a Higgs boson by the ATLAS [1] and CMS [2] Collaborations at the CERN LHC represents the latest major milestone in the validation of the SM. Despite its success, the SM is known to be incomplete because, for example, it does not offer an explanation for dark matter and it contains ad-hoc features, such as the fine-tuning [3–9] required to stabilize the Higgs boson mass at the electroweak scale. Many extensions to the SM have been proposed. In particular, supersymmetry (SUSY) may provide a candidate for dark matter in R-parity conserving models [10] as well as a natural solution to the fine-tuning problem [3–9].

The CMS and ATLAS Collaborations have performed many searches for physics beyond the SM. Thus far, no significant evidence for new physics has been obtained. The search for supersymmetry is particularly interesting phenomenologically because of the large number of new particles expected. The LHC SUSY search program consists therefore of a wide array of searches [11–22]. Any particular manifestation of SUSY in nature would likely result in topologies that are detectable in a variety of final-states. Individual searches can therefore be combined to provide complementarity and enhanced sensitivity in the global search for new physics.

Naturalness arguments suggest that the supersymmetric partners of the gluon (gluino, \( \tilde{g} \)) and third-generation quarks (the top and bottom squarks, \( \tilde{t} \) and \( \tilde{b} \)) should not be too heavy [23–26]. Direct or cascade production of third-generation squarks can lead to final states with several W bosons and bottom quarks, and considerable imbalance in transverse momentum. The missing momentum arises from neutrinos in events where one or more W bosons decay leptonically, but also, for the R-parity conserving models considered here, because the lightest SUSY particle (LSP), taken to be the lightest neutralino \( \tilde{\chi}_1^0 \), is weakly interacting and stable, escaping without detection. The studies presented here focus on SUSY simplified model scenarios [27, 28] with four W bosons. Each of the W bosons can decay either into a quark-antiquark pair or into a charged lepton and its neutrino. Depending on the decay modes of the W bosons, the final states contain 0–4 leptons. This makes combining the final states with different lepton multiplicities beneficial. The dilepton signature is split according to the relative electric charges of the leptons, providing five mutually exclusive analyses for the combination: fully hadronic, single-lepton, opposite-sign dilepton, same-sign dilepton, and \( \geq 3 \) leptons (multilepton). The results are based on proton-proton collision data collected at \( \sqrt{s} = 8 \text{ TeV} \) with the CMS experiment at the LHC during 2012, and correspond to an integrated luminosity of 19.5 fb\(^{-1}\).

The first simplified model we consider describes gluino pair production, followed by the decay of each gluino to a top quark-antiquark pair (tt) and the LSP. For cases where the top squark mass is larger than the gluino mass, the decay will proceed through a virtual top squark (T1tttt model, Fig. 1(left)). Alternatively, when the top squark mass is smaller than the gluino mass and phase space allows, the decay will proceed through an on-shell top squark (T5tttt model, Fig. 1(middle)). Each top quark decays to a bottom quark and a W boson, leading to final states with four W bosons, four bottom-quark jets (b jets), and considerable \( \vec{p}_T \) in transverse momentum. The second simplified model we consider describes bottom-antibottom squark pair production, where we assume that each bottom squark decays to a top quark and a chargino (\( \tilde{\chi}_1^\pm \)), and that the chargino then decays to yield a W boson and the LSP (T6ttWW model, Fig. 1(right)). The final state thus contains four W bosons, two b jets, and large \( \vec{p}_T \) in transverse momentum.

The paper is organized as follows. Section 2 describes the CMS detector. The event simulation, trigger, and reconstruction procedures are described in Section 3. Section 4 presents details of...
the individual analyses, with particular emphasis on the opposite-sign dilepton search, which is presented here for the first time. The combination methodology and results are presented in Section 5. Section 6 provides a summary.

2 Detector

The central feature of the CMS detector is a superconducting solenoid, of 6 m internal diameter, that produces an axial magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter, and a brass and plastic scintillator hadron calorimeter. Muons are detected in gas ionization chambers embedded in the steel flux-return yoke outside the magnet. The tracking system covers the pseudorapidity range $|\eta| < 2.5$, the muon detectors $|\eta| < 2.4$, and the calorimeters $|\eta| < 3.0$. Steel and quartz-fiber forward calorimeters cover $3 < |\eta| < 5$. A detailed description of the CMS apparatus and coordinate system are given in Ref. [29].

3 Event reconstruction, trigger, and simulation

The recorded events are reconstructed using the CMS particle-flow algorithm [30, 31]. Electron candidates are reconstructed by associating tracks to energy clusters in the electromagnetic calorimeter [32, 33]. Muon candidates are reconstructed by combining information from the tracker and the muon detectors [34].

Particle-flow constituents are clustered into jets using the anti-$k_T$ clustering algorithm with a distance parameter of 0.5 [35]. Corrections are applied as a function of jet transverse momentum ($p_T$) and $\eta$ to account for non-uniform detector response [36, 37]. Contributions from additional pp collisions overlapping with the event of interest (pileup) are estimated using the jet area method [38, 39] and are subtracted from the jet $p_T$. The total visible jet activity $H_T$ is defined as the scalar sum of the jet $p_T$ in the event, and $H_T^{\text{miss}}$ as the $p_T$ imbalance of the reconstructed jets, where the $p_T$ and $\eta$ requirements for accepted jets are specified for the individual searches in Section 4. The identification of b jets is performed using the combined secondary vertex algorithm at the medium working point [40], which has a b-jet tagging efficiency of 70% and a light-flavor jet misidentification rate below 2% for jets with $p_T$ values in the range of interest for this analysis. The missing transverse momentum vector $p_T^{\text{miss}}$ is defined as the projection on the plane perpendicular to the beam axis of the negative vector sum of the momenta of all reconstructed particles. Its magnitude is referred to as $E_T^{\text{miss}}$.

The data sample used for the fully hadronic analysis was recorded with trigger algorithms that required events to have $H_T > 350$ GeV and $E_T^{\text{miss}} > 100$ GeV. The single-lepton analysis uses triple- or double-object triggers. The triple-object triggers require a lepton with $p_T > 15$ GeV,
together with $H_T > 350 \text{ GeV}$ and $E_T^{\text{miss}} > 45 \text{ GeV}$. The double-object triggers have the same $H_T$ requirement, no $E_T^{\text{miss}}$ requirement, and a lepton $p_T$ threshold of 40 GeV. The data samples for the dilepton and multilepton analyses were collected with ee, $e\mu$, and $\mu\mu$ double-lepton triggers, which require at least one $e$ or one $\mu$ with $p_T > 17 \text{ GeV}$ and another with $p_T > 8 \text{ GeV}$.

Simulated Monte Carlo (MC) samples of signal events and SM $t\bar{t}$, Drell–Yan, $W^+\text{jets}$, single-top quark, $t\bar{t}W$, and $t\bar{t}Z$ events are produced using the MADGRAPH 5.1.3.30 generator. The PYTHIA 6.4.24 generator is used to simulate the generic multijet QCD and diboson (WW, ZZ, and WZ) processes, as well as to describe the parton shower and hadronization for the MADGRAPH samples. All SM samples are processed with the full simulation of the CMS detector, based on the GEANT4 package, while the signal samples are processed with the CMS fast simulation program. The fast simulation is validated through comparison of its predictions with those of the full simulation, and efficiency corrections based on data are applied. The effect of pileup interactions is included by superimposing a number of simulated minimum bias events on top of the hard-scattering process, with the distribution of the number of reconstructed vertices matching that in data.

4 Search channels

This paper reports the combination of five individual searches for new physics by CMS. The fully hadronic [19], single-lepton [20], same-sign dilepton [21], and multilepton [22] searches have all been published, and are summarized briefly below. The opposite-sign dilepton search is presented here for the first time and is therefore described in greater detail.

4.1 Fully hadronic analysis

Considering that signal events contain four W bosons, the fully hadronic branching fraction is about 24%. The fully hadronic analysis [19] requires at least three jets with $p_T > 40 \text{ GeV}$ and $|\eta| < 2.5$, and vetoes events containing an isolated electron or muon with $p_T > 10 \text{ GeV}$ and $|\eta| < 2.5\ (2.4)$ for electrons (muons). The $H_T$ and $H_T^{\text{miss}}$ values are required to exceed 500 and 200 GeV, respectively. To render the analysis more sensitive to a variety of final-state topologies resulting from longer cascades of squarks and gluinos, and therefore a large number of jets, the events are divided into three exclusive jet-multiplicity regions: $N_{\text{jets}} = (3–5), (6–7), \text{ and } \geq 8$. The events are further divided into exclusive regions of $H_T$ and $H_T^{\text{miss}}$. The exploitation of higher jet multiplicities is motivated by natural SUSY models in which the gluino decays into top quarks [19]. This analysis does not impose a requirement on the number $N_{\text{bjets}}$ of tagged b jets, thereby maintaining a high signal efficiency.

The main SM backgrounds for the fully hadronic channel arise from $Z^*\text{jets}$ events in which the $Z$ boson decays to a $\nu\bar{\nu}$ neutrino pair; from $W^*\text{jets}$ and $t\bar{t}$ events with a $W$ boson that decays directly or through a $\tau$ lepton to an $e$ or $\mu$ and the associated neutrino(s), with the $e$ or $\mu$ undetected or outside the acceptance of the analysis; from $W^*\text{jets}$ and $t\bar{t}$ events with a $W$ boson that decays to a hadronically decaying $\tau$ lepton and its associated neutrino; and from QCD multijet events. For the first three background categories, the neutrinos provide a source of genuine $H_T^{\text{miss}}$. For the QCD multijet event background, large values of $H_T^{\text{miss}}$ arise from the mismeasurement of jet $p_T$ or from the neutrinos produced in the semileptonic decays of hadrons. All SM backgrounds are determined from control regions in the data, and are found to agree with the observed numbers of events in the signal regions.
4.2 Single-lepton analysis

With four W bosons, the branching fraction of signal events to states with a single electron or muon is about 42%, including contributions from leptonically decaying τ leptons. The single-lepton analysis \[20\] requires the presence of an electron or muon with \( p_T > 20 \text{ GeV} \) and no second electron or muon with \( p_T > 15 \text{ GeV} \), with the same \( \eta \) restrictions on the e and \( \mu \) as in Section 4.1. Jets are required to have \( p_T > 40 \text{ GeV} \) and \( |\eta| < 2.4 \). The \( S_T^{\text{lep}} \) variable is evaluated, defined by the scalar sum of \( E_T^{\text{miss}} \) and the lepton \( p_T \). Events must satisfy \( N_{\text{jets}} \geq 6, N_{\text{bjets}} \geq 2, H_T > 400 \text{ GeV} \), and \( S_T^{\text{lep}} > 250 \text{ GeV} \). A further variable, the azimuthal angle \( \Delta \phi(W, \ell) \) between the W boson candidate in single-lepton \( t\bar{t} \) background events and the lepton, is evaluated. For this variable, the \( p_T \) of the W boson candidate is defined by the vector sum of the lepton \( p_T \) and \( \vec{p}_T^{\text{miss}} \). The analysis requires \( \Delta \phi(W, \ell) > 1 \). The search is then performed in exclusive regions of \( S_T^{\text{lep}} \) for \( N_{\text{bjets}} = 2 \) and \( N_{\text{bjets}} \geq 3 \).

The main SM backgrounds for the single-lepton channel arise from dilepton \( t\bar{t} \) events in which one lepton is not reconstructed or lies outside the acceptance of the analysis, from residual single-lepton \( t\bar{t} \) events, and from events with single-top quark production. The backgrounds are evaluated using data control samples. The total number of background events is found to agree with the observed number of events in each signal region.

4.3 Same-sign dilepton analysis

The branching fraction for events with four W bosons to a final state with at least two same-sign leptons (ee, \( \mu\mu \), or \( e\mu \)) is 7%, including the contributions of \( \tau \) leptons. For the present study, we make use of the high-\( p_T \) selection of the same-sign dilepton analysis in Ref. \[21\], which requires at least two same-sign light leptons (e, \( \mu \)) with \( p_T > 20 \text{ GeV} \), \(|\eta| < 2.4\), and invariant mass above 8 GeV. To prevent overlap between the same-sign dilepton and multilepton analyses, an explicit third-lepton veto is added in the same-sign dilepton analysis, as in the search for \( t\bar{t} \) production described in Ref. \[22\]. Jets are required to satisfy \( p_T > 40 \text{ GeV} \) and \(|\eta| < 2.4\). Events must have \( N_{\text{jets}} > 2, H_T > 200 \text{ GeV} \), and \( E_T^{\text{miss}} > 50 \text{ GeV} \). The events are examined in exclusive regions of \( H_T \) and \( E_T^{\text{miss}} \) for \( 2 \leq N_{\text{jets}} \leq 3 \) and \( N_{\text{jets}} \geq 4 \), all for \( N_{\text{bjets}} = 0, 1, \) and \( \geq 2 \).

There are three main sources of SM background in this analysis: non-prompt leptons, rare SM processes, and electrons with wrong charge assignments. The main sources of non-prompt leptons are leptons from bottom- and charm-quark decays, misidentified hadrons, muons from light-meson decays in flight, and electrons from unidentified photon conversions. The background from non-prompt leptons is evaluated from data control regions. Diboson, \( t\bar{t}W \), and \( t\bar{t}Z \) production are the most important rare SM background sources. Their contributions are estimated from MC simulation. Opposite-sign dileptons can also contribute to the background when the charge of an electron is misidentified because of bremsstrahlung emitted in the tracker material. This contribution is estimated using a technique based on \( Z \rightarrow e^+e^- \) data. No significant deviations are observed from the SM expectations.

4.4 Multilepton analysis

The branching fraction for events with four W bosons to decay to a final state with three or more charged leptons (e or \( \mu \)) is 6%, including \( \tau \) lepton contributions. The multilepton sample used in the present study corresponds to the selection of events with three or more such leptons presented in Ref. \[22\]. The electrons or muons are required to have \( p_T > 10 \text{ GeV} \) and \(|\eta| < 2.4\), except at least one of the three leptons must have \( p_T > 20 \text{ GeV} \). Jets are required to have \( p_T > 30 \text{ GeV} \) and \(|\eta| < 2.4\). Events must satisfy \( N_{\text{jets}} \geq 2, N_{\text{bjets}} \geq 1, H_T > 60 \text{ GeV} \), and
$E_T^{\text{miss}} > 50 \text{ GeV}$. The events are examined in exclusive regions of $H_T$ and $E_T^{\text{miss}}$ for $2 \leq N_{\text{jets}} \leq 3$ and $N_{\text{jets}} \geq 4$, both with $N_{\text{bjets}} = 1$ and 2, and for $N_{\text{jets}} \geq 3$ with $N_{\text{bjets}} \geq 3$.

Compared to the fully hadronic, single-lepton, or dilepton signatures, the multilepton search targets final states with small branching fractions, but provides good signal sensitivity because the three-lepton requirement strongly suppresses backgrounds. Only a few SM processes exhibit such signatures. Background from diboson production is highly suppressed by the $N_{\text{bjets}}$ requirement. The main backgrounds arise from events with a combination of $t\bar{t}$ production and non-prompt leptons, as well as from rare SM processes like $t\bar{t}W$ and $t\bar{t}Z$ production. The non-prompt lepton background is evaluated using data control regions and the rare SM background from simulation. There is no statistically significant excess of events found in the signal regions above the SM expectations.

4.5 Opposite-sign dilepton analysis

The branching fraction for events with four W bosons to a final state with at least one opposite-sign lepton pair (e or $\mu$) is 14%, including the contributions of $\tau$ leptons. The opposite-sign dilepton search requires the presence of exactly two opposite-sign leptons (e or $\mu$), each with $p_T > 20 \text{ GeV}$ and $|\eta| < 2.4$. Jets must satisfy $p_T > 30 \text{ GeV}$ and $|\eta| < 2.5$. This analysis targets the T1tttt and T5tttt scenarios described in the Introduction.

Many variables are examined in order to define a signal region (SR) that maximizes signal content while minimizing the contributions of SM events. We choose those variables that demonstrate the greatest discriminating power between signal and SM events, and that exhibit the smallest level of correlation amongst themselves: $N_{\text{jets}}$, $N_{\text{bjets}}$, $E_T^{\text{miss}}$, and the $\eta$ values of the two jets with largest $p_T$. The criteria that yield the highest sensitivity in the parameter space of the T1tttt model, summarized in Table 1, are optimized using simulated events. Events are divided into bins of $E_T^{\text{miss}}$. The bin with highest $E_T^{\text{miss}} (>180 \text{ GeV})$ is the most sensitive for the bulk of the signal phase space, but the bins with lower $E_T^{\text{miss}}$ are important for compressed spectra, i.e., for signal scenarios with small mass differences between the SUSY particles. After applying the selection criteria summarized in Table 1, the remaining SM background is primarily composed of events with $t\bar{t}$, Drell–Yan, and W+jets production.

A control region (CR) is defined by the sum of the two event samples obtained by separately inverting the $\eta_1 < 1$ and $\eta_2 < 1$ requirements. The contribution of signal events to the control region depends on the gluino mass ($m_{\tilde{g}}$) and the LSP mass ($m_{\tilde{t}1}$) and can be as large as 10%. The contributions of signal events to the CR are taken into account in the interpretation of the results.

An extrapolation factor $R_{\text{ext}}$ is defined as a function of $E_T^{\text{miss}}$ and $N_{\text{bjets}}$, as the ratio of the number of SM events in the SR to that in the CR. In simulated events the $R_{\text{ext}}$ factor is observed to change slowly as a function of $E_T^{\text{miss}}$, as shown in Fig. 2. The $R_{\text{ext}}$ ratio is similarly found to be independent of $N_{\text{bjets}}$, making it possible to extract its value directly from data using events with $N_{\text{bjets}} = 2$, without altering the other signal and control selection criteria. Thus the
background estimate is derived entirely from data, minimizing systematic uncertainties.

The SM background prediction for the SR is obtained by multiplying $R_{\text{ext}}$ with the number of data events in the CR:

$$N_{\text{SR}}^{\text{predicted}} = R_{\text{ext}} N_{\text{data}}^{\text{CR}}.$$  

(1)

Figure 2: Extrapolation factors from the control region to the signal region, $R_{\text{ext}}$, as a function of $E_T^{\text{miss}}$, for simulated events with $N_{\text{bjets}} = 2$ (black triangles) and $N_{\text{bjets}} \geq 3$ (red points). All the other signal selection criteria have been applied. The lower panel shows the ratio of the $N_{\text{bjets}} \geq 3$ to the $N_{\text{bjets}} = 2$ results.

The performance of the background estimation method is studied both in the SR, using simulation, and in a cross-check region defined by $2 \leq N_{\text{jets}} \leq 4$, using data and simulation. Figure 3 shows agreement between the predicted and actual $E_T^{\text{miss}}$ distributions for the SR and cross-check regions.

The systematic uncertainty in the background prediction is based on the statistical uncertainties in the data, used to extract the $R_{\text{ext}}$ factors, and on the level of agreement between the predicted and actual results found using simulation in the SR (Fig. 3 middle). No significant bias in the method is observed in simulation, and an additional systematic uncertainty of 25–50% is assigned to account for the statistical precision of the latter term.

The predicted and observed $E_T^{\text{miss}}$ distributions for the signal region are shown in Fig. 4 and listed in Table 2. No excess of events is observed with respect to the SM prediction. For the
Figure 3: $E_{\text{T}}^{\text{miss}}$ distribution predicted for SM backgrounds by extrapolation from the control region (red bands), compared to actual distribution (black points) for (left) simulated events in the cross-check region, (middle) data events in the cross-check region, and (right) simulated events in the search region. The lower panels show the ratios of the actual to predicted distributions.
5 Combination of analyses

The results from the five analyses are combined to provide more stringent conclusions. The combined results are interpreted in the context of the SUSY scenarios illustrated in Fig. 1. The 95% confidence level (CL) upper limits (UL) on the cross sections are calculated using the LHC-style CL$_S$ method. Because of their large branching fractions, the fully hadronic and single-lepton analyses are most sensitive in the largest part of the phase space. However, the analyses based on higher lepton multiplicities become important for the more compressed mass spectra and for models with fewer b jets.

Systematic uncertainties in the signal selection efficiency are evaluated using the same techniques for all analyses. They are evaluated separately for the different signal models, search.
regions, and for each hypothesis for the SUSY particle masses. The systematic uncertainties in the signal modeling are taken to be 100% correlated among the mass hypotheses. As an example, a summary of systematic uncertainties for the T1tttt model is given in Table 3. The total systematic uncertainty varies between 7 and 35% depending on the decay modes considered, the search regions, and the mass points. An important source of systematic uncertainty for the analyses that require multiple leptons arises from the lepton identification and isolation efficiencies, which are evaluated using $Z \rightarrow \ell^+ \ell^-$ events. The uncertainty in the energy scale of jets gives rise to a 1–15% systematic uncertainty that increases with more stringent kinematic requirements. For compressed spectra, the modeling of initial-state radiation (ISR) [18] is an important source of uncertainty. The PDF4LHC recommendations [49, 50] are used to evaluate the uncertainty associated with the parton distribution functions (PDFs). For most of the analyses the background evaluation methods differ, and so the systematic uncertainties are treated as uncorrelated. The overlap between most control regions is studied and found to be negligible. The only exception occurs for the same-sign dilepton and multilepton analyses, which use the same methods to predict the background from non-prompt leptons and rare SM processes. For this case, the systematic uncertainties are taken to be fully correlated.

Table 3: Relative (%) systematic uncertainties in the signal efficiency of the T1tttt model for the fully hadronic (0 ℓ), single-lepton (1 ℓ), opposite-sign dilepton (2 OS ℓ), same-sign dilepton (2 SS ℓ), and multilepton (≥3 ℓ) analyses. The given ranges reflect the variation across the different search regions and for different values of the SUSY particle masses.

5.1 Gluino-mediated top squark production with virtual top squarks

The results are first interpreted in the context of $\tilde{g} \tilde{g}$ production with $\tilde{g} \rightarrow \tilde{t}\tilde{\chi}^0_1$ through a virtual $\tilde{t}$, the process referred to as T1tttt. The signature contains four top quarks and has significant jet activity (Fig. 1 left). The fully hadronic and single-lepton analyses are therefore expected to be especially sensitive, because of their larger signal efficiencies. Figure 5 left, shows the 95% CL upper limits on the product of the cross section and branching fraction in the $(m_{\tilde{g}}, m_{\tilde{\chi}^0_1})$ plane. The exclusion curves are evaluated by comparing the cross section upper limits with the next-to-leading-order (NLO) plus next-to-leading-logarithm (NLL) theoretical production cross sections [52–56]. The thick red dashed line indicates the 95% CL expected limit, which is defined as the median of the upper limit distribution obtained using pseudo-experiments and a likelihood model. The ±1 standard deviation experimental systematic uncertainties $\sigma_{\text{experiment}}$ are shown by the thin red line around the expected limit. The observed limit is given by the thick solid black line, where the uncertainty band (thin black lines) indicates the ±1 standard deviation uncertainty $\sigma_{\text{theory}}$ in the theoretical cross section. The theoretical uncertainty is mainly due to uncertainties in the renormalization and factorization scales, and in the knowledge of
the PDFs. To quote the gluino mass exclusion, we conservatively consider the observed upper limit minus $\sigma_{\text{theory}}$. It is seen that gluinos below 1280 GeV are excluded for $m_{\tilde{\chi}^0_1} \approx 0$ GeV. Assuming a gluino mass of 1000 GeV, an LSP with a mass below 600 GeV is excluded.

The exclusion curves for each individual analysis are shown in Fig. 5 middle. As expected, for low LSP masses, the single-lepton and fully hadronic analyses provide the most stringent results. For $m_{\tilde{\chi}^0_1} \approx 0$ GeV, the combination is seen to extend the gluino mass exclusion by about 35 GeV compared to the single-lepton analysis, which provides the most stringent corresponding individual result. Large values of $m_{\tilde{\chi}^0_1}$ lead to more compressed mass spectra, softer decay products, and therefore smaller $E_T^{\text{miss}}$. As a result, the fully hadronic and single-lepton analyses become less sensitive, since they require high-$p_T$ jets and large $E_T^{\text{miss}}$. The dilepton and multilepton analyses depend less on the $p_T$ spectrum of the final-state particles, and their sensitivity decreases less for smaller mass splittings. Thus the analyses requiring two or more leptons contribute most to the overall sensitivity when the difference $m_{\tilde{g}} - m_{\tilde{\chi}^0_1}$ becomes small. For $m_{\tilde{g}} \approx 1000$ GeV, the exclusion limit on $m_{\tilde{\chi}^0_1}$ is extended by about 60 GeV because of the addition of the multilepton channels.

Figure 5: (left) The 95% CL cross section upper limits for gluino-mediated squark production with virtual top squarks, based on an NLO+NLL reference cross section for gluino pair production. The solid and dashed lines indicate, respectively, the observed and expected exclusion contours for the combination of the five analyses. The thin contours indicate the $\pm 1$ standard deviation regions. (right) Exclusion contours for the individual searches, plus the combination.

5.2 Gluino-mediated top squark production with on-shell top squarks

If the top squarks are light enough, the gluino can decay through an intermediate on-shell top squark. In this model, referred to as T5tttt, the values of $m_{\tilde{\chi}^0_1}$, $m_{\tilde{t}}$, and $m_{\tilde{g}}$ function as independent parameters. Results are presented for a fixed mass $m_{\tilde{\chi}^0_1} = 50$ GeV and scanned over the masses of the on-shell top squark and gluino. The 95% CL upper limits on the product of the cross section and the branching fraction in the $m_t$ versus $m_{\tilde{g}}$ plane are shown in Fig. 6 left. In the context of the T5tttt model, gluinos with masses below around 1300 GeV are excluded for top squark masses around 700 GeV. Figure 6 right, shows the results for the individual
studies. The contribution from the fully hadronic analysis remains important even for relatively small top squark masses \( m_{\tilde{t}} \approx 200 \text{ GeV} \) because of the high \( H_T \) search regions: signal events in this case contain smaller \( E_T^{miss} \) but larger \( H_T \). However, for \( m_{\tilde{t}} < 150 \text{ GeV} \), the fully hadronic analysis loses sensitivity. The single-lepton analysis provides the most stringent individual results, but loses sensitivity as \( m_{\tilde{t}} \) decreases. The sensitivity of the dilepton and multilepton searches depends less strongly on \( m_{\tilde{t}} \), but their sensitivity even in the compressed region is rather small, although they contribute to the combination at very small \( m_{\tilde{t}} \). The combination improves the exclusion reach in the gluino mass by about 50 GeV for small \( m_{\tilde{t}} \).

![Figure 6](image)

**Figure 6**: (left) The 95% CL cross section upper limits for gluino-mediated squark production with on-shell top squarks, assuming an LSP mass of \( m_{\tilde{\chi}^0_1} = 50 \text{ GeV} \), based on an NLO+NLL reference cross section for gluino pair production. The solid and dashed lines indicate, respectively, the observed and expected exclusion contours for the combination of the five analyses. The thin contours indicate the \( \pm 1 \) standard deviation regions. (right) Exclusion contours for the individual searches, plus the combination.

### 5.3 Bottom squark pair production

We also consider bottom squark pair production with the bottom squarks decaying as \( \tilde{b}_1 \rightarrow t \tilde{\chi}^-_1 \) and \( \tilde{\chi}^-_1 \rightarrow W^- \tilde{\chi}^0_1 \), known as T6ttWW (Fig. 1 right). The single-lepton and opposite-sign dilepton analyses have very little sensitivity to such a model because of the stringent \( N_{bjets} \) and \( N_{jets} \) requirements, and are not included in the combination. The fully hadronic analysis, which does not impose a requirement on \( N_{bjets} \), contributes some sensitivity. The main sensitivity comes from the same-sign and multilepton searches with either \( N_{bjets} = 1 \) or 2.

For the T6ttWW model, the LSP mass is set to 50 GeV. The resulting 95% CL upper limits on the product of the cross section and branching fraction in the \( m_{\tilde{\chi}^0_1} \) versus \( m_{\tilde{b}_1} \) plane are shown in Fig. 7 left. In the context of this model, bottom squark masses up to 570 GeV are excluded for LSP masses around 150-300 GeV. Figure 7 right, shows the exclusion limits for the individual analyses assuming a fixed bottom squark mass of 600 GeV. The same-sign dilepton analysis provides the best sensitivity for chargino masses below 400 GeV, and the combination with the multilepton analysis leads to a 15% improvement in the cross section upper limit and even up to 35% improvement in the expected cross section upper limit, which represents an improvement in the expected sbottom mass exclusion limits of around 50 GeV. For larger chargino masses,
the fully hadronic analysis becomes more sensitive because jets from W boson decays become more energetic.

Figure 7: (left) The 95% CL cross section upper limits for bottom-squark pair production, assuming an LSP mass of $m_{\tilde{\chi}_1^0} = 50$ GeV, based on an NLO+NLL reference cross section. The solid and dashed lines indicate, respectively, the observed and expected exclusion contours for the combination of the fully hadronic, same-sign dilepton, and multilepton analyses. The thin contours indicate the $\pm 1$ standard deviation regions. (right) Exclusion contours for the individual searches, plus the combination, assuming a bottom squark mass of 600 GeV.

6 Summary

Five searches for supersymmetry with non-overlapping event samples are combined to obtain more stringent exclusion limits on models in which b jets and four W bosons are produced. The results are based on data corresponding to an integrated luminosity of 19.5 fb$^{-1}$ of pp collisions, collected with the CMS detector at $\sqrt{s} = 8$ TeV in 2012. Because of their large branching fractions, the single-lepton and fully hadronic analyses have the largest sensitivity for most of the range of the supersymmetric mass spectra, whereas the analyses with higher lepton multiplicities have higher sensitivity for models with more compressed mass spectra. The complementarity of the searches is exploited to provide comprehensive coverage across a wide region of parameter space. The combined searches yield 95% confidence level exclusions of 1280 and 570 GeV for the gluino and bottom-squark masses in the context of gluino and bottom-squark pair production, respectively. The increase in sensitivity that arises from the combination of the five analyses corresponds to an increase of about 50 GeV in the SUSY mass reach compared to the individual analyses.

Acknowledgments

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we
acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: BMWFW and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES and CSF (Croatia); RPF (Cyprus); MoER, ERC IUT and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMWF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NIH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); MSIP and NRF (Republic of Korea); LAS (Lithuania); MOE and UM (Malaysia); CINVESTAV, CONACYT, SEP, and UASLP-FAI (Mexico); MBIE (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Dubna); MON, RosAtom, RAS and RFBR (Russia); MESTD (Serbia); SEIDI and CPAN (Spain); Swiss Funding Agencies (Switzerland); MST (Taipei); ThEPCenter, IPST, STAR and NSTDA (Thailand); TUBITAK and TAEK (Turkey); NASU and SFFR (Ukraine); STFC (United Kingdom); DOE and NSF (USA).

Individuals have received support from the Marie-Curie programme and the European Research Council and EPLANET (European Union); the Leventis Foundation; the A. P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds pour la Formation à la Recherche dans l’Industrie et dans l’Agriculture (FRIA-Belgium); the Agentschap voor Innovatie door Wetenschap en Technologie (IWT-Belgium); the Ministry of Education, Youth and Sports (MEYS) of the Czech Republic; the Council of Science and Industrial Research, India; the HOMING PLUS programme of Foundation for Polish Science, cofinanced from European Union, Regional Development Fund; the Compagnia di San Paolo (Torino); the Consorzio per la Fisica (Trieste); MIUR project 20108T4XTM (Italy); the Thalis and Aristeia programmes cofinanced by EU-ESF and the Greek NSRF; and the National Priorities Research Program by Qatar National Research Fund.

This appendix presents additional results for the opposite-sign dilepton search. The results of this analysis alone for the T1tttt (Fig. 8 left) and T5tttt (Fig. 8 middle) models are shown, respectively, in Figs. 8 left and right. In the context of the T1tttt model, gluinos with masses below around 980 GeV are excluded for LSP masses below 400 GeV. In the T5tttt model, gluinos with masses below 1000 GeV are probed for top squark masses around 650 GeV.
