Abstract

Oxygen and sulfur nuclei with energies of 200 GeV/nucleon from CERN (experiment EMU07) interacted in nuclear emulsions, which were scanned with minimum bias criteria so that essentially all the interactions are detected. Approximately 1000 interactions of each projectile have been analyzed. Results on the multiplicity distributions, the pseudorapidity distributions and the fragmentation of the projectile and target nuclei are presented. The mean number of intranuclear collisions occurring in each interaction, calculated from a superposition model, provides a useful parameter to organize the data. No significant deviations are found, even at these energies, from models such as the "Venus" model, of the nucleus—nucleus interactions as being the superposition of individual nucleon-nucleon collisions.

1 Introduction

The interactions of relativistic nuclei with target nuclei have been studied by numerous authors using a variety of experimental techniques, see e.g. [1,2]. During the exploratory phase of these studies, as the available energy of the projectile nuclei increased, the nuclear emulsion technique has provided a global view of the phenomena that occur, a view that can hardly be matched by other techniques that provide specific data with higher statistical significance.

The principal goal of the studies of high energy nucleus-nucleus interactions has been the search for the phase transition predicted by QCD [3-7] or for other collective effects. Observations of nonstatistical fluctuations [8-11] may indeed signal the occurrence of new phenomena. On the other hand, it has been known for many years that the superposition models, where the individual nucleon-nucleon collisions are the main concern, adequately describe hadron-nucleus interactions [12-14]. It is, however, anticipated that the superposition models will begin to fail and new physics will appear as the projectile mass and energies are increased. Yet, the studies of the global characteristics of nucleus-nucleus interactions with the currently available projectiles and energies seem to confirm the validity of these models. It may mean that either collective effects are very rare or their influence on the global properties of interactions is weak.

In this paper we present some of the results obtained from the CERN experiment EMU07 in which nuclear emulsions were exposed to oxygen (\(^{16}\text{O}\)) and sulfur (\(^{32}\text{S}\)) beams with an energy of 200 GeV/nucleon. These results have concentrated on obtaining a global view of the inelastic interactions by attempting to detect an unbiased sample of all the interactions occurring. The characteristics of these minimum bias samples as well as of subsamples with different impact parameters are presented. It is shown that the superposition model is essentially valid over the whole range of the number of elementary in intranuclear nucleon-nucleon collisions occurring in these interactions. It was possible to reach this conclusion because the nuclear emulsion technique provides us with a relatively simple and efficient trigger for selecting events on the basis of their impact parameter on the target nuclei.

2 Experimental

Stacks composed of BR-2 nuclear emulsion pellicles with dimensions of 5x10cm and 600 \(\mu\)m thick were exposed at CERN to the 200 GeV/nucleon \(^{16}\text{O}\) and
32S beams. These stacks were orientated so that the beams were parallel to the pellicles. The emulsions were developed with a minimum ionization of approximately 28 grains/100μm, and then analyzed with optical microscopes. An along-the-track minimum bias scanning was performed. The interaction mean free paths in emulsion were determined and were found to be (12.3 ± 0.3)cm and (8.5 ± 0.2)cm for oxygen and sulfur primaries, respectively. These experimentally obtained values are in good agreement with those calculated using the predicted cross-sections published in [15] or [16] and the known composition of BR-2 nuclear emulsion [17]. Consequently, the efficiency of detecting interactions during the scanning must have been very high even for those interactions with low multiplicities.

In the following we will deal only with those interactions in which at least one particle was produced. Pure nuclear fragmentation or electromagnetic dissociation of at least one of the two colliding nuclei were rejected. The data samples contained 868 interactions of oxygen and 929 interactions of sulfur.

Interactions were analyzed by studying the tracks emitted from each interaction detected. These tracks were classified according to the commonly accepted emulsion-experiment terminology, based upon their ionization and measured properties. We defined the following groups of tracks:

1. \( N_Z \) — multicharged projectile fragments, tracks due to relativistic nuclei with \( Z \geq 2 \). Typically we determine the number of alpha particles, \( N_\alpha \), and the number of fragments, \( N_F \), with charge \( Z > 2 \), separately.

2. \( N_s \) — shower particles, (fast particles with \( \beta > 0.7 \)), tracks with ionization \( I < 1.4I_0 \) where \( I_0 \) is the minimum ionization produced by singly charged particle. This group includes tracks due to particles produced in the interactions as well as those singly charged particles, predominantly protons, released from the projectile nucleus or knocked-on from the target nucleus.

3. \( N_g \) and \( N_b \) — grey and black tracks, which are often combined into a single group of heavy tracks, \( N_h \). These tracks are formed by slower (\( \beta < 0.7 \)) heavily ionizing (\( I > 1.4I_0 \)) particles emitted from the struck target nucleus. Grey tracks are mostly recoil protons with energies from 30 to 400 MeV, with a small number of heavier hydrogen isotopes and a few percent admixture of low-momentum pions. The black tracks are produced by low-energy singly and multicharged target fragments. The experimental separation between black and grey tracks is somewhat subjective. We have based it on the criteria that the track should have an ionization that is greater (black), or less (grey), than that of a 30 MeV proton, which corresponds to a grain density of about eight times minimum and
would have a residual range for a proton of 3 mm in emulsion. Since only a few of the tracks in this group are ambiguous, the slightly subjective nature of the separation criteria does not affect our analysis and conclusions significantly.

For each multicharged projectile fragment, shower particle and heavily ionizing particle emitted from the interaction vertex the emission angles \( \theta \) (the polar angle of the track with respect to the direction of the primary \( ^{16}\text{O} \) or \( ^{32}\text{S} \) ion track) were determined under high magnification in the microscope. The angles of shower particles were measured with an accuracy of \( \sim 0.1 \) in pseudorapidity \( \eta = -\ln \tan(\theta/2) \), which required increasing accuracy as \( \theta \) became smaller. The angles of the black and grey tracks were measured with an accuracy of less than one degree. The charges of the projectile fragments with \( Z > 2 \) were determined by counting a sufficient number of \( \delta \)-rays to determine the charge with a standard deviation of about 0.5 of a charge unit. The helium nuclei were identified from their ionization and lack of multiple scattering and the identification was essentially unambiguous.

These data for oxygen and sulfur interactions have been compared with those obtained earlier from the analysis of 2595 proton—emulsion interactions [18,19] at the same primary energy of 200 GeV.

3 Centrality of Collisions

The analysed data samples of oxygen and sulfur interactions have been divided into groups of events characterized by the different degree of centrality, a quantity which can be related to the value of the impact parameter of nucleus-nucleus collisions. We have chosen to represent the degree of centrality by the number, \( N_{\text{coll}} \), of intranuclear nucleon-nucleon collisions, a parameter that is an essential part of any superposition model and allows us to organize the data in a coherent fashion. For each interaction one can determine the forward charge, \( Q_F(\theta_c) \), as the absolute value of the total charge emitted within the very forward cone of half-angle \( \theta_c \), i.e.,

\[
Q_F(\theta_c) = \sum \left| Z_F \right| + 2 \cdot N_\alpha + N_s(\theta_c)
\]

(1)

where \( \sum Z_F \) is the sum of charges of all \( N_F \) projectile fragments with charge \( Z > 2 \), \( N_\alpha \) is the number of alpha particles, and \( N_s(\theta_c) \) denotes the number of singly charged shower particles within the forward cone of half-angle \( \theta_c \).

Forward charge \( Q_F(\theta_c) \) would be equal to the total charge carried by noninteracting projectile nucleons, if \( N_s(\theta_c) \) included only spectator protons. However, independently of the choice of \( \theta_c \), \( N_s(\theta_c) \) is contaminated by produced particles.
Thus, we attempted to choose such a cone in which all spectator protons are contained and the number of produced particles is as small as possible. Comparing experimentally obtained $Q_F$ values with the calculated ones from the Venus' Monte Carlo model of nucleus-nucleus interactions [20,21] we find that for interactions at 200 GeV/nucleon a choice of $\theta_c = 3$ mrad represents our best compromise to the requirements above. This is the same value as that adopted by other emulsion groups analyzing similar data [22,23]. We have compared in Fig.1 our experimental probability distributions of $Q_F$ for $\theta_c = 3$ mrad with the model distributions from the Venus program for oxygen and sulfur interactions. With the exception of the relatively small inconsistencies in the region of large $Q_F$ values (peripheral collisions), which are probably due to uncertainties in the charge measurements of heavy projectile fragments, there is generally good agreement between the data and the model predictions. Decreasing the assumed value of $\theta_c$ worsens the agreement.

This agreement justifies the use of the Venus model to relate the experimentally measured values of $Q_F$ with the mean number $\langle N_{\text{coll}} \rangle$ of intranuclear nucleon-nucleon collisions. From simple geometrical Glauber type calculations assuming the cross sections for the various components of emulsion, one can calculate $\langle N_{\text{coll}} \rangle$ for both the oxygen and sulfur inclusive interactions. The relation between $\langle N_{\text{coll}} \rangle$ and $Q_F$ is shown in Fig.2 for both oxygen and sulfur interactions in emulsion. Using this relation we can assign a value of $\langle N_{\text{coll}} \rangle$ to every event on the basis of the measured value of $Q_F$. It can be seen that the maximum values of $\langle N_{\text{coll}} \rangle$ for Oxygen and Sulfur interactions in emulsion are about 60 and 120 collisions, respectively. These values are for the most central events, those with minimum $Q_F$, and since they greatly exceed the mass numbers of the projectile nuclei, imply, as does the Venus model, that some of the projectile nucleons interact several times during their passage through the average target nucleus. As a consequence, these interactions cannot be characterized as all being due to nucleons with the incident energy of the projectile nucleons. Some must be secondary and between nucleons with less than the initial energy.

*In our calculations we used the version 3.12 of the Venus model.
4 Multiplicity of Produced Particles

The multiplicity of produced charged particles is defined as:

\[ N^* = N_e - [Z_p - (2 \cdot N_o + \sum Z_F)] \]  

(2)

where \( Z_p \) represents the charge of the projectile. Using this definition, singly charged projectile fragments (spectator protons) as well as protons from the projectile which interacted, are subtracted from the total number \( N_e \) of shower particles observed. This quantity \( N^* \) can be determined experimentally and is predicted by the Venus program (see Table I).

Table I: The mean multiplicities of shower \( N_e \) and produced \( N^* \) particles for oxygen and sulfur interactions in emulsion at 200 GeV/nucleon, including the Venus model predictions.

The experimental and predicted probability distributions for Oxygen and Sulfur interactions are shown in Fig.3. The distribution of \( N_e \) for sulfur interactions reaches much larger values than that for oxygen and extends up to about 400 charged particles. The predictions of the Venus model are in satisfactory agreement with the experimental data except for the very high multiplicity region where the yield predicted by the Venus model is higher than that observed. This discrepancy concerns less than two percent of the total number of interactions for both the oxygen and sulfur projectiles. However, it does suggest that this version of the Venus model overestimates the large multiplicity tail. We will see later that this is also confirmed by the analysis to follow.

In Fig.4 we present the dependence of the measured mean multiplicity \( \langle N^*_e \rangle \) on the mean number \( \langle N_{\text{coll}} \rangle \) of intranuclear nucleon-nucleon collisions calculated for interactions of proton, oxygen and sulfur projectiles with nuclear emulsion at 200 GeV/nucleon. These three points define a linear relation between the two parameters of the form:

\[ \langle N^*_e \rangle = (3.78 ± 0.15)\langle N_{\text{coll}} \rangle + (4.14 ± 0.39) \]  

(3)
Such a linear relation is in agreement with the expectations from a superposition model.

In order to test in more detail whether the observed multiplicities in the oxygen and sulfur interactions can be described by the Venus superposition model, we divided our samples of oxygen and sulfur interactions into subgroups characterized by different values of \( \langle N_{\text{coll}} \rangle \) for intranuclear nucleon-nucleon collisions. To do this we applied the procedure described in Sec. 3. Using the relation between \( Q_F \) and \( \langle N_{\text{coll}} \rangle \) (see Fig. 2), the samples of oxygen and sulfur interactions were divided into groups of collisions with different degree of centrality. This procedure makes it possible to extend the analysis to significantly larger values of \( \langle N_{\text{coll}} \rangle \) than in Fig. 4 for the full inclusive data set.

The relation between the mean multiplicity \( \langle N_e \rangle \) and the corresponding mean number of collisions \( \langle N_{\text{coll}} \rangle \) is shown in Fig. 5 for both projectiles. The straight line represents Eq. 3. It is seen that the oxygen and sulfur data can be described by this equation for values of \( \langle N_{\text{coll}} \rangle \) less than about 30. However, for higher values of \( \langle N_{\text{coll}} \rangle \) the values of \( \langle N_e \rangle \) are smaller than predicted. This may be a consequence of the effects of the lower energies of secondary and later nucleon-nucleon interactions in central collisions with heavy target nuclei (Ag, Br), which will become progressively more important as \( \langle N_{\text{coll}} \rangle \) increases.

It is interesting to compare the above results with similar ones for proton-nucleus interactions. The relation between \( \langle N_e \rangle \) and \( \langle N_{\text{coll}} \rangle \) for proton interactions at 200 GeV is shown in Fig. 6. Note the very small range of \( \langle N_{\text{coll}} \rangle \) for these interactions. Two sets of data are presented: the proton-emulsion interactions [18, 19] divided into subgroups with different \( \langle N_{\text{coll}} \rangle \) using the method described in ref. [24] and the results from an electronic experiment [25] performed on different targets (carbon, emulsion, copper, silver and lead). Eq. 3 provides a very good agreement with the data.

Finally, we have looked at the normalized mean multiplicity in nucleus—nucleus collisions, \( M \), defined by \( M = \langle N_e \rangle / \langle \langle N_e \rangle_{pp} \rangle \) (where \( \langle \langle N_e \rangle_{pp} \rangle \) stands for the mean produced charged particle multiplicity in inclusive proton-proton collisions at the same energy per nucleon). This quantity has been plotted as a function of \( \langle N_{\text{coll}} \rangle \) for our sample of oxygen and sulfur data at 200 GeV/nucleon in Fig. 7. In the same Figure the data from interactions of oxygen projectiles at 14.5, 60 and 200 GeV/nucleon reported previously [26] are also shown. No systematic mass or energy dependence can be seen in Fig. 7. All the data seem to follow a common linear relation, apart from events with very large \( \langle N_{\text{coll}} \rangle \), those which are the very central collisions of sulfur with Ag, Br nuclei, for which \( M \) is
less than expected by extrapolation.

The common linear dependence of the scaled multiplicity over a wide range of the number of intranuclear nucleon-nucleon collisions, irrespective of the mass of the projectile and its energy, strongly supports the superposition models.

5 Pseudorapidity Distributions of Shower Particles

The pseudorapidity \( \eta = -\ln \tan \theta /2 \) distributions for central collisions of oxygen projectiles at 14.6, 60 and 200 GeV/nucleon were analysed in [27].

The inclusive pseudorapidity distributions of shower particles \( N_s \), produced in proton, oxygen and sulfur interactions in nuclear emulsion are shown in Fig.8. The areas under the histograms represent the average multiplicities of shower particles and illustrate the dependence of the average multiplicities on atomic mass of the projectile. The increase of particle production in heavy ion interactions relative to the proton induced reactions is evident over the entire range of pseudorapidity. In Table II we present the experimental and the Venus model predictions of the mean values and dispersions of the pseudorapidity distributions of shower particles \( N_s \). The mean value of \( \eta \) increases with the increasing mass of the projectile, both for experimental data and the Venus model predictions. The pseudorapidity distributions for interactions with different

values of \( \langle N_{\text{coll}} \rangle \), selected from the appropriate intervals of \( Q_F \) , (see Table III) are plotted in Fig.9 for oxygen and sulfur projectiles. One can see that the average multiplicity \( \langle N_s \rangle \) depends strongly on the number of intranuclear nucleon-nucleon collisions and that the mean value of pseudorapidity, \( \langle \eta \rangle \), shown by the black dots in Fig.9 decreases with the increasing centrality of the collision. The numerical
values of \( \langle N_e \rangle \) and \( \langle \eta \rangle \) are listed in Table III. It is shown in Fig.5, that the mean

multiplicities \( \langle N_e \rangle \) in oxygen-emulsion and sulfur-emulsion interactions depend mainly on the average number \( \langle N_{\text{coll}} \rangle \) of intranuclear nucleon-nucleon collisions and not on the atomic mass of the projectile. To study this feature in more detail we have compared the pseudorapidity distributions for oxygen and sulfur interactions characterized by closely similar values of \( \langle N_{\text{coll}} \rangle \). These comparisons are shown in Fig.10 for three different selections of \( \langle N_{\text{coll}} \rangle \) (see Table III). We can conclude from these comparisons that the angular distributions of the shower particles from oxygen and sulfur interactions are essentially, but not entirely, the same for groups of events characterized by similar values of collisions \( \langle N_{\text{coll}} \rangle \). The observed small differences can be explained by the fact that the same number of \( \langle N_{\text{coll}} \rangle \) can be realized by different combinations of projectile and target nucleons participating in the intranuclear nucleon-nucleon collisions.

An alternative way of presenting these distributions is to study the variation of the pseudorapidity density of the shower particles, \( \rho(\eta) \), with \( \langle N_{\text{coll}} \rangle \). The densities \( \rho(\eta) \) for three intervals of \( \eta \) are given in Fig.11 both for oxygen and sulfur interactions. The dependence of \( \rho(\eta) \) on \( \langle N_{\text{coll}} \rangle \) in all three of the intervals can be satisfactorily fitted by linear relations, where the slight projectile mass
dependences are a reflection of the differences seen in the distributions shown in Fig.10.

These pseudorapidity densities for nucleus-nucleus interactions can be normalized by using the proton data for nucleon-nucleon interactions. A measure of the enhancement of particle production in different pseudorapidity bins in nucleus-nucleus interaction is the ratio:

$$R(\eta) = \frac{\rho_A(\eta)}{\rho_P(\eta)}$$

where $\rho_A(\eta)$ and $\rho_P(\eta)$ denote the particle densities in nucleus-nucleus and proton-proton collisions respectively, at the same primary energy. The ratio $R(\eta)$ for oxygen and sulfur interactions in emulsion as a function of $\eta$ is depicted in Fig.12. In the pseudorapidity region $-2 < \eta < 6.5$ the parameter $R$ depends only weakly on $\eta$. Nowhere in this $\eta$ range does the value of $R$ exceed that of $(N_{coll})$ for the appropriate projectiles. This indicates that in nucleus-nucleus collisions there is no significant intranuclear cascading of produced particles.

6 Fragmentation of the Projectile Nucleus

We have already presented the projectile fragmentation data for the Oxygen primaries as a function of the energy of the incident beam [28] and have found that the yield of fragments increases significantly as the energy increases. This increase can be related to the growth of the cross-section for electromagnetic dissociations at these very high energies.

The data presented here are restricted to the interactions in which the fragmentation of the oxygen and sulfur projectiles is associated with the particle production. Thus, they do not include the electromagnetic dissociation nor the pure nuclear fragmentation processes and therefore the results given below cannot be compared with previously published results [28].

The probability distributions of charge, $Z_F$, of the heavy fragments and alpha particles emitted in sulfur and oxygen interactions are presented in Fig.13. For comparison with this data we have also considered an extensive data set of 4154 interactions of $^{22}\text{Ne}$ projectiles with an energy of 4.2 GeV/nucleon [29]. The $Z_F$ distribution for this set is shown.

"The pseudorapidity region $\eta > 6.5$ is strongly dominated by spectator protons and is not relevant to considerations of the produced particle multiplicities."
The measured percentage probabilities for the different modes of fragmentation are summarized in Table IV.

Table IV: Some parameters describing the projectile fragmentation for inelastic interactions of oxygen, neon and sulfur in emulsion.

A number of conclusions can be drawn from Table IV and Fig.13.

First, the probability of producing a single fragment with no accompanying alpha particles is independent of mass and energy. The increase in the probability of producing a fragment that is observed as the mass of the projectile increases is entirely due to those fragments that are accompanied by alpha particle(s).

Second, the probability that only alpha particles but no heavier fragments are
produced decreases with increasing mass of energetic projectile. However, since low energy neon and high energy sulfur have the same probability of producing only alpha particles it would appear that this mode may increase with increasing energy.

Third, there is a rapid decrease in the number of events with no multiply charged fragments, as the mass of the projectile increases.

Fourth, the mean number of fragments and alpha particles as well as the mean charge of the fragments all increase as the mass of the projectiles increase.

Finally, the probability of producing multiple fragments with \( Z > 2 \) in a collision is always small but increases very rapidly with increasing mass, which is consistent with the large numbers of multiple fragments, observed in interactions of low energy \((\lesssim 1.0 \text{ GeV/nucleon})\) \(^{197}\text{Au}\) nuclei in emulsion \([30]\).

7 Fragmentation of the Target Nucleus

Due to the collision with the projectile, the target nucleus becomes excited and fragments. The process of the fragmentation of the target nucleus can be investigated by analyzing the grey \( N_g \) and black \( N_b \) tracks (defined in Sec.2) of the particles emitted from the struck nucleus. In Table V we present the mean values of \( N_g \) and \( N_b \) in oxygen and sulfur interactions with nuclear emulsion.

Table V: The mean values \( \langle N_g \rangle \) of grey and \( \langle N_b \rangle \) of black tracks for oxygen, sulfur and proton interactions in emulsion at 200 GeV/nucleon.

We have also included in this table the corresponding quantities for proton interactions \([18,19]\). In Fig.14 the multiplicity distributions of grey and black tracks from oxygen and sulfur interactions are compared with those of proton interactions. From Fig.14 we can see that the distribution of black tracks is, essentially, independent of the mass of the projectile. The small differences in the distributions between the proton and heavy nuclei projectiles can be explained by the different relative cross-sections of these projectiles on the different groups of nuclei which are the components of nuclear emulsion.
The behavior of grey tracks differs from that of black tracks. Although the multiplicity distributions of grey tracks for oxygen and sulfur projectiles are practically the same, the tails of the distributions are longer than that for proton interactions. Thus the mean values of the \( N_g \) distributions for oxygen and sulfur projectiles agree with each other within statistical errors, but are significantly higher than for protons (see Table V).

The angular distributions of grey and black tracks are plotted in Fig.15. The shapes of the angular distributions of black tracks are the same for proton, oxygen and sulfur projectiles, and there is no evidence for the sharp decrease in probability at backward angles reported by [26]. As stated in [26], the slight angular dependence for the black tracks suggests that they could well be emitted isotropically from a moving frame of reference with the velocity \( \beta = 0.01 \).

The angular distributions of grey tracks, similarly as of black tracks, are the same for all projectiles. However, they are strongly peaked forward compared to the black tracks.

The differences in the multiplicity and the angular distributions of grey and black tracks point out to the fact that these particles originate in two different processes: the initial interaction, and the subsequent evaporation of the excited target nucleus. The fact that the angular distributions are independent of the type of projectile indicates that the mechanism of slow particle production is identical in all cases, irrespective of the number of intranuclear nucleon-nucleon collisions.

A similar conclusion can be drawn from the correlation between the numbers of black and grey tracks shown in Fig.16. Again, the oxygen and sulfur data are very similar both to one another and to that observed from the earlier analysis of proton-nucleus interactions [18,19]. Hence this correlation is essentially independent of the mass of the projectile. For \( N_s \leq 7 \) there is a strong positive correlation in Fig.16, but for larger values of \( N_s \), the mean value of \( N_b \) levels off at a constant value of about 12, independent of the type of projectile.

It was shown in an analysis of oxygen interactions [26] that the mean values of \( N_g \) as well as \( N_b \) for interactions at 14.6, 60 and 200 GeV/nucleon scale as a function of \( Q_F \). In Fig.17 the same relations are plotted for both oxygen and sulfur projectiles at 200 GeV/nucleon as a function of \( Q_F/2P \). In this representation, the \( \langle N_g \rangle \) and \( \langle N_b \rangle \) values scale for the two different projectiles. The mean value of \( N_g \) increases almost linearly with decreasing values of \( Q_F \) i.e. increasing centrality of the collision, while the \( \langle N_b \rangle \) value for central collisions with Ag,Br nuclei, i.e. for small values of \( Q_F \), becomes constant.
8 Conclusions

Interactions of oxygen and sulfur ions at 200 GeV/nucleon with nuclei of emulsion were investigated and compared with proton-emulsion interactions at the same primary energy. It was found for inclusive data samples that the mean multiplicity \( \langle N_e \rangle \) of produced particles increases linearly with the increasing number \( \langle N_{\text{coll}} \rangle \) of intranuclear nucleon-nucleon collisions. The same dependence, except for the largest values of \( N_{\text{coll}} \), holds when the inclusive data are divided into subsamples characterized by different degree of centrality. This implies that the multiplicity \( \langle N_e \rangle \) depends on \( \langle N_{\text{coll}} \rangle \), and not on the projectile mass. More detailed analysis performed on the pseudorapidity distributions has shown that the linear dependence of \( \langle N_e \rangle \) on \( \langle N_{\text{coll}} \rangle \) holds for each particular pseudorapidity interval. We have further found that the normalized particle multiplicity i.e. the ratio of particles produced in nucleus-nucleus interactions to that in proton-proton interactions, is a function of the number of collisions only and depends neither on the mass of the projectile nor on its energy.

All of these results strongly support the interaction models in which hadron-nucleus and nucleus-nucleus interactions are considered as an incoherent superposition of intranuclear nucleon-nucleon collisions. Also, the behavior of slow particles emitted from the target nucleus, in particular their angular distributions which are independent of the mass of the projectile, supports the superposition hypothesis. Finally we would like to point out the fact that the low energy cascade of produced particles which is clearly seen in inclusive hadron—nucleus interactions, is negligible in nucleus-nucleus collisions.

Acknowledgements

We would like to express our thanks to the technical staff involved in the heavy ion emulsion experiments at CERN for their great help in the preparation of the experiment and during the exposure. We are very indebted to L.H. Bokova for the development of emulsion pellicles. The skillful work of our scanning team is greatly appreciated. This work has been supported in Poland by KBN Grant No 203799101 and in the U.S. by NSF Grants DHY-8907660 and INT-8913051 at Louisiana State University and by DOE-DE-FG02-89ER40528 at University of Minnesota.
