Abstract

The proton and deuteron structure functions F_2^p and F_2^d are measured in inelastic muon scattering with an average beam energy of 470 GeV. The data were taken at Fermilab experiment 665 during 1991-92 using liquid hydrogen and deuterium targets. The F_2 measurements are reported in the range $0.0008 < x < 0.6$ and $0.2 < Q^2 < 75\ GeV^2$. These are the first precise measurements of F_2 in the low x and Q^2 range of the data. In the high x range of the data where they overlap in x and Q^2 with the measurements from NMC, the two measurements are in agreement. The E665 data also overlap in x with the HERA data, and there is a smooth connection in Q^2 between the two data sets. At high Q^2 the E665 measurements are consistent with QCD-evolved leading twist structure function models. At lower Q^2 the data show that there are large negative higher-twist contributions to F_2. The data are qualitatively described by structure function models incorporating the hadronic nature of the photon at low Q^2. The Q^2 and the W dependence of the data measure the transition in the nature of the photon between a point-like probe at high Q^2 and a hadronic object at low Q^2.

Acknowledgements

I am fortunate to have been part of the E665 collaboration for the last few years. I have learnt much through my participation in this experiment, and I am grateful to all the people who worked to build and run it. This thesis would not have been possible without their efforts.

I joined the experiment under the guidance of Professor Frank Pipkin, who passed away in January 1992. Frank was encouraging and supportive during my early years as a graduate student, even when I had naive and crazy ideas. He stayed up late to help me track down electronic oscillations and fix power supplies. His "hands-on" approach to experimental science was refreshing. He motivated me to be careful and thorough in doing the job at hand.

I learnt much from my advisor, Professor Richard Wilson, during my later years of graduate school. He encouraged me to pursue the structure function analysis, and I was able to draw on his experience and insight. His insistence on thinking through the issues carefully and formulating a game-plan early in the project proved to be valuable advice. He instilled in me the desire to try and understand the fundamental concepts relevant to any physics analysis. For his guidance and generosity, and also the many entertaining stories of his world travels, I thank him.

I had a very fruitful experience working with some of the members of the Calorimeter group, Guang Fang, Richard Nickerson and Michael Schmitt. I would like to thank Guang for all his help over the years. He was willing to help with any problem I encountered, no matter how mundane. Richard taught me a lot about Calorimetry and electronics early on, and we had many useful discussions on a wide variety of physics and experimental issues. On the projects that we worked together I benefited from his energy and effectiveness.

I would like to thank all the senior E665 physicists who took a special interest in my work and devoted their time and thought to guide me through my analysis. I would like to thank Hugh Montgomery for many physics discussions that helped to broaden my perspective. His willingness to listen to my arguments and explain the rights and wrongs helped me to absorb new ideas. Heidi Schellman, Harry Melanson, Jorge Morfin, Don Geesaman and Steve Wolbers were always available for long discussions. They gave me confidence, caught my mistakes and made suggestions that improved my analysis. I appreciate all their help and guidance. I also thank Wolfgang Wittek and Helmut Braun for their suggestions, and the staff at Harvard and Fermilab for their assistance.

My days as a graduate student were made enjoyable by the company of many col-

leagues at E665. Vassili Papavassiliou and Janet Conrad helped me in understanding the experiment when I first joined E665, and in making the transition from Cambridge to the Fermilab environment. Sharing the Muon Lab offices with Rurngsheng Guo, Tim Carroll, Pat Madden, Harsh Venkataramania, Bogdan Pawlik, Panagiotis Spentzouris and Arijit Banerjee made for a fun experience. There was a lot of camaraderie between us. We learnt from each other and had fruitful discussions on many issues, not just physics. I would especially like to thank Panagiotis for all the work we did together. I value very much our partnership and friendship. In the final stages of graduate school when there weren't too many people in the Muon lab, the company of Panagiotis, Harsh and Arijit was much appreciated.

I would like to thank all the friends I made outside of E665 during my years of graduate school. My roommates at Fermilab, Fotis Ptohos and Tom Baumann, and my roommate in Cambridge, Tejvir Khurana, were a lot of fun. At Fermilab, I shared good times with Satyadev, Balamurali, Vipin, Mrinmoy, Sailesh, Shankar, Prem and Prajakta, Brajesh and Dhiman. Thanks, and keep that VCR rolling!

Finally, none of this work would have been possible without the support and encouragement of my parents. Their strength, spirit and wisdom were always behind me in everything I have done. I hope this thesis does them proud and that I shall continue to do so in the future.

Chapter 1

Introduction

Scattering experiments have proven to be a very effective technique for probing the structure of matter. The large angle scattering of α particles off a gold foil led Rutherford to conjecture that the bulk of the mass of the atom must be contained in a very small, positively charged nucleus of the atom. The momenta of the α particles varied between 4 and 9 MeV. This, and the angular distribution of the scattered α particles, provided the estimate that the nuclear radius was less than 10^{-12} cm.

The formulation of this scattering process was based on the Coulomb force law. At these distances the electromagnetic interaction dominates, simplifying the interpretation of the results of the scattering experiments. But the ability of α particles to probe smaller distances was hampered by the fact the interaction ceased to be purely electromagnetic. At short distances the α particle starts to interact through the strong interaction with the nucleus.

Charged lepton scattering promised to be an effective technique of probing the internal structure of nuclear matter, since the interaction of the probe is purely electromagnetic. In the 1950's, starting with electron scattering experiments at SLAC [1], experiments were performed at Darmstadt, Orsay, Yale and the CEA to measure the charge distributions of various nuclei. At the energies available, the experiments were restricted to elastic scattering or excitation of the low-lying resonances. The measured elastic form factors fall rapidly with increasing 4-momentum transferred, indicating that the charge distribution in nuclei is spatially extended and smoothly varying (i.e. there is no hard core in the nucleus). As higher energy electron beams became available at SLAC in the late 1960's, inelastic scattering experiments could be performed. These experiments [2] showed that, at large 4-momentum transfers, the inelastic nucleon structure functions were independent of any dimensioned quantity, a phenomenon known as scal-

ing. This result was interpreted as evidence for the existence of point-like constituents in the nucleons [3], as this behavior was predicted on the basis of current algebra [4]. These "partons" are now associated with quarks [5], which were first introduced to describe hadron spectroscopy [6, 7].

Higher energy electron beams became difficult to produce as electrons, being light, are good at losing energy through synchrotron radiation. Muons became a natural choice as high energy charged lepton probes. The 1970's and 1980's saw the development of the CHIO, EMC, BCDMS, NMC and E665 muon scattering experiments, and the ep collider HERA at DESY [8, 9, 10, 11, 12, 13, 14]. In the meantime, the quark-parton model developed into a dynamic gauge field theory of interactions called Quantum Chromo-Dynamics (QCD). This theory has been quite effective in making perturbative calculations of the short distance behavior of quark interactions. In particular, QCD predicted a pattern of scaling violations of the inelastic structure functions at large 4-momentum transfers, which has been confirmed by the high energy muon experiments and the HERA experiments.

However, at low values of 4-momentum transfers, the perturbative QCD framework breaks down. Real photoproduction measurements at high energy reveal the hadronic nature of the photon. This behavior is different from the point-like photon-parton interactions manifested at large 4-momentum transfers. The transition from the regime of perturbative QCD to the domain of the hadronic photon must involve some change in the nature of photon-hadron interactions as a function of 4-momentum transfer. The experiment 665 provides a wide range of energy and 4-momentum transfer and thus an opportunity to understand the nature of this transition.

This work presents the measurement of the proton and deuteron structure functions at E665, using the data taken during 1991-92. In the next chapter, we discuss the theory and phenomenology of the photon-nucleon interaction. In chapter 3, a brief description of the experimental apparatus will be given. In chapter 4, the structure function measurement technique will be described. In the following chapters, detailed discussions will be provided of the analysis. The analysis issues are the estimation of the muon reconstruction and triggering efficiencies, the detector calibration and resolution, the radiative corrections and the luminosity measurement. In chapter 10, the results and the systematic uncertainties will be presented. The results will be compared with measurements from other experiments and with theoretical models in chapter 11.

Throughout this thesis, we use a right-handed coordinate system, where the x-axis points along the nominal beam direction (north). The y-axis points to the west and the z-axis points upwards. Hodoscopes and wire chambers are labelled by the coordinate they measure.

Chapter 2

Virtual and Real Photon - Nucleon Interactions

The reason that charged lepton scattering is such an effective tool to probe nucleon structure is twofold. Firstly, the coupling of the photon to the lepton is calculable in terms of Quantum Electro-Dynamics (QED). The electromagnetic coupling constant being small, allows the perturbative techniques of QED to be applied and the radiative corrections to the Born diagram to be calculated. Secondly, the single photon exchange approximation allows the diagram to be factorized, i.e. separated into the lepton vertex and the hadron vertex. The hadron vertex can then be expressed in general without regard to the source of the virtual photon. Once the general form of the photon-nucleon vertex is written down, the rules of QED allow us to write down the photoproduction cross-section, and the lepto-production cross-sections assuming single photon exchange. Hence let us start with the formulation of the photon-nucleon interaction.

2.1   Formulation of the Photon-Nucleon Interaction

2.1.1   Photon-Nucleon Vertex and the Hadron Tensor

The interaction of a photon of 4-momentum q^μ and polarization ϵ^μ with a nucleon of 4-momentum p^μ to produce a final state X is depicted in figure 2.1.

The electromagnetic current of the nucleon A_μ coupling to the photon may be written as the matrix element of the current operator J_μ between the initial and final hadronic
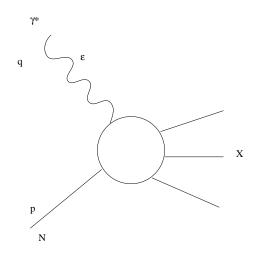

Figure 2.1: Feynman diagram for $\gamma^* N \to X$.

states:

$$A_\mu = \langle X | J_\mu | N \rangle \tag{2.1}$$

The cross-section is given in terms of the hadronic tensor $W_{\mu\nu}$, defined by

$$W_{\mu\nu} = \frac{1}{2} \sum_X A_\mu^* A_\nu (2\pi)^3 \delta^4(p + q - p_X) \tag{2.2}$$

In the case of the electromagnetic interaction the general form of $W_{\mu\nu}$ is constrained by parity conservation and gauge invariance. Parity conservation forces $W_{\mu\nu}$ to be symmetric. Since the photon tensor and the lepton tensor (discussed below) are symmetric, only the symmetric parts of $W_{\mu\nu}$ contribute to the photoproduction and leptoproduction cross-sections. Gauge invariance forces the conservation of the electromagnetic current $q^\mu A_\mu = 0 = q^\mu W_{\mu\nu}$. For an unpolarized nucleon the most general Lorentz invariant expression for $W_{\mu\nu}$ can be written as

$$W_{\mu\nu} = W_1 \left(-g_{\mu\nu} + \frac{q_\mu q_\nu}{q^2} \right) + \frac{W_2}{M^2} [(p_\mu - \frac{p.q}{q^2} q_\mu)(p_\nu - \frac{p.q}{q^2} q_\nu)] \tag{2.3}$$

where the "structure functions" W_1 and W_2 are Lorentz invariant functions of q^2 and $\nu (\equiv \frac{p.q}{M})$, and M is the nucleon mass (see discussion in [15]).

The structure functions are often redefined in the following way:

$$F_1 = M W_1 \tag{2.4}$$

$$F_2 = \nu W_2 \tag{2.5}$$

2.1.2 Photon Tensor

Let us now turn to the photon. Throughout this thesis we work in the Lorentz gauge, so that $q.\epsilon = 0$ where ϵ is the photon polarization vector. In general the photon may be described by a superposition of three polarization states: left- and right-transverse photons (helicity ± 1) and longitudinal-scalar photons (helicity 0). For a space-like photon moving along the z-axis the 4-momentum may be written as

$$q^{\mu} = (\nu, 0, 0, \sqrt{Q^2 + \nu^2}) \tag{2.6}$$

The conditions $q.\epsilon = 0$ and $|\epsilon_i^*.\epsilon_j| = \delta_{ij}$ then define the polarization vectors for the three states to be:

$$\epsilon(\pm 1) = \mp \frac{1}{\sqrt{2}}(0, 1, \pm i, 0) \tag{2.7}$$

and

$$\epsilon(0) = \frac{1}{\sqrt{Q^2}}(\sqrt{Q^2 + \nu^2}, 0, 0, \nu) \tag{2.8}$$

where $Q^2 = -q^2$ (see discussion in [15, 16]).

2.1.3 Photoabsorption Cross-sections

Since parity is conserved and the target is unpolarized there are two independent photoabsorption cross-sections, σ_S for the scalar photons and $\sigma_T = (\sigma_+ + \sigma_-)/2$ for the transverse photons. The photoabsorption cross-sections are obtained by contracting the appropriate photon polarization vectors with the hadronic tensor $W_{\mu\nu}$.

$$\sigma_{\pm,S} = \frac{4\pi^2\alpha}{K}\epsilon_{\pm 1, 0}^{\dagger\mu}W_{\mu\nu}\epsilon_{\pm 1, 0}^{\nu} \tag{2.9}$$

where K is the photon flux. This yields the following relationships [15]

$$W_1 = \frac{K}{4\pi^2\alpha}\sigma_T \tag{2.10}$$

$$W_2 = \frac{K}{4\pi^2\alpha}(\sigma_T + \sigma_S)\frac{Q^2}{Q^2 + \nu^2} \tag{2.11}$$

$$R = \frac{\sigma_S}{\sigma_T} = \frac{W_2}{W_1}(1 + \frac{\nu^2}{Q^2}) - 1 \tag{2.12}$$

2.1.4   Leptoproduction Cross-sections

The kinematics of the lepton-nucleon scattering are expressed in terms of the 4-momenta of the incoming lepton (k), the outgoing lepton (k') and the target nucleon (p). The 4-momentum of the exchanged virtual photon is $q = k - k'$, and that of the hadronic final state is p_X. M is the rest mass of the target nucleon. The useful kinematic quantities are the following:

$$Q^2 = -q^2 \tag{2.13}$$

$$\nu = p.q/M \tag{2.14}$$

$$W^2 = (p+q)^2$$

$$= p_X^2 \tag{2.15}$$

$$x_{Bj} \equiv x$$

$$= Q^2/2p.q$$

$$= Q^2/2M\nu \tag{2.16}$$

$$y_{Bj} \equiv y$$

$$= M\nu/p.k \tag{2.17}$$

In the laboratory frame in which the target is at rest, ν reduces to the energy of the virtual photon (or the energy lost by the lepton), and y_{Bj} or y equals ν/E, where E is the energy of the incoming lepton. Using the Born diagram shown in figure 2.2, the leptoproduction cross-section may be written down in terms of $W_{\mu\nu}$:

$$\frac{d^2\sigma}{d\Omega dE'} = \frac{\alpha^2}{Q^4} L_{\mu\nu} W^{\mu\nu} \tag{2.18}$$

where $L_{\mu\nu}$ is the lepton tensor calculated for the lepton-photon vertex [15]. This is completely calculable in QED and is identical in almost all respects for the electron and the muon, due to lepton universality. The difference is only in mass of the lepton m_l. $L_{\mu\nu}$ is given by:

$$L_{\mu\nu} = 2(k_\mu k'_\nu + k'_\mu k_\nu - (k.k' - m_l^2)g_{\mu\nu}) \tag{2.19}$$

The lepton mass can usually be ignored at high energies[1]. This gives the following double differential lepton-nucleon scattering cross-section [17],

$$\frac{d^2\sigma}{d\Omega dE'} = \frac{\alpha_{em}^2}{4E^2 sin^4\frac{\theta}{2}} (2W_1 sin^2\frac{\theta}{2} + W_2 cos^2\frac{\theta}{2}) \tag{2.20}$$

where E' is the energy of the scattered lepton, θ is the lepton scattering angle and Ω is the solid angle in the laboratory frame. The differential cross-section may also be

---

[1]except in the calculation of certain quantities like Q^2 which could be small even at high energies.

expressed in terms of the following invariants:

$$\frac{d^2\sigma_{1\gamma}}{d(Q^2)dx} = \frac{4\pi\alpha_{em}^2}{Q^4 x}F_2(x,Q^2)[1-y-\frac{Mxy}{2E}+\frac{y^2(1+4M^2x^2/Q^2)}{2(1+R(x,Q^2))}] \qquad (2.21)$$

where the single photon exchange cross-section is explicitly denoted. R, which is the ratio of scalar to transverse photon cross-sections defined in equation 2.12, can also be defined as

$$R = \frac{(1+4M^2x^2/Q^2)F_2}{2xF_1} - 1 \qquad (2.22)$$

Thus we see that we need two functions, which we choose to be $F_2(x,Q^2)$ and $R(x,Q^2)$, to describe the scattering of photons, electrons and muons off unpolarized nucleons.

8

2.1.5 Optical Theorem

We now turn our attention to the hadronic tensor $W_{\mu\nu}$. As shown in figure 2.1 and equation 2.2, it represents the sum over all final states produced in the interaction of the photon and the nucleon. Since the total probability is conserved, there must be a corresponding loss of intensity which the photon beam suffers because of the scattering. The optical theorem (see discussion in [18]) shows that this loss is related to the imaginary part of the amplitude for photon-nucleon scattering in the forward direction. The Feynman diagram for this process is shown in figure 2.3. Based on the optical theorem, $W_{\mu\nu}$ may be written as (see discussion in [17])

$$W_{\mu\nu}(p,q) = \frac{1}{4M} \sum_{\sigma} \int \frac{d^4\xi}{2\pi} e^{iq\cdot\xi} <p,\sigma|[J_\mu(\xi),J_\nu(0)]|p,\sigma> \qquad (2.23)$$

Here p and q denote the 4-momenta of the target nucleon and the virtual photon respectively. $|p,\sigma>$ denotes the wavefunction of the nucleon, where σ denotes its spin which is summed over. The commutator denotes the creation of the electromagnetic current at spacetime coordinate 0 and its annihilation at spacetime coordinate ξ.

The advantage of this formulation is that the total cross-section may be studied by understanding the forward scattering amplitude.

2.1.6 Operator Product Expansion

For small spacetime separation ξ, the bilocal operator may be expanded in the Wilson Operator Product Expansion [19]

$$iT(J_\mu(\xi),J_\nu(0)) \xrightarrow{\xi^2 \to 0} \sum_{\tau=2}^{\infty} \sum_{n=0}^{\infty} C_{\tau,n}(\xi^2,\mu^2)\xi^{\nu_1}\ldots\xi^{\nu_n} \mathcal{O}^\tau_{\nu_1\cdots\nu_n}(\mu^2) \qquad (2.24)$$

where T denotes the time-ordering operation. The coefficients $C_{\tau,n}$ are complex numbers, n being the spin of the operator $\mathcal{O}^\tau$ and τ is called the "twist". It is the mass dimension of $\mathcal{O}^\tau$ minus its spin. As we shall see, it determines the singularity structure of the terms in the expansion as $\xi^2 \to 0$. μ^2 is the renormalization point.

In the operator product expansion, the long distance physics is absorbed into the operators $\mathcal{O}^\tau$, while the coefficients $C_{\tau,n}$ contain the physics at short distances. The momentum cutoff distinguishing between long and short distances is the renormalization scale μ^2, which occurs in both $C_{\tau,n}$ and $\mathcal{O}^\tau$, so that the total amplitude is independent of the arbitrary cutoff.

The coefficients $C_{\tau,n}$ become singular as $\xi^2 \to 0$. It can be shown [17] that

$$C_{\tau,n}(\xi^2, \mu^2) \overset{\xi^2 \to 0}{\sim} (\frac{1}{\xi^2})^{1-\frac{\tau}{2}} \tag{2.25}$$

so that the structure functions have the following form as $\xi^2 \to 0$ (corresponding to $Q^2 \to \infty$)

$$W \to \bar{C}_{\tau,n}(Q^2, \mu^2)\bar{O}_n^{\tau}(\mu^2)x^{-n}(\frac{1}{Q^2})^{\frac{\tau}{2}-1} \tag{2.26}$$

The $\bar{O}_n^{\tau}$ describe various components of the nucleon wavefunction, and the $\bar{C}_{\tau,n}(Q^2, \mu^2)$ describe the hard scattering of the photon off these components. The dominant contribution at high Q^2 comes from the twist-2 component, and higher twist contributions are suppressed by powers of Q^2 that increase with the twist.

2.2 Quark Parton Model (QPM)

Taking the limit as $Q^2 \to \infty$ for fixed x (known as the Bjorken limit), it has been shown [20] that the dominant contribution to the cross-section comes from the diagram shown in figure 2.4. This diagram is sometimes called the "handbag" diagram. It corresponds to the photon scattering incoherently off point-like constituents in the nucleon. The reason that this contribution dominates is as follows. In the Bjorken limit, the time scale associated with the scattering process becomes very small. A spatially extended charge distribution is unable to scatter the photon, because this would require some amount of time for the different parts of the charge cloud to communicate with each other. The shrinking time scale of the scatter leads us to the impulse approximation, in which the nucleon wavefunction appears "frozen" to the virtual photon.

Figure 2.4: Feynman diagram for Quark Parton Model contribution to the forward scattering amplitude.

Since point-like particles do not have momentum dependent form factors, the structure functions in the Bjorken limit are expected to scale, i.e. they will not depend on any dimensional quantity. This is the statement of Bjorken Scaling [4]. When the structure functions measured at SLAC in the early 1970's [2] showed approximate scaling behavior, this was in fact interpreted as evidence for the presence of point-like constituents in the nucleon [3].

The elastic scattering of the photon by a parton i carrying a momentum fraction x_i of the nucleon, leads to the kinematic constraint that $x_{Bj} = x_i$. That is to say, x_{Bj} measures the fractional momentum of the parton in the nucleon. This result is valid as long as the parton moves on the light-cone, i.e. it has no transverse momentum and is massless. The structure functions are then related to the number density and momentum density of the partons.

Quarks had been invented to explain hadron spectroscopy [6, 7]. The combination of the parton model, and the properties of the quarks led to the hypothesis that quarks were the partons [5]. The Quark-Parton model explained most of the features of the measured structure functions in the early 1970's. The spin 1/2 nature of the quarks and the quark charge assignments led to the following relations:

$$F_1(x) = \sum_i e_i^2 q_i(x) \tag{2.27}$$

$$F_2(x) = \sum_i e_i^2 x q_i(x) \tag{2.28}$$

where i labels the species of the quark, $q_i(x)$ is the number density of the quarks with momentum fraction x and e_i is the electric charge of species i. The spin 1/2 nature of the quarks is reflected in the Callan-Gross [21] relation

$$F_2(x) = 2x F_1(x) \tag{2.29}$$

implying that $R \sim 0$. This is because, as the spin 1/2 quark moving on the light cone absorbs the virtual photon and rebounds, its spin must flip in order to conserve its helicity. Therefore it absorbs one unit on angular momentum. By angular momentum conservation, the virtual photon must be transversely polarized, and a scalar virtual photon cannot be absorbed by the quark. The small value of R measured at SLAC supported the Quark-Parton Model.

2.2.1   Quantum Chromo-Dynamics

Quantum Chromo-Dynamics (QCD) is a local gauge field theory that attempts to describe the strong interactions between quarks. The gauge group is the non-Abelian

SU(3) group, and the generators of the gauge transformations are called gluons. Thus, we say that the quarks interact with each other through the exchange of gluons, and the QCD 'charge' possessed by the quarks is called color. The non-Abelian nature of SU(3) causes the gluons to couple to each other directly, i.e. the gluons are colored as well. This latter property proves crucial in the result that QCD is an asymptotically free theory [22, 23, 24].

As in QED, the effective coupling constant in QCD (α_s) is momentum-dependent due to the presence of vacuum fluctuations. The fermion loops (quark loops in the case of QCD) in the gluon propagator have the effect of screening the color charge at large distances. The quark loops alone would cause α_s to reduce with increasing distance. However, the gluon loops have the effect of spreading out the color charge, so that a smaller net charge remains at small distances. In SU(3) with eight gluons, the gluon anti-screening effect wins over the screening effect of the quarks as long as the number of quark flavors is less than 16 (based on the leading order calculation). Thus, α_s decreases at small distances, i.e. large momentum transfers. The leading order expression for α_s is [17]

$$\alpha_s(Q^2) = \frac{4\pi}{(11 - \frac{2}{3}N_f)ln(Q^2/\Lambda^2)} \tag{2.30}$$

where Q^2 is the square of the 4-momentum transferred by the gluon, and N_f is the number of quark flavors. Λ is the natural momentum scale that sets the magnitude of α_s, and it must be measured by experiment. As the leading order expression indicates, $\alpha_s(Q^2) \to 0$ as $Q^2 \to \infty$.

Asymptotic freedom provides the justification for the application of perturbative QCD techniques to the interactions of quarks and gluons in processes involving large momentum transfers. We shall now study the QCD radiative processes that affect the parton momentum densities inside the nucleon.

2.2.2   QCD Evolution of Structure Functions

At high Q^2 we may neglect the higher-twist contributions to the structure functions, so we will restrict our attention to the twist-2 contributions. In that case, the structure functions can still be expressed in terms of parton distributions. However, in the presence of QCD radiative effects, the parton distributions acquire an explicit momentum dependence. The study of these effects leads to the development of the QCD-improved parton model.

At first order in α_s, a quark or an antiquark may radiate a gluon, before or after absorbing the virtual photon. In addition, a gluon may split into a quark-antiquark pair,

and one of the pair may absorb the photon. These processes are shown in figure 2.5. The diagrams have divergences when the internal propagators become close to mass-shell. This situation occurs either when the radiation or the splitting is collinear with the incoming parton, or when one of the radiated partons becomes very soft. In addition to these diagrams, there are virtual gluon loops.The divergences in the soft virtual gluon diagrams serve to cancel the divergences in the soft real gluon emission, order by order in perturbation theory. The collinear divergences are removed by absorbing them into the definition of the incoming parton. This introduces a renormalization scale μ. If the transverse momentum of the radiation is below this cutoff, the contribution is absorbed into the redefinition of the parton distribution. For a transverse momentum larger than the cutoff, the matrix element of the radiative diagram is explicitly carried through. Clearly, if all the diagrams were calculated to all orders in perturbation theory, absorbing a part of phase space into the definition of the parton distribution and keeping the remainder of the phase space in the matrix element explicitly would make no difference. So the exact answer will be independent of the renormalization scale μ. In practice, the calculations are not performed exactly to all orders. As a result of the approximate nature of the calculation, there is a renormalization scale dependence in the final answer. One expects the renormalization scale dependence to reduce as higher order diagrams are calculated and better techniques are developed to sum up all the diagrams.

The cross-section calculated from the radiative diagrams depends on the momentum scale of the process. This dependence comes from the virtuality of the internal propagators, and the phase space available for the radiated gluons or the $q\bar{q}$ produced in photon-gluon fusion. In addition, α_s is expected to vary with the momentum scale. One expects this scale to be set by the photon-parton center-of-mass energy. All the momentum scales can be related to each other through dimensionless variables. The general convention in inclusive scattering is to use the square of the 4-momentum of the photon, Q^2, to represent the momentum scale of the scatter, while the dimensionless variables are either held fixed or integrated out.

The field-theoretic calculations of these processes are given in [25, 26]. The Altarelli-Parisi (AP) evolution equations [27] for parton densities indicate how the effective parton densities change with the momentum scale of the scatter. As shown in figure 2.5, a parton with apparent momentum fraction x that scatters the photon may in fact be derived from a parton with higher momentum fraction y. The probability that a parton will split to produce another parton carrying a momentum fraction z of itself is called the "splitting function" and denoted by $P(z)$. The AP evolution equations are written as:

$$\frac{dq(x,Q^2)}{dlnQ^2} = \frac{\alpha_s(Q^2)}{2\pi} \int_x^1 \frac{dy}{y} [q(y,Q^2)P_{qq}(\frac{x}{y}) + G(y,Q^2)P_{qG}(\frac{x}{y})]$$

$$\frac{dG(x,Q^2)}{dlnQ^2} = \frac{\alpha_s(Q^2)}{2\pi} \int_x^1 \frac{dy}{y} [q(y,Q^2)P_{Gq}(\frac{x}{y}) + G(y,Q^2)P_{GG}(\frac{x}{y})] \qquad (2.31)$$
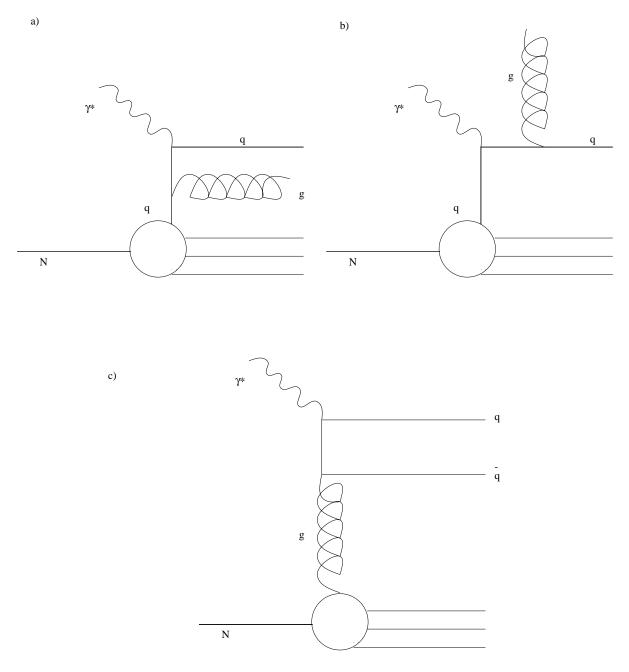

Figure 2.5: Feynman diagrams for leading order QCD radiative processes contributing to virtual photon-nucleon scattering. a) Initial state gluon radiation. b) Final state gluon radiation. c) photon-gluon fusion to $q\bar{q}$.

$q(x, Q^2)$ is the quark density and $G(x, Q^2)$ is the gluon density. The change in the quark density is due to the splitting processes $q \to gq$ and $g \to q\bar{q}$. The gluon density changes due to the processes $q \to qg$ and $g \to gg$.

The interesting thing to note is that the change in the parton densities is logarithmic in Q^2. This can be traced back to the integration of the matrix elements (shown in figure 2.5) over the available phase space for the radiated parton. The integrand has the form dp_t^2/p_t^2 leading to a lnp_t^2 dependence of the quark density. The maximum p_t^2 of the final state partons depends on the c.m.s. energy of the photon - initial parton system, which in turn can be related to Q^2. The minimum p_t^2 chosen in the integration corresponds precisely to the renormalization scale μ^2 mentioned earlier.

Thus, for a set of defined parton distributions at scale μ^2, the parton distributions relevant for hard scattering at a scale $Q^2 > \mu^2$ may be calculated using the evolution equations. For example, the structure function F_2 may be related to the parton distributions observed in hard photon-parton scattering. There is some arbitrariness in defining which parton actually scatters the photon. In a photon-gluon fusion event, should one think of the gluon as the scatterer or the quark coupling to the photon as the scatterer? This ambiguity leads to "scheme dependence" of the parton distributions. In the DIS scheme, the partons that scatter the photon are always defined to be the quarks. In this scheme, F_2 still has the same expression as in the Quark-Parton model

$$F_2(x, Q^2) = \sum e_i^2 x q(x, Q^2) \tag{2.32}$$

where the sum is over all species of quarks and antiquarks.

QCD radiation also plays a role in the determination of R. As noted earlier, in the Quark-Parton model the spin 1/2 quarks can only absorb transverse photons. However, if the quark were to radiate a real gluon carrying spin 1, the helicity of the virtual quark is flipped already. Therefore it can absorb a scalar photon and rebound with the appropriate helicity for an on-shell quark. Thus the ability to radiate gluons allows the quarks to absorb scalar photons and produce a contribution to R.

The x dependence of the parton distributions (and hence the structure functions) is influenced by the QCD radiative processes. The effect of these processes is to create partons carrying less momentum than the parent partons, since the QCD radiation carries away some of the momentum. This produces a pile-up of partons at low x and a depletion of partons at high x. Through the emission of multiple partons, QCD radiative processes play the dominant role in the determination of the x dependence of the structure functions. We will discuss this in the next section.

2.2.3   Low x Behavior of Structure Functions in QCD

The splitting functions for a quark or a gluon to radiate a gluon, $P_{Gq}(z)$ and $P_{GG}(z)$, behave as $1/z$ for small z. This is a reflection of the tendency of the matrix elements to diverge as the radiated gluon becomes soft. There is therefore a propensity to radiate multiple soft gluons, leading to diagrams such as shown in figure 2.6a. The corresponding diagram contributing to the forward scattering amplitude is shown in figure 2.6b. At low x such processes are expected to produce a pile-up of partons and hence a rapid rise in the structure functions as x falls.

These diagrams are difficult to calculate because of the complexity of the multi-particle phase space. In the leading logarithm approximation, the total phase space is approximated by that part in which the transverse momenta of the radiated partons are ordered and the parton coupling to the photon has the maximum transverse momentum. At each order in perturbation theory this part of the phase space gives the dominant contribution, which upon integration gives a term like $(\alpha_s ln Q^2)^n$. In the double leading logarithmic approximation, one deals with the situation in which the longitudinal momenta of the radiated partons are also ordered such that the parton coupling to the photon has the minimum longitudinal momentum. This corresponds to the situation where the parton distribution at low x is being probed. At low x the gluon distribution becomes more singular than the quark distributions. If the quark distributions are ignored, the AP equation may be solved for the gluon distribution, with the result

$$xG(x,t) = exp[(-2Kt ln x)^{\frac{1}{2}}] \tag{2.33}$$

where $t = ln[\frac{ln Q^2/\Lambda^2}{ln Q_0^2/\Lambda^2}]$ and $K = 24/(11 - 2N_f/3)$. This rapid increase in the gluon momentum density at small x is the result of taking the small x limit of the AP evolution equations in the double leading log approximation (DLLA) where $ln(1/x)$, $ln ln Q^2/Q_0^2$ $\gg 1$.

Relaxing the ordering of the radiated partons in transverse momentum introduces terms beyond leading order in $ln Q^2$. The sum of the leading powers of $ln(1/x)$ (and arbitrary powers of $ln Q^2$) corresponds to the leading $ln(1/x)$ approximation. In this approximation is obtained the Balitskij-Fadin-Kuraev-Lipatov (BFKL) solution (see discussion in [28]) for the parton densities, which rises at low x even more rapidly than the DLLA solution. For instance, the gluon density in the BFKL solution behaves as

$$\begin{aligned} xG(x,Q^2) &\sim& exp[(n_0 - 1)ln(1/x)] \\ &\sim& x^{-D} \end{aligned} \tag{2.34}$$

where $D = (n_0 - 1) = (3\alpha_s/\pi)4 ln 2 \sim 0.5$. Therefore the small x behavior in the region where $\alpha_s ln(1/x) \gg 1$ is singular

$$xG(x,Q^2) \sim x^{-0.5} \tag{2.35}$$

This rapid rise in the number of partons at low x would eventually cause the virtual photon-nucleon cross-section to violate the Froissart[2] bound. At very low x some new physics must enter to soften the singular asymptotic behavior of the parton distributions. The new ingredients are expected to be the self-interactions of the gluons, which will increase as the gluon density increases. The AP equations are modified to take into account the effect of gluon recombination in the nucleon, in terms of a two-gluon correlation function [29].

2.2.4   Transition to Low Q^2

So far we have been discussing the behavior of the structure functions when Q^2 is large enough that the nucleon can be considered an incoherent superposition of partons. We have ignored the interference contributions to the photon-quark cross-section, such as the one shown in figure 2.7. This diagram is sometimes called the "cat's ears" diagram. In contrast to the "handbag" diagram of figure 2.4, the "cat's ears" diagram corresponds to the outgoing photon being emitted from a *different* quark than the one that absorbed it. How can this happen? The two quarks must be correlated with each other, and the photon is scattering off a two-quark wavefunction inside the nucleon. The statement of Bjorken scaling is that the "cat's ears" diagram is heavily suppressed with respect to the "handbag" diagram. The reason for this may be understood as follows. We may look at the "cat's ears" diagram in the Breit frame without loss of generality. In this frame, the photon has 3-momentum $\sqrt{Q^2}$ and no energy. Therefore it transfers a 3-momentum $\sqrt{Q^2}$ to the quark that absorbs it. The first quark must somehow transfer this large momentum to the second quark so that it can emit the final state photon. This transfer must occur through an internal propagator connecting the two, which must be off-shell by at least Q^2. This is illustrated in figure 2.8a. So we expect that the "cat's ears" diagram is suppressed with respect to the "handbag" diagram by a power of Q^{-2}. This is an example of a higher-twist process. Another example of a higher-twist process is shown in figure 2.8b, which may be interpreted as multiple interactions of the struck quark with other partons in the nucleon.

Higher twist contributions have been studied in terms of multiparton distributions and the corresponding parton cross-sections [30]. An analysis of SLAC data on $R = \frac{\sigma_S}{\sigma_T}$ at $Q^2 = 5 GeV^2$ [31, 32] shows that twist-4 terms are required in addition to the leading twist (next-to-leading order QCD corrections included) plus consistent target mass corrections. Low Q^2 data provides further opportunities to study higher twist processes.

---

[2]The Froissart bound is a consequence of unitarity and analyticity. It implies that, asymptotically, the total cross-sections cannot increase faster than $ln^2 s$. See [28] for a review.

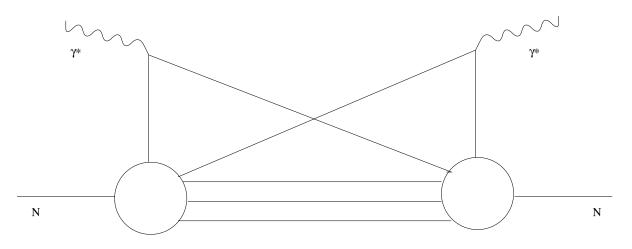

Figure 2.7: Interference contribution to the photon-quark cross-section.
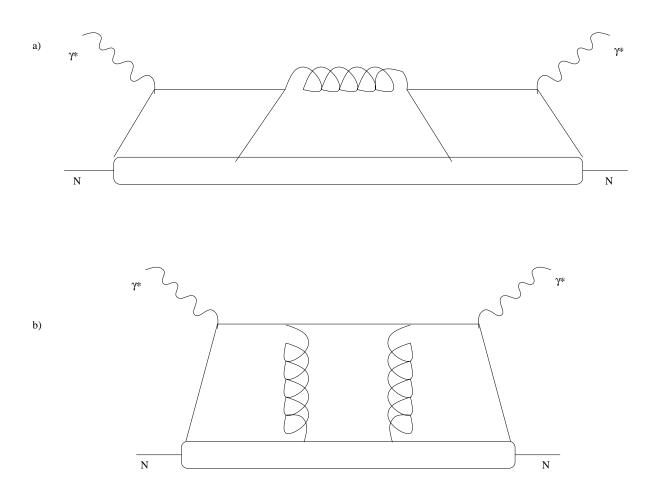

Figure 2.8: Examples of diagrams contributing to higher twist = 4 processes.

2.3   Low Q^2 Phenomenology

In the preceeding discussions, we have treated the photon as a purely electromagnetic probe. Its interaction with the nucleon is understood in terms of its interaction with the charged quarks. The photon may scatter incoherently off a quark (quark parton model - QPM), the struck quark may be derived by radiation from other quarks or gluons (QCD-improved parton model), and the struck quark may re-interact with other partons in the nucleon (higher twist effects). All the structure has been assigned to the nucleon and the photon has been considered a point particle. This approach was taken using the operator product expansion on the light cone, which is a kind of Taylor expansion that works well in the high Q^2, high ν limit.

Another approach has evolved that examines the structure of the photon itself. Unlike the previous approach which worked best in the infinite-momentum frame (nucleon is on the light cone), the second approach examines the photon-nucleon scattering process in the frame in which the nucleon is at rest (referred to as the laboratory frame in fixed-target experiments).

2.3.1   Hadronic Nature of the Photon

In a relativistic quantum field theory such as QED, a photon may fluctuate into a particle-antiparticle pair. The physical photon state is a superposition of the bare (non-interacting) photon state and the particle-antiparticle state, since the interaction Hamiltonian causes a mixing between the latter two states. The particle-antiparticle state may be a lepton pair, or it may be quark-antiquark state which may evolve further. Since the leptons will have small cross-section to interact with the target nucleon, we will not consider them further. Using lowest order time independent perturbation theory, we may write (see discussion in [33])

$$|\gamma_{physical}> = |\gamma_{bare}> + \sqrt{\alpha_{em}} \sum_n \frac{|n><n|H'|\gamma_{bare}>}{\nu - E_n} \qquad (2.36)$$

where the sum is over all hadronic states $|n>$ that couple through the interaction Hamiltonian H' to the bare photon state $|\gamma_{bare}>$. ν is the energy of the photon and E_n is the energy of the hadronic state with invariant mass m_n with 3-momentum equal to that of the photon. At high energy the energy difference may be approximated, $\nu - E_n \simeq (m_n^2 + Q^2)/2\nu$, yielding

$$|\gamma_{physical}> = |\gamma_{bare}> + \sqrt{\alpha_{em}} \sum_n \frac{2\nu}{(m_n^2 + Q^2)} |n><n|H'|\gamma_{bare}> \qquad (2.37)$$

As the energy increases the hadronic states become degenerate with the photon and degenerate state perturbation theory must be used. The amount of mixing between degenerate states is not suppressed by powers of the coupling constant, and the hadronic component of the physical photon can be quite large. The picture of the photon-nucleon interaction is that it proceeds through the interaction of the hadronic component of the photon with the nucleon.

2.3.2 Vector Meson Dominance (VMD)

The spectrum of hadronic states $|n>$ is limited to those sharing the same quantum numbers as the photon. The spectrum will be dominated by the low-mass vector mesons ρ, ω and ϕ due to the large values of the mixing matrix elements for these states. Using the VMD model, the predicted form of the structure function F_2 is [34]

$$F_2(Q^2, W^2) = \frac{Q^2}{4\pi} \sum_v \frac{M_v^4 \sigma_{vN}(W^2)}{\gamma_v^2 (Q^2 + M_v^2)^2} \tag{2.38}$$

where the Q^2 factor arises due to gauge invariance as will be shown below. The sum is carried out over the ρ, ω and ϕ vector mesons, M_v is the mass of the vector meson, $\sigma_{vN}(W^2)$ is the meson-nucleon cross-section, and the denominator contains the vector meson propagator. γ_v^2 is the coupling of the photon to the vector meson and may be obtained from the measured leptonic width. The meson-nucleon cross-sections may be derived from the measured πp and Kp total cross-sections. [34].

2.3.3 Real Photoproduction Limit of σ_S and R

Let us try to study the behavior of σ_S as $Q^2 \to 0$. The amplitude for the absorption of a helicity 0 photon is

$$A(S) = \epsilon(0).A = \frac{1}{Q}(\sqrt{Q^2 + \nu^2} A_0 - \nu A_3) \tag{2.39}$$

In our choice of gauge, $q.A = 0$. This means that

$$\nu A_0 = \sqrt{Q^2 + \nu^2} A_3 \tag{2.40}$$

Substituting for A_0 in the previous equation gives

$$A(S) = A_3 \frac{Q}{\nu} \tag{2.41}$$

or

$$\sigma_S = \frac{4\pi^2\alpha}{K}\frac{Q^2}{\nu^2}\sum_X |A_3|^2 \tag{2.42}$$

If we assume that the hadronic current A_μ smoothly tends to a finite value as $Q^2 \to 0$, then we find that $\sigma_S \sim Q^2$ in this limit. Physically, this means that longitudinal-scalar photons decouple from matter as $Q^2 \to 0$. Even though the state may always exist, these photons cannot be produced or absorbed (see discussion in [16]).

Since $lim_{Q^2\to 0}\sigma_T = \sigma_{\gamma N}$ (the real photoproduction cross-section), we can also say that

$$R \equiv \frac{\sigma_S}{\sigma_T} \sim Q^2 \tag{2.43}$$

Let us venture to make a stronger assumption about the behavior of the hadronic current A_μ as $Q^2 \to 0$. Let us assume that the photon interacts with a complicated object which is a superposition of many different spin states. At high center-of-mass energies this might be a reasonable assumption, since all kinds of long lived quark-antiquark-gluon fluctuations are possible[3]. We may then argue based on the equipartition principle that there are equal numbers of states that could couple to the three kinds of polarized photons. This means that we make the following assumption[4] :

$$|A_1|^2 = |A_2|^2 = |A_3|^2 \tag{2.44}$$

Let us make also the assumption that the longitudinal and transverse photons produce similar final states. At high energies, with large particle multiplicities produced in the "soft" photon-hadron collision, this may be a fair assumption. This allows us to write

$$\sum_{X_S} |A_3|^2 = \frac{1}{2}\sum_{X_T}(|A_1|^2 + |A_2|^2) \tag{2.45}$$

Since

$$\sigma_T = \frac{4\pi^2\alpha}{K}\frac{1}{2}\sum_{X_T}(|A_1|^2 + |A_2|^2) \tag{2.46}$$

we arrive at the result

$$R = \frac{Q^2}{\nu^2} \tag{2.47}$$

This is a stronger statement about R than equation 2.43, but it based on a stronger assumption about the behavior of A_μ at low Q^2, which is perhaps defensible at high ν.

---

[3]This is of course completely different from the picture in Bjorken scaling limit $Q^2 \to \infty$, where the dominant interaction mechanism would be scattering off individual particles with a definite spin state.

[4]Since the nucleon is unpolarized the two transverse components should be equal, $|A_1|^2 = |A_2|^2$.

2.3.4   Real Photoproduction Limit of F_2

In the real photoproduction limit, we may use equation 2.43 to drop the σ_S term from the expression for $F_2 \equiv \nu W_2$ (equation 2.11). Since the flux of real photons $K = \nu$, we obtain (see discussion in [15, 33])

$$lim_{Q^2 \to 0} \frac{F_2}{Q^2} = \frac{\sigma_T}{4\pi^2\alpha} = \frac{\sigma_{\gamma N}(\nu)}{4\pi^2\alpha} \qquad (2.48)$$

2.3.5   Regge Phenomenology at High Energies

The photoproduction limiting form of F_2, does not have to be inconsistent with scaling even though it seems to be explicitly Q^2 dependent. This is because we have not yet expressed the scale dependence of the photoproduction cross-section $\sigma_{\gamma N}$. Scaling of the structure function implies that the interaction is point-like. If the interaction of the photon and the nucleon could be described by point-like Compton scattering, the total cross-section $\sigma_{\gamma N}(s) \sim 1/s$, where s is the square of the c.m.s. energy. The inverse power of s would cancel the power of Q^2 in equation 2.48, resulting in a scale-invariant structure function. Therefore the scale dependence of the structure function in the photoproduction limit is determined by the energy dependence of the real photoproduction cross-section. As we shall see below, the real photoproduction cross-section does not behave like $1/s$, hence we know that scaling does not hold in the real photoproduction limit.

The hadronic nature of the photon allows us to relate the photoproduction cross-section to the hadron-hadron cross-sections. It has been known that hadron-hadron scattering is dominated by small momentum transfers t. A phenomenological description of the scattering process in terms of exchange of a hypothetical particle with appropriate quantum numbers is given by Regge theory [28]. Regge pole exchange is a generalization of single particle exchange. The Regge pole corresponds to a pole in the t-channel amplitude in the complex angular momentum plane. The position of the pole is described by the trajectory $\alpha(t)$. The high energy behavior of the two-body scattering amplitude due to Regge pole exchange is

$$A(s,t) \sim s^{\alpha(t)} \qquad (2.49)$$

Using the optical theorem the imaginary part of the forward scattering amplitude, i.e. $t = 0$ gives the total cross-section. Therefore

$$\sigma_{tot} \sim s^{\alpha(0)-1} \qquad (2.50)$$

The value of the trajectory function $\alpha(t)$ at $t = 0$ is called the *intercept*. The Regge pole carrying the quantum numbers of the vacuum, which gives the largest intercept,

is called the *Pomeron*. Therefore Pomeron exchange determines the energy dependence of the total hadronic cross-sections at high energies. The non-vacuum trajectories of Regge poles are called *Reggeons*. The Pomeron intercept is assigned a value close to 1 to describe the weak-energy dependence of the total hadronic cross-sections at high energy. Reggeon intercepts have values close to 1/2 or less, thus the contribution due to Reggeon exchange decreases with increasing energy.

One manifestation of the hadronic nature of the photon is that the γp cross-section as well as the pp, $\bar{p}p$, πp and Kp cross-sections have been successfully described by the same Regge powers [35]. The following parametrizaton of the data has been obtained

$$\sigma_{tot}(s) = X s^{0.0808} + Y s^{-0.4525} \tag{2.51}$$

where X and Y are parameters and the powers have been fitted to the data. The first term corresponds to Pomeron exchange, yielding a cross-section slowly increasing with energy, while the second term corresponds to Reggeon exchange.

Correspondingly, Donnachie and Landshoff [35] have constructed the following parametrization for F_2

$$F_2 = 0.324 x^{-0.0808} \left(\frac{Q^2}{Q^2 + a}\right)^{1.0808} + 0.098 x^{0.4525} \left(\frac{Q^2}{Q^2 + b}\right)^{0.5475} \tag{2.52}$$

where Q^2 is in GeV^2 and $a = 0.562$ GeV^2, $b = 0.011$ GeV^2. This parametrization is obtained by fitting the photoproduction data and the NMC data for $Q^2 < 10$ GeV^2. The form of the parametrization is chosen to have the following properties. In the limit $Q^2 \to 0$, F_2 tends to the photoproduction limiting form given in equation 2.48 with the photoproduction cross-section given by equation 2.51. At high Q^2, F_2 is forced to become a scaling function of x only in order to recover scaling behavior. At low Q^2, the Q^2 dependence is obtained from a propagator-like factor which is motivated by vector meson dominance.

2.3.6   QCD and Regge models at low x

It is interesting to note that Regge theory predicts the structure function F_2 to behave as $x^{1-\alpha(0)}$ at low x, if the Regge behavior is forced to match with Bjorken scaling expected from the parton model. This is because, at fixed Q^2, the high energy behavior of the photon-nucleon cross-section predicted by Regge theory maps into the low x behavior of the structure functions. Following this connection, one can think of the gluon ladders (figure 2.6) that dominate the low x behavior in QCD as the structure of the Pomeron. Similarly, the exchange of $q\bar{q}$ would correspond to Reggeon exchange. Quantitatively

though, the soft Pomeron describing photon-nucleon scattering at low Q^2 (equation 2.51) and the QCD perturbative Pomeron at high Q^2 (equation 2.35) predict different x dependence of the structure function at low x. This is a very interesting transition in the nature of the Pomeron between low and high Q^2, that can be studied by measuring the x dependence of the structure function in the intermediate Q^2 range.

2.3.7 Transition from Low to High Q^2 in the Hadronic Photon Picture

We note that the simple VMD expression for F_2 given in equation 2.38 goes as $1/Q^2$ at high Q^2. This is the consequence of limiting the sum over the hadronic components to the lowest mass vector mesons. Generalized Vector Meson Dominance models (GVMD) extend the sum to higher mass states and include off-diagonal transitions. Destructive interferences between the off-diagonal transitions are expected, so that the expression for the structure function may be restricted to diagonal transitions (see discussion in [33, 36]),

$$F_2(Q^2, s) = \frac{Q^2}{\pi} \int_{4m_\pi^2}^{\infty} d\mu^2 \frac{\mu^2 \Pi(\mu^2)}{(Q^2 + \mu^2)^2} \sigma_N^\mu(s) \tag{2.53}$$

where $\Pi(\mu^2)$ is the dimensionless spectrum of hadronic fluctuations with mass μ, which can be measured in $e^+ e^- \to hadrons$ using the following relation

$$\Pi(s) = \frac{\sigma(e^+ e^- \to hadrons)}{12\pi^2 \sigma(e^+ e^- \to \mu^+ \mu^-)} \tag{2.54}$$

$\sigma_N^\mu(s)$ is the cross-section of a hadronic state of mass μ to interact with the nucleon, when the c.m.s. energy squared is s.

Dimensional counting indicates that the GVMD expression for F_2 is inconsistent with scaling if σ_N^μ has the same size as the real hadronic cross-section for all μ. As $\Pi(\mu^2)$ becomes independent of μ^2 at high μ^2, F_2 would be proportional to Q^2. Scaling behavior of F_2 requires that $\sigma_N^\mu \sim 1/\mu^2$. It is interesting to see how this comes about for high mass states.

The original prediction of Bjorken scaling arose out of the concept that the photon couples to point-like quarks. Therefore, the formation of the hadronic component of the photon must be initiated by the photon splitting into a $q\bar{q}$ pair. The average transverse momentum p_t of the $q\bar{q}$ pair would be proportional to μ. Through the uncertainty relation, the transverse separation of the $q\bar{q}$ pair would be $\sim 1/p_t \sim 1/\mu$. Hence the color dipole moment of the $q\bar{q}$ pair would behave as $1/\mu$. The interaction cross-section of the dipole with the nucleon would be proportional to the square of the dipole moment,

thereby giving us the required relation

$$\sigma_N^\mu \propto \frac{1}{\mu^2} \qquad (2.55)$$

This shrinking cross-section with mass restores the consistency between the derivation of the scaling behavior of the structure functions and the hadronic nature of the photon. It has been referred to as the "shrinking photon" [37, 38, 39, 40] and "color transparency" [41, 42]. Through the integration over μ^2 in equation 2.53, the μ^2 dependence of σ_N^μ is reflected in the Q^2 dependence of F_2. The measurement of this dependence in the intermediate Q^2 region may be used to extract information about σ_N^μ and shed light on strong interaction dynamics.

Chapter 3

The E665 Experimental Apparatus

3.1 Introduction

The Fermilab Experiment 665 (E665) was a fixed-target muon scattering experiment, with the highest energy muon beam to date. The experiment was located in the New Muon Laboratory which is situated at the end of the NM beamline at Fermilab. The location of the experiment, and the other fixed target areas with respect to the accelerator (Tevatron) is shown in figure 3.1.

The goal of the experiment was to measure structure functions and their ratios, and to study the hadronic final state produced in the muon interaction. Data were taken on hydrogen and deuterium, as well as heavy targets to study the nuclear dependence of the above. The experiment took data in 1987-88, 1990 and 1991-92. The emphasis was on the identification and reconstruction of the incoming beam muon and the scattered muon in every event with high precision, and the measurement of the charged and neutral particles in the final state. Assuming the muon interacts through vector boson (mainly photon) exchange, the kinematics of the photon-nucleon interaction could be measured without any final state bias by using only the muon. The detector was constructed to measure the final state also in as much detail as possible.

These considerations dictated the construction of the experiment. The apparatus consisted of a beam spectrometer, followed by an open-geometry forward spectrometer, followed by a muon detector. The apparatus has been described in detail in [12], and the upgrades to the detector made for the 90-91 runs are described in [43, 44, 45]. In the following we will provide a summary of the beamline and the detector.

26
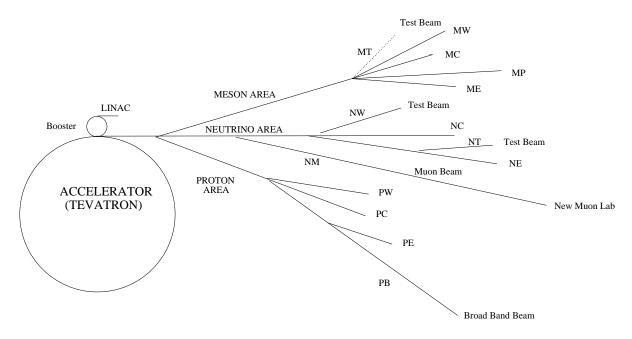

Figure 3.1: Fixed target areas at Fermilab.

3.2   New Muon Beamline

The muon beam delivered to E665 is a tertiary beam, obtained from the decay of charged pions, which in turn are obtained from the interaction of primary protons extracted from the Tevatron. The Tevatron is a synchrotron that accelerates protons (and antiprotons when used in collider mode) to $800GeV$ for use in fixed target experiments. In fixed-target mode, the total cycle of filling, acceleration and extraction lasts approximately one minute. The protons are extracted in the latter 23 seconds of the "cycle" called the "spill". Approximately 4×10^{12} protons are delivered per spill to the New Muon beamline, out of the total of about 10^{13}. These protons interact with a beryllium target, and the secondary pions and kaons are transported down a $1.1km$ beamline in which they are allowed to decay. About 5% of the particles decay to muons, and the remainder are stopped using a beryllium absorber. Positive muons are chosen for the beam because they provide a beam of higher momentum than negative muons (the primary protons being positive). In order to tailor the muon beam phase space, they are then transported through a beam pipe surrounded by a toroidal magnetic field. The toroid has the effect of 'spreading out' the halo of the beam. The beam that is finally used is about $4cm$ wide in the vertical direction and about $6cm$ wide in the horizontal direction. The mean beam energy was about $465GeV$ in run91, with a spread of about $50GeV$.

The muon beam maintains the 53.1 MHz radio-frequency (RF) structure of the Tevatron accelerating field. Thus the muons are localized in time to within $1ns$ in the RF "buckets", which are $18.8ns$ wide. This time structure proved very useful in the con-

struction of the electronic trigger signals, in that the RF can be used to provide time synchronization for all the electronic pulses. The final intensity of the muon beam is about 1 MHz, so that about 1-2% of the buckets are occupied by a muon. A small fraction of the buckets contains multiple muons. The trigger hodoscopes and electronics provide almost single-bucket resolution. Events with multiple occupancy in a bucket can be identified both at the trigger level and using offline reconstruction.
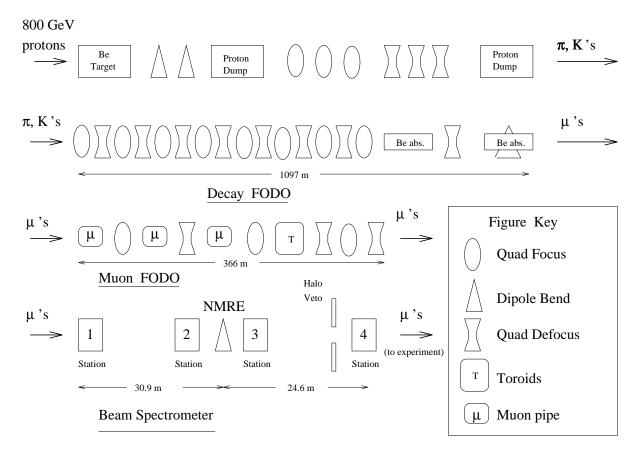

Figure 3.2: New Muon beamline and the E665 beam spectrometer.

3.3 Beam Spectrometer

As shown in figure 3.2, the New Muon beamline is followed by the E665 beam spectrometer. The beam spectrometer serves a number of purposes. Firstly, the hodoscopes in the beam spectrometer provide a fast electronic signal on the passage of a beam muon. This is an essential component for all the beam-related triggers. The transverse segmentation of the beam hodoscopes (SBTs) is fine enough to define the accepted beam phase space

at the trigger level, and to detect multiple occupancy in the bucket. The beam trigger signal produced by the hodoscopes is counted by scalers to provide a total beam count. The hodoscope hits are latched so that in-time and stale beam tracks can be identified offline.

Secondly, the beam spectrometer contains a number of $1mm$ multiwire proportional chambers (PBTs) and a dipole magnet (NMRE). These are used to provide precise reconstruction and momentum measurement of the beam track. The spectrometer consists of two arms with the NMRE magnet in the middle. Each arm is reconstructed using chambers arranged in two groups called stations, with six PBT chambers in each station. The six chambers contain 2 Y, 2 Z and 1 U and 1 V view planes, where the U and V stereo views have wires oriented $\pm 30°$ from the vertical. In addition, one vertically and one horizontally segmented SBT hodoscope is placed in each station (except for station 2 which only contains a vertically segmented hodoscope). The NMRE magnet draws 3350 amps and provides a transverse momentum kick of about $1.54 GeV$. The length of the beam spectrometer helps to provide an excellent resolution on the curvature of $\delta p^{-1} \sim 8 \times 10^{-6} GeV^{-1}$, corresponding to a $2 GeV$ momentum uncertainty on a $500 GeV$ track.

3.4   Target Assembly

The target assembly is placed in the path of those beam muons which can be tagged and reconstructed by the beam spectrometer. It underwent a significant upgrade between the 1987-88 run and the 90-91 runs. In the first run, one target was in place at a time for an extended period. In contrast, for the 90-91 runs, all the targets were mounted on a precision table that moves the targets laterally. The different targets are moved into the beam every few minutes in a specified cycle. This arrangement produces a great advantage when comparative measurements between different targets are done. Many sources of uncertainty do not change very rapidly, so they cancel in the comparative measurements when the targets are cycled. For the absolute cross-section measurement, this feature is also relevant in that an empty (MT) liquid target vessel is also cycled in and out of the beam. The empty target data is used to subtract out the off-target scatters on a statistical basis.

Secondly, for run90/91 the targets are placed in the nominally field-free region[1] in front of the vertex magnet (CVM). By having the muon scattering vertex in the field-free region, the correlations between the errors on reconstructed kinematics are greatly reduced, simplifying the analysis of the data. During the 87-88 run, the target was

---

[1]A small fringe field does exist near the downstream edge of the targets, see [46].

placed inside a streamer chamber which was was placed inside the CVM. The advantage of the old arrangement was the nearly full acceptance in solid angle afforded by the streamer chamber when it was triggered. Since the streamer chamber could be triggered only for a subset of the events due to its slow speed, it was replaced by vertex drift chambers (VDC) in the 90/91 runs. The targets were then moved upstream into the field-free region.

The view of the target assembly along the beam direction is shown in figure 3.3. During run90, data were taken on both the light liquid and the heavy solid targets. This analysis is based on the run91 data which were taken only on the liquid targets. The longitudinal view of one of the liquid targets is shown in figure 3.4. The three target vessels were identical and two contain liquid hydrogen (H_2) and deuterium (D_2) respectively. The target positions and pressures were monitored during the course of data-taking.

The length of the active target material was nominally $1m$ for the liquid targets. Longer targets would provide a significant gain in statistical power for muon cross-section measurements, however for hadron studies they are a disadvantage because of the increased probability of secondary interactions. $1m$ targets provided a good compromise between the muon cross-section and the hadron studies.

3.5 Forward Spectrometer

3.5.1 Tracking Detectors

The purpose of the forward spectrometer is to provide the trigger for muon scattering events, and to record the information necessary to reconstruct the scattered muon and the final state properties. Charged particle measurements are provided by proportional and drift chambers which form part of a double-dipole, open geometry spectrometer. Photon detection and energy measurement is provided by an electromagnetic calorimeter, which also serves to identify electrons in conjunction with the spectrometer. Downstream of the spectrometer and a $3m$ thick iron absorber which stops all particles but muons, there is a muon detector. The muon detector provides information for online muon triggering and offline muon reconstruction. In the forward spectrometer, some $\pi/K/p$ identification capability was intended using time-of-flight (ToF) and Cerenkov detectors.

The most important parts of the forward spectrometer for this structure function analysis are the tracking and muon detectors. Immediately downstream of the target assembly is placed a set of vertex drift chambers (VDC) inside the CERN Vertex Magnet (CVM). The main purpose of the VDC is to provide measurements of low momentum tracks that do not fall within the acceptance of the downstream chambers. They do not contribute significantly to the muon-finding process, but they do improve the resolution

of the muon track found by the downstream chambers. At the downstream end of the CVM, a set of 6 MWPCs called PCV ($2mm$ wire spacing) are installed. The PCV forms an important anchor for the low-momentum track finding. As far as the muon track is concerned, the PCV-VDC combination serves to increase the length of the lever arm upstream of the Chicago Cyclotron Magnet (CCM), thus improving the resolution significantly. The VDC contain Y, Z, U and V views. The PCV contain 2 Y, 2 U and 2 V planes, with stereo angles $\pm18°$ and $\pm45°$.

The muon track-finding process hinges on the PC (also referred to as PCN), PCF, and DC chambers. The 12 PC chambers are placed upstream of the CCM, while the 15 PCF chambers are arranged in 5 groups (stations) of 3 chambers each inside the CCM. Both are multi-wire proportional chambers, with $3mm$ and $2mm$ wire spacing respectively. The PC chambers contain 3 planes in each of 4 views, Y, Z, U and V with $\pm28°$ stereo angles. Each PCF station contains 1 Z, 1 U and 1 V plane with $\pm15°$ stereo angles. Downstream of the CCM are two stations of drift chambers, labelled DCA and DCB for the upstream and downstream set respectively. Each station contains 2 pairs of Z chambers and a pair each of U and V chambers. The wire spacing is $5cm$, and the chambers in a pair are staggered by half a wire spacing to resolve left-right ambiguities. The stereo angles are $\pm5°$. The spatial resolution is about $300\mu m$. Since drift chambers cannot operate at high rate, they are deadened by construction in the region where the beam passes. In this region small MWPCs called PSC and PSA are placed, near DCA and DCB respectively. The PSC was not used in the offline reconstruction for run91 because its efficiency was very low. The PSA contains 8 planes with $1mm$ wire spacing, two in each of the Y,Z,U and V views. The stereo angles are $\pm45°$.

Tracks that span the length of the forward spectrometer are able to achieve a curvature resolution of $\delta p^{-1} \sim 2 \times 10^{-5} GeV^{-1}$. The CVM field strength is 15.131 Tesla with a transverse momentum kick of $1.293 GeV$. The CCM provides a transverse momentum kick of $2.019 GeV$. The polarities of the two magnets are reversed with respect to each other. This causes the tracks to follow an S-shaped trajectory, which gains some momentum resolution and resolution on the angle of intersection between two tracks. In particular, this geometry gives a better resolution on muon energy loss and scattering angle than a single dipole geometry. Also, the two magnets are positioned such that the position of the scattered muon at a "focussing" plane is independent of momentum and depends only on the scattering angle. The muon detector is placed at the focussing plane, thereby allowing the construction of muon triggers that can select on scattering angle.
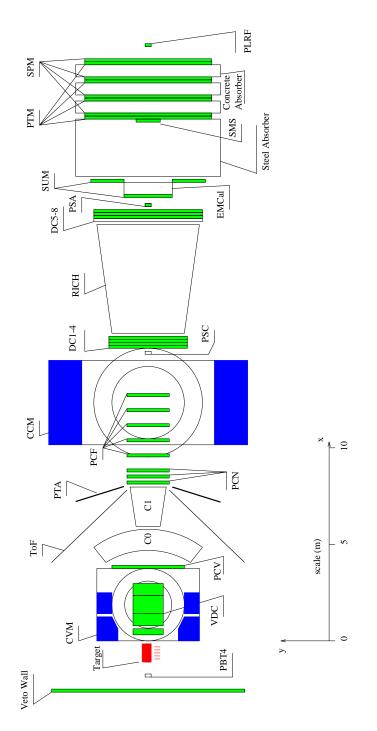

Figure 3.5: The E665 forward spectrometer and muon detector.

3.5.2   Muon Detectors

The muon detectors are arranged in four sets or stations behind a $3m$ hadron absorber made of iron ($\sim$ 18 interaction lengths and $\sim$ 170 radiation lengths). The four stations are separated by concrete absorbers that stop shower particles from propagating between one station and another. Each station contains proportional tube planes (PTMs) and hodoscopes (SPMs and SMSs). The PTMs and SMSs are arranged in Y and Z views, the PTMs covering the wide angles and the SMSs covering the central dead regions in the PTMs where the rates are high. The SPMs provide wide angle hodoscope coverage. All three detectors provide information for various muon triggers. The PTMs and SMSs are approximately 1/2 inch detectors and are also used for offline muon tagging. The SMS hodoscopes are covered in front by a lead sheet $12 - 13mm$ thick, which serves to absorb soft shower particles and reduce the SMS hit multiplicity.

Some new hodoscopes were installed between the 87-88 and the 90-91 runs. These were the SUM, SSA and SVS hodoscopes. The SUM and SSA hodoscopes were installed immediately downstream of the DCB drift chambers. The large-aperture SUM hodoscopes were used in conjunction with the SPM hodoscopes to improve the speed of the large angle muon trigger signals. The SSA is a small hodoscope with good position resolution placed in the beam, to provide a veto signal for the small angle trigger (SAT). The SVS is also another small hodoscope, placed in the beam inside a hole bored into the iron absorber at the downstream end. It provided a fast beam veto signal that was used to construct the "SVS" large angle trigger. It was placed as close to the iron as possible so that shower particles accompanying the muon are localized when they hit the hodoscope.

3.5.3   Electromagnetic Calorimeter

The calorimeter is placed immediately upstream of the hadron absorber. It is a lead-gas sampling calorimeter [47, 48, 49], consisting of 20 planes of $\sim$ $5mm$ thick lead sheets (one radiation length each) separated by Iarocci proportional tube planes. The wire spacing was $1cm$. 16 wires were encased in a unit called a bitube, and over most of the planes their signal was summed before readout. In planes 4-7 from the front, which are located at the maximum of electromagnetic showers, signals from individual wires were read out to improve the transverse position resolution. Each plane contained 18 bitubes stacked side-to-side, and the view alternated from one plane to the next. The bitube readout provided information on the longitudinal energy profile of the shower, and transverse energy and position information in one dimension.

In addition to the bitubes, copper pads were placed on both sides of the Iarocci planes, which picked up signals through capacitive coupling. The double-sided feature made the coupling insensitive to the position of the wire to first order. Pads in the successive planes were placed to overlap each other to form "towers", and the signals from all pads in a tower were summed before readout. The towers were not projective, i.e. they point in the direction normal to the plane and not towards the target. The pads measured the two-dimensional transverse energy distribution. The pad size used was $4cm \times 4cm$ in the inner $1m \times 1m$ region, $8cm \times 8cm$ in the central $2m \times 2m$ region outside the inner region, and $16cm \times 16cm$ in the outer region.

The calibration of the calorimeter involved the measurement of ADC pedestals and amplifier gains, pressure, temperature, high voltage and gas gain as a function of time. All of this information was recorded continuously during data-taking and analysed offline to produce database files containing calibration constants. Corrections were applied for the time dependence of all these quantities. The energy scale calibration and the alignment of the calorimeter was performed using electron calibration data. Once during each run, the muon beamline was modified to transport electrons to the muon lab. This involved the temporary removal of the beryllium absorber and alterations to the beamline magnets. Electrons and positrons were produced by converting photons obtained from π^0 decay, and both species were used for calibration. The hadron contamination in the beam increased with momentum. The E/p ratio of calorimeter cluster energy to track momentum measured by the forward spectrometer was used to set the energy scale. A simultaneous fit to the E/p spectrum for an electron and a hadron component was made, in bins of track momentum. During the run90 calibration, a beam with good electron content was obtained in the energy range of 15-50 GeV. During the run91 calibration, a good electron beam was obtained in the range 10-100 GeV, beyond which the beam was almost purely hadronic. The position dependence of the calorimeter response was studied by sweeping the calibration beam vertically and horizontally across the face of the calorimeter. The run91 calibration included, in addition to the above-mentioned effects, corrections for the measured position dependence. The details can be found in [50, 51, 52, 53, 54, 55, 56, 57].

The calorimeter shows linear response up to about 50 GeV. Beyond this there is evidence of non-linear saturation effects. There is 3% reduction from unit gain at $60GeV$, 4% at $70GeV$, 5% at $80GeV$, 7% at 90 GeV and 12% at $100GeV$. No correction is made for the non-linearity in the standard production code. The electron response is Gaussian with a resolution on electromagnetic energy of $\sigma_E = 38\%\sqrt{E}$ where the energy E is in units of GeV. The hadron response can be characterized by the form $e^{-3E/p}$ for $E/p > 0.2$. At low values of E threshold and noise effects cause the hadron response to deviate from this form.

It should be noted that these measurements were made using the electron calibra-

tion data at a fixed point on the calorimeter, and give no evidence of a constant (i.e. energy independent) term in the fractional energy resolution. However, variation of gain with time (pedestals, amplifier gains, gas pressure, temperature and composition) and position can introduce a constant term in the fractional energy resolution. The time dependence of the various calorimeter parameters is studied extensively using the online monitoring data and corrections are applied as a function of run number. Judging from the procedure used to extract the corrections from the monitoring data, the corrected calorimeter response should be stable with time within 5%.

The central region of the calorimeter is exposed to a large muon flux. It shows definite aging effects when comparisons are made between the response of this region for the 87, 90 and 91 runs. The overall gain in this region is seen to fall steadily with time. As the detectors are multi-wire gas chambers, they are definitely susceptible to radiation damage. Many forward spectrometer tracking chambers also show evidence of radiation damage in the central region for run91, and the problem of high integrated flux is exacerbated for the calorimeter by the lead sheets which produce more shower particles. In addition to the long term effects of the flux, there are also possibilities of instantaneous rate effects reducing the gain. These include voltage drops due to steady state current flow through the resistive cathode, and space charge effects in the gas reducing the gas amplification. Due to all these reasons, the linearity and saturation effects in the central region are very likely to be different from the rest of the calorimeter, and must be studied separately. This is best done using electrons and photons obtained during normal data taking, provided by μe scatters and bremsstrahlung. These studies are documented in appendix D and in [58]. It should be noted that these studies of the central region were done after the main data production, so they could not be included in the standard calorimeter calibration database. However, simple parametric forms for the energy correction in the central region are provided, so they can be applied at the analysis stage.

The standard calorimeter production code includes corrections for dead channels and noise suppression. Dead pad channels were isolated using the test-pulsing data, and dead bitubes were found using a combination of test-pulsing data, calorimeter self-triggers on incidental activity (in the absence of beam), and the MIP signals produced by cosmic and beam halo muons. The incidental activity resulting in large isolated signals (above $5 GeV$) is not electronic noise but is in fact due to cosmic rays, residual radioactivity or sparking. It occurs at a low rate of a few Hertz. By using the calorimeter trigger (to be discussed below) to fire on these signals, unresponsive bitubes which are dead due to high voltage problems (as opposed to dead electronics) can be isolated. In the case of a high voltage problem, the bitube readout as well as all the overlapping pad readouts must be corrected. In the case of a dead bitube electronics channel, only the bitube readout is corrected. The readout for a dead channel is estimated for pads by averaging the neighboring pad signals, and for bitubes by using the measured longitudinal profile

of electromagnetic clusters. About 10 bitubes had missing high voltage problems and 6 had dead electronics problems in run91, out of a total of 360. There were 17 dead pads in run91 out of the total of 1152. These dead channels turn out to be isolated from each other, so that no clusters can be completely lost and the average over the neighboring pads provides a good estimate of the dead pad signal.

Due to repairs carried out on low voltage power supplies, various sympathetic oscillations in the bitube signals that plagued the detector during run87 were eliminated before run91 started. The cause of these oscillations is attributed to failing power supplies that were suffering under the current load of the bitube amplifiers. A handful of pad channels suffered from oscillation problems. These were isolated by reading out the detector in the absence of beam. These oscillations were suppressed in software in a very conservative manner, i.e. care was taken in developing the algorithm to minimize the loss of real physics signals. Following these corrections, the dominant source of "noise" is the beam energy loss in the calorimeter. About 20% of the beam triggers (triggering only on the passage of a beam muon in the beam spectrometer) have at least one cluster, which are concentrated in the central region $10cm$ high and $25cm$ wide. 99% of these beam-induced clusters have energy less than $5GeV$. The removal of these low energy clusters in this central region should be sufficient to remove all noisy clusters from a physics analysis sample.

The alignment of the calorimeter with respect to the tracking chambers is performed using the calibration data which sweeps in position. The overall alignment is good to at least $1mm$. The minimum residue between a track and the cluster induced by it is obtained by extrapolating the track into the calorimeter. This is justifiable since the cluster is in fact an extended object in the longitudinal direction. If the track is not normally incident, the cluster centroid is shifted in the transverse direction of propagation of the track. It is found that the residue for electron tracks is minimized on average when it is measured at a depth of $1.1 \times CoG$, where CoG is the distance of the longitudinal center-of-gravity of the cluster from the front face of the calorimeter. The corresponding minimum for hadrons is achieved at a depth equal to the CoG. Since the CoG distributions for electromagnetic and hadronic showers are different, some discrimination between electrons and hadrons is achieved by calculating the longitudinal position at which the track-cluster residue is minimized. This position is sensitive to the longitudinal profile of the shower if the track is obliquely incident. The distribution of this X coordinate peaks strongly near planes 4-7 for electrons and is very wide for hadrons. Thus a cut on this X coordinate can provide electron/hadron discrimination independently of a cut on E/p.

The position resolution for clusters induced by tracks in the 5-25 GeV range, when measured using the minimized residue, is as follows:

	σ_{xy} (mm)	
particle	$4cm \times 4cm$ pads	$8cm \times 8cm$ pads
Electrons	5.5	8.0
Hadrons	14.5	17.7

The position resolution is expected to improve slowly as the cluster energy increases because more pads contribute to the centroid determination.

3.6 Triggers

E665 operated with a number of triggers. These could be classified into three categories:

- Physics triggers look for events in which the muon interacts.

- Normalization triggers. These are also called random beam triggers. Every physics trigger includes in its definition the requirement that a valid beam muon signal exist. The beam signal by itself is randomly sampled to create a random beam trigger. The count of these triggers is used to obtain the count of the total number of beams available to the physics trigger, and hence the luminosity. Some physics triggers used the same beam definition while others were different; a separate random beam trigger was created for each beam definition.

- Monitoring triggers provide data to study the detector performance.

The physics triggers could be classified into three sub-categories:

- Large angle triggers (LAT). These triggers used the wide angle muon detectors and the SUM hodoscope to indicate a scattered muon, in conjunction with the absence of a signal in a fixed veto hodoscope placed at small angle. The idea is to ensure that there is no signal in the beam region that is consistent with an unscattered muon, and at the same time see a signal at large angles that is consistent with a scattered muon. The three large angle triggers were the SVS, SVSWAM2 and CVT. They used different combinations of veto elements and wide angle detectors. A description of the LATs is provided in [43]. The data from the LATs is not used in the structure function measurement, but they are used to study an aspect of the small angle trigger efficiency.

- Small angle trigger (SAT). This trigger only uses veto hodoscopes to indicate the absence of an unscattered beam. The special feature is that the veto region is dynamically defined for each beam muon depending on the beam trajectory. This allows the veto region to be smaller than the total beam phase space, thereby allowing triggers on smaller angle scatters than was possible with the large angle triggers. For this reason the structure function measurement is performed with the SAT data. The SAT is described in more detail in chapter 6 and in [45]. A similar trigger called the SATPS was also defined, which did not use all the veto hodoscopes used by the SAT. Specifically, the SATPS does not use the SSA hodoscope while the SAT does. This causes an increase in the trigger rate, making it necessary to pre-scale the SATPS (hence the PS extension). Due to the pre-scale the SATPS does not provide sufficient data for the cross-section measurement. We use it to study the effect of the SSA veto on the SAT efficiency. The LAT mentioned above are also used for the same purpose.

- Calorimeter trigger (CAL) uses signals from the electromagnetic calorimeter to select muon interaction events.

Each category used a different beam definition for reasons specific to each type of trigger. The RLAT, RSAT and RCAL random beam triggers were associated with these sets of physics triggers.

3.6.1   Calorimeter trigger

We describe here the construction of the calorimeter trigger as it was used during run91. The calorimeter trigger is fundamentally different from the other physics triggers used in E665. The other triggers attempt to trigger on the scattered muon trajectory alone, thereby involving no dependence on the final state activity. This is a very important philosophy for a muon scattering experiment, that there be no final state bias in the trigger, from the point of view of muon cross-section studies and the final state studies. In contrast, the calorimeter trigger explicitly selects on final state activity. In spite of this disadvantage, it actually is a very useful trigger.

Firstly, the calorimeter trigger can select muon interactions occurring at any scattering angle, down to zero scattering angle, and Q^2 as low as the kinematic limit imposed by the muon mass would allow. The muon triggers are limited in their acceptance at low scattering angle, because the scattered muon cannot be distinguished from unscattered beams within the resolution of the hodoscopes. The data at very low Q^2 are interesting and extend the kinematic coverage of the world data. The low Q^2, low x data provided by the calorimeter trigger have been used to make the neutron-to-proton cross-section

ratio measurement at E665 [59], because the ratio is not very sensitive to the final state biases. Further understanding of the trigger could lead to absolute cross-section and final state measurements in the low Q^2, low x regime where prior data do not exist. At the time of this absolute structure function analysis, the priority was to understand the efficiencies of the muon triggers and the spectrometer, and other structure function-related issues. Hence the measurement with the calorimeter trigger data was not attempted.

Secondly, the calorimeter trigger was the only physics trigger in E665 that did not incorporate a muon veto detector behind the hadron absorber. In fact, the trigger included no veto at all, and no information from any muon detector behind the absorber. This was a very important consideration in the design of the trigger. Due to this feature, the calorimeter trigger data provides the unique opportunity to measure the rate of suicides induced in all the muon triggers by the muon showering in the absorber. In particular, this measurement is crucial in order to understand the absolute efficiency of the SAT for the structure function measurement.

The trigger uses the signals produced by the bitubes, because these are faster than the pad signals. As mentioned earlier, each plane in the calorimeter contains 18 bitubes side-to-side, and the bitubes in successive planes are lined up behind each other. In each view separately, signals from the 10 bitubes that lie behind each other in the 10 planes are summed to produce a "bitube tower" signal. Thus we have 18 bitube tower signals in each view. These are the raw signals used to construct the trigger.

The main backgrounds to the trigger rate were expected to be the muon interactions in the calorimeter itself, since the calorimeter represents 20 radiation lengths of "target" material compared to the $\sim 12\%$ radiation length and $\sim 14\%$ and $\sim 30\%$ interaction lengths in the H_2 and D_2 targets respectively. The bulk of the muon rate is concentrated in the central region. The rate in individual bitube towers was measured in the presence of beam, and the central four bitube towers in each view were excluded from the trigger. The calorimeter was then split into four sections, the top and bottom halves of the horizontal planes, and the left and right halves of the vertical planes. All the bitube tower signals in each half were summed to arrive at four analog signals, one from each of the shaded regions shown in figure 3.6. These four signals are used to create the calorimeter trigger signal.

The rate in the individual halves is very high due to the electromagnetic showers produced by halo muons. Increasing the discriminator thresholds has the undesirable effect of reducing rapidly the efficiency for triggering on hadronic target scatters, while not reducing the halo muon trigger rate as fast. Therefore at high thresholds the only triggers are due to halo muons. Instead, we use the difference between the topologies of energy flow for halo triggers and hadronic target scatters. Halo muons produce single clusters while hadronic scatters in the target produce a spray of particles in both vertical
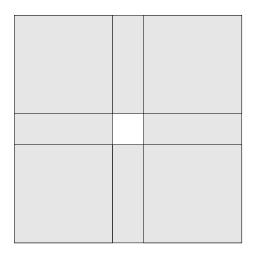

Figure 3.6: A frontal view of the calorimeter showing the four "half" regions producing signals for the calorimeter trigger.

and horizontal directions. Thus we trigger on the spread of energy in both directions. The requirement of some vertical energy flow eliminates electromagnetic events produced in the target. Through the focussing condition, the electromagnetic energy in μe and bremsstrahlung events arrives at the calorimeter in the central region, which is removed. Even if the bremsstrahlung were to convert or the electron were to radiate downstream of the target, the magnet can only spread the energy in the horizontal direction. The requirement of some vertical energy flow is completely effective in removing such events.

The energy spread requirement is satisfied by making a 3 out of 4 coincidence of the four half signals after discrimination. This requirement reduces the trigger rate from tens of kiloHertz to about 2 Hertz, so that a viable trigger is formed. Single halo clusters only satisfy a 2 out of 4 requirement. The energy flow in electromagnetic events remains in the central horizontal plane, thereby satisfying at most a 2 out of 4 coincidence. About 60% of the triggers were hadronic scatters, most of the remainder being halo interactions in the iron yoke of the CCM. The shower particles emanating from the yoke are swept laterally by the field, producing a spray across the top or bottom of the calorimeter. This would satisfy the 3/4 requirement. They could be eliminated by a 4/4 requirement. However, the reduction in the trigger rate, which was already low enough, did not justify the loss in trigger efficiency for hadronic scatters.

Since the trigger was constructed out of proportional chamber signals, speed was an issue. In order to produce a fast preliminary trigger, the analog sum of all four half signals was formed and converted to a digital pulse using a discriminator threshold of $100mV$. The time necessary to make the coincidence logic is saved, and the low threshold allows triggering early on the electronic pulse. This produces a high trigger rate, so this discriminated signal is used as a Level1 trigger for the experiment. The Level1 trigger

initiates latching and digitizing of detector signals. Detector readout is initiated by a Level2 trigger, which must be the final low-rate trigger since readout incurs significant dead time. However, there is more time available to make a Level2 decision. The 3/4 coincidence requirement is made at Level2, with discriminator thresholds on each half signal set at 175 mV. A $100mV$ threshold roughly corresponds to a $5GeV$ signal.

Another issue was how to define the trigger time. The bitube signals were approximately $200ns$ wide, during which time multiple beam muons can pass through the detector. For this reason, a special "no-neighbour" beam for the calorimeter trigger was created. The beam hodoscope signal used for the large angle triggers (LATbeam) was used as a starting point. Furthermore, the requirement was made that an acceptable beam muon must not be preceeded or succeeded by another beam muon (defined as a 7/7 SBT signal) for at least $200ns$. This wide "no-neighbour" requirement ensured that there was only one candidate beam that could have produced the calorimeter trigger. In the final calorimeter trigger, this beam signal was used in coincidence with the calorimeter Level2 signal to set the trigger time. The Level1 time was defined by using the LATbeam signal alone in coincidence, since one must wait at least $200ns$ to satisfy the special "no-neighbour" condition. The loss in luminosity due to the wide "no-neighbour" requirement was typically 30%, but it would depend on the instantaneous rate and the local time structure of the beam.

Finally, a copy of the final calorimeter beam signal used at Level2 was randomly prescaled (by 2^{19}, the same prescale factor used for all random beam triggers) to create a random beam trigger (RCAL) for normalization purposes.

Chapter 4

Structure Function Analysis

In the single photon exchange approximation, the double differential cross-section for lepton-nucleon scattering can be written as

$$\frac{d^2\sigma_{1\gamma}}{d(-Q^{-2})d(lnx)} = 4\pi\alpha_{em}^2 F_2(x, Q^2)[1 - y - \frac{Mxy}{2E} + \frac{y^2(1 + 4M^2x^2/Q^2)}{2(1 + R(x, Q^2))}] \qquad (4.1)$$

where E is the incoming lepton energy in the laboratory frame, and $-Q^2$ is the square of the 4-momentum transferred from the lepton. In the laboratory frame ν is the lepton energy loss, $x = Q^2/2M\nu$ is the Bjorken scaling variable, and $y = \nu/E$. α_{em} is the electromagnetic coupling constant and M is the nucleon mass. $F_2(x, Q^2)$ is the structure function of the target nucleon and $R(x, Q^2)$ is the ratio of the longitudinal to the transverse virtual photon cross-sections.

The relation between the single photon exchange cross-section and the total (radiative) muon cross-section is given in equation 4.4. The number of muon scattering events observed in a bin of measured kinematics, in the absence of background, is related to the total muon cross-section σ_{tot} in the following manner:

$$N_{obs}^{Data} = \int_{\vec{\xi_1'}}^{\vec{\xi_2'}} d\vec{\xi'} \int d\vec{\xi}\mathcal{L}(\vec{\xi})\mathcal{A}(\vec{\xi'}, \vec{\xi})\sigma_{tot}(\vec{\xi}) \qquad (4.2)$$

where $\mathcal{A}$ is the acceptance kernel of the detector and $\mathcal{L}$ is the luminosity. $\vec{\xi}$ is the vector of true variables and $\vec{\xi'}$ is the vector of observed variables. If the detector were perfect, we would have $\mathcal{A}(\vec{\xi'}, \vec{\xi}) = \delta(\vec{\xi'} - \vec{\xi})$ and we would observe every event exactly as it was produced. Equation 4.2 would collapse to

$$N_{true}^{Data} = \int_{\vec{\xi_1'}}^{\vec{\xi_2'}} d\vec{\xi'}\mathcal{L}(\vec{\xi'})\sigma_{tot}(\vec{\xi'}) \qquad (4.3)$$

The relation between the single photon exchange cross-section and the total (radiative) muon cross-section is

$$\sigma_{tot}(\vec{\xi''}) = \int d\vec{\xi} \mathcal{R}(\vec{\xi''}, \vec{\xi}) \sigma_{1\gamma}(\vec{\xi}) \qquad (4.4)$$

where $\mathcal{R}$ is the kernel of radiative corrections. Therefore, the fully expanded relation between the number of observed events in a bin, and the single photon exchange cross-section is

$$N_{obs}^{Data} = \int_{\vec{\xi}_1^l}^{\vec{\xi}_2^l} d\vec{\xi'} \int d\vec{\xi} \mathcal{L}(\vec{\xi}) \mathcal{K}(\vec{\xi'}, \vec{\xi}) \sigma_{1\gamma}(\vec{\xi}) \qquad (4.5)$$

$\vec{\xi}$ are the variables describing the kinematics of the virtual photon exchanged between the muon and the nucleon. In the measurement of inclusive muon scattering, the events are binned in the measured kinematics at the scattered muon vertex, denoted by $\vec{\xi'}$. $\vec{\xi}_1^l$ and $\vec{\xi}_2^l$ denote respectively the lower and upper edges of the bin. The integrand contains the single photon exchange cross-section $\sigma_{1\gamma}$, the luminosity $\mathcal{L}$ and the overall response kernel $\mathcal{K}$. The complete set of variables includes the following:

- The five parameters associated with the beam whose distribution is described by $\mathcal{L}$. These are the transverse positions and slopes, and the energy. We integrate over the beam distribution when the observed events are binned in the scattering kinematics.

- The longitudinal position of the scattering point. Since the muon beam suffers negligible attenuation in the target, the true distribution of this variable is uniform in the target. We integrate over the longitudinal position of the scatter.

- The variables describing the muon scatter, which we have chosen as x and Q^2, and the azimuthal angle ϕ of the scatter. The ϕ distribution is expected to be uniform, hence we integrate over it. The observed events are binned in two-dimensional x and Q^2 bins.

- All the variables needed to describe the final state produced in the muon-nucleon scatter (excluding the scattered muon). In this inclusive measurement, we integrate over all the final states.

The process by which a hypothetical "single photon exchange" event appears as a scattered muon in the detector is indicated by the flow chart in figure 4.1. The response kernel $\mathcal{K}$ gives the probability distribution of a single photon event with kinematics $\vec{\xi}$ appearing in the detector with kinematics $\vec{\xi'}$. It contains contributions from processes that change the probability of the muon scatter to occur or be detected, and processes that cause the measured muon vertex kinematics to be different from those of the exchanged virtual photon. These processes can be enumerated as follows:

- Radiative Corrections to the single photon exchange Born diagram. These processes change both the cross-section and the kinematics.

- Multiple scattering and energy loss of the muon tracks in the detector, before and after the hard scatter of interest. These processes change the kinematics of the event.

- Efficiency of triggering on a scattered muon event. Triggering inefficiency causes loss of events and hence a reduction in the observed cross-section.

- Efficiency of reconstructing the scattered muon trajectory. The efficiency of reconstructing incoming beam tracks is subsumed into the measurement of the usable luminosity. Reconstruction inefficiency for the scattered muon causes loss of events because the kinematics of the event cannot be determined unless both the incoming and outgoing muon tracks have been measured.

- Smearing in the muon kinematics due to the finite spatial resolution of the tracking chambers.

- Systematic errors in the measured muon kinematics due to mis-calibration of the detector.

When all these processes are understood, the response kernel $\mathcal{K}$ can be constructed. As discussed in other chapters, these processes are studied and incorporated into a Monte Carlo model of muon scattering and the detector. The reconstructed Monte Carlo events are then subjected to the same exercise of counting muon scatters in a bin of reconstructed kinematics. Thus, we count N_{obs}^{MC} (where MC denotes Monte Carlo) analogous to equation 4.5. We also count the number of generated events in a bin for the Monte Carlo, thus:

$$N_{gen}^{MC} = \int_{\vec{\xi}_1^l}^{\vec{\xi}_2^l} d\vec{\xi}' \int d\vec{\xi} \mathcal{L}(\vec{\xi}) \sigma_{tot}(\vec{\xi}) \qquad (4.6)$$

The ratio $\epsilon = N_{obs}^{MC}/N_{gen}^{MC}$ is computed in each bin. The product

$$N_{obs}^{Data} \times \frac{N_{gen}^{MC}}{N_{obs}^{MC}} = \frac{N_{obs}^{Data}}{\epsilon} \qquad (4.7)$$

would be the estimate for N_{true}^{Data}, the true number of data events occurring in the bin. In order to extract the total cross-section σ_{tot} in the bin according to equation 4.3, we must also correct for the bin width and the luminosity. The bin width Δ, the integrated luminosity L and an overall correction factor for the data ω_σ are computed as follows:

$$\Delta = \int_{\vec{\xi}_1^l}^{\vec{\xi}_2^l} d\vec{\xi}'$$

$$L = \int d\vec{\xi} \mathcal{L}(\vec{\xi})$$

$$\omega_\sigma = \epsilon \times L \times \Delta \tag{4.8}$$

N_{obs}^{Data} can be corrected in each bin by weighting each data event by $1/\omega_\sigma$. This gives us the total muon cross-section $\sigma_{tot}(\vec{\xi})$ in the bin, thus:

$$\sigma_{tot} = \sum_{i=1}^{N} \frac{1}{\omega_\sigma} \tag{4.9}$$

To extract the structure function F_2, we must correct σ_{tot} for radiative effects, and then extract F_2 from the resulting $\sigma_{1\gamma}$ using equation 4.1. The radiative kernel $\mathcal{R}$ can be collapsed into a radiative correction factor K, by using equation 4.4 making the following definition:

$$\sigma_{tot}(\vec{\xi''}) = \int d\vec{\xi} \mathcal{R}(\vec{\xi''}, \vec{\xi}) \sigma_{1\gamma}(\vec{\xi}) \equiv K(\vec{\xi''}) \sigma_{1\gamma}(\vec{\xi''}) \tag{4.10}$$

The calculation of K is done by the computer program FERRAD35 [61]. Also, a kinematic factor λ is defined as:

$$\lambda = 4\pi\alpha_{em}^2 [1 - y - \frac{Mxy}{2E} + \frac{y^2(1 + 4M^2x^2/Q^2)}{2(1 + R(x, Q^2))}] \tag{4.11}$$

Defining

$$\omega_{F2} = \omega_\sigma \times K \times \lambda \tag{4.12}$$

where ω is defined in equation 4.8, F_2 is extracted by weighing each data event by $1/\omega_{F2}$ as follows:

$$F_2 = \sum_{i=1}^{N} \frac{1}{\omega_{F2}} \tag{4.13}$$

So far we have neglected the possibility that there are background events occurring in the data which should not be included in the measurement. Muon scatters originating from material outside the target constitute such background. Therefore,

$$N_{obs}^{Data} = N_{target} + N_{out-of-target} \tag{4.14}$$

Consequently, F_2 extracted by equation 4.13 actually contains two contributions:

$$F_2^{full-target} = \sum_{i=1}^{N_{target}} \frac{1}{\omega_{F2}} + \sum_{i=1}^{N_{out-of-target}} \frac{1}{\omega_{F2}} \tag{4.15}$$

We are interested only in the first component produced by the in-target scatters. The second component is measured by taking data on an identical target vessel which is empty. The structure function measured from the empty target is:

$$F_2^{empty-target} = \sum_{i=1}^{N_{out-of-target}} \frac{1}{\omega_{F2}} \tag{4.16}$$
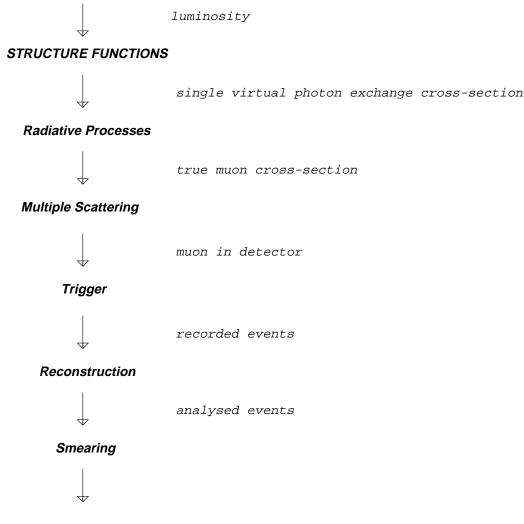

The number of beam muons to which the empty target is exposed is used to normalize the empty target measurement. Since all the running conditions are the same for the full-target and the empty target data, the contribution to $F_2^{full-target}$ coming from the out-of-target scatters is statistically equal to $F_2^{empty-target}$. This allows us to statistically subtract the background as follows:

$$F_2^{target} = F_2^{full-target} - F_2^{empty-target} \qquad (4.17)$$

The same method for subtracting the contribution of out-of-target scatters can also be used for the measurement of the total cross-section.

4.1   The E665 Monte Carlo

We note from the discussion in the previous section that the corrections applied to the data involve integrations over kernels and underlying distributions. In order to extract the corrections properly, we must have the right simulation of the three components of the integrand in equation 4.5. These are the beam phase space distributions $\mathcal{L}$, the cross-section and the final state distributions σ, and the detector simulation which contains the kernel $\mathcal{K}$. These three components are incorporated in a Monte Carlo model of the experiment.

Reconstructed random beam triggers are used to produce files containing the five parameters (the momentum, and the transverse Y and Z positions, and Y and Z slopes, at a fixed longitudinal X position) needed to specify beam tracks. Each file typically contains a list of parameters describing approximately ten thousand beam tracks. Separate files are created for different periods of the run in order to track any changes in the phase space occupied by the beam [62]. Therefore the beam phase space is reproduced in the Monte Carlo on an event-by-event basis as it is in the data.

The Monte Carlo event generation proceeds in two stages. In the first stage, which is called MC1, the beam, scattered muon and all the final state particles are generated and tracked through the detector. In the second stage called MC2, hits are digitized for all the charged particle tracks in the proportional and drift chambers and the scintillation hodoscopes. The output of the MC12 chain is provided in the same format as the decoded data from the detector. It is then subjected to the same tracking program as the real data, so that the reconstructed Monte Carlo can be directly compared to the data.

The event generation begins with the generation of a beam track whose parameters have been read in from a beam file. The beam is tracked from the beam spectrometer into the target by the GEANT 3.15 program [63]. The longitudinal position of the scattering vertex is picked within the target according to a flat distribution. The azimuthal angle of the scatter is also picked according to a flat distribution. The kinematics of the scatter are generated following the total cross-section. The inelastic structure functions are constructed from various parametrizations of data, and a model due to Donnachie and Landshoff [35]. Parametrizations of the proton elastic form factors due to Gari and Kruempelmann [64] are used. For deuterium, the nuclear form factor due to Locher and Svarc ([65] using 1990 fit solution 1 - including meson exchanges), and the quasi-elastic suppression factor due to Bernabeu [66] is used. The radiative kernel is calculated by the GAMRAD program [67] for the full Monte Carlo and by FERRAD [61] for the final correction to the data, both of which are based on the calculation of Mo and Tsai [68, 69]. This differentiation is made because GAMRAD has been interfaced to the E665 Monte

Carlo, but its integration accuracy is limited by the hard-coded binning. It is sufficiently accurate as a generator of the underlying distributions and the radiated photons. Hence we use the GAMRAD Monte Carlo only to calculate the detector acceptance corrections. FERRAD is maintained independently, so it can be made more flexible and accurate through finer integration steps. Therefore it is used to make the final radiative correction to the data.

The LUND programs LEPTO 5.2 and JETSET 6.3 [70] are used to generate all the particles in the hadronic final state. The GRV HO [71] set of parton distributions are used because they are specified down to Q^2 of 0.3 GeV^2. These parton distributions are only used to calculate the relative cross-sections for q, $q\bar{q}$ and qg events, and not for the total muon-nucleon cross-section. The GAMRAD program generates photons that are radiated by the muon.

The scattered muon, radiative photons and all the hadronic final state particles are tracked through the detector by the GEANT program. The detector simulation specifies all the materials present and their locations. This information is used by GEANT to calculate the multiple scattering, energy loss and re-interactions of all the primary particles as well as any generated secondaries and decay products. The following physics processes are simulated by GEANT in the E665 Monte Carlo:

- Multiple scattering using the Gaussian approximation.

- Particle decay.

- Energy loss as particles traverse material.

- Compton scattering.

- Pair production.

- Bremsstrahlung.

- Delta-ray production.

- e^+e^- Annihilation.

- Hadronic interactions (simulated using the GHEISHA program [70]).

GEANT tracks each particle (photons, electrons, muons, and charged and neutral hadrons) until the energy of the particle falls below 500 MeV.

The second stage Monte Carlo MC2 [72] simulates hits made by charged particles in the hodoscopes and the proportional and drift chambers. The measured resolutions

of the chambers are used to smear the hits. The drift chamber simulation includes the inefficiencies induced by the presence of multiple hits. The position and time dependence of the chamber efficiencies are measured from the data and incorporated into the MC2 program. Studies of the chamber and reconstruction efficiency are described in a following chapter, in which Table I gives the run blocks in which the chamber efficiencies were studied. Separate Monte Carlo event samples were generated in each of these run blocks. The number of events generated were distributed in these run blocks so as to match the distribution in the data. Thus any variation in the chamber efficiencies and beam parameters were appropriately represented in the Monte Carlo sample.

Two types of Monte Carlo samples are generated for this analysis. In the first sample, events are generated normally using the total cross-section. In the second sample, the F_2 structure function used is actually $Q^2.F_2$. This biases the cross-section to higher values of Q^2. The combination of these samples gives us the statistics to evaluate the detector acceptance at low and intermediate Q^2 where there are certain large acceptance losses. The events in the second sample are re-weighted by Q^{-2} to regenerate the correct underlying distribution.

4.2   The Input Structure Functions

For the Monte Carlo generation and the initial calculation of the radiative corrections, we use a structure function parametrization obtained from existing data. The details of the construction of this parametrization can be found in appendix A. We use published parametrizations of SLAC and DESY electroproduction data and Daresbury photoproduction data, as well as NMC and BCDMS muoproduction data [73, 74, 75, 11]. In the kinematic domain of high W and low Q^2, the structure functions have not been measured. In this regime we use the model of Donnachie and Landshoff [35], which the authors have constrained to match the photoproduction data and the NMC data.

The photoproduction, electroproduction and muoproduction data sets used to obtain F_2 are, in principle, diverse data sets. They are simply related only in the single photon exchange approximation, in which case the cross-section factorizes and all of these data are sensitive to the same nucleon structure functions. In order to extract F_2, a consistent treatment of the radiative corrections and the use of R (the ratio of longitudinal to transverse photon -nucleon cross-sections) is required.

Photoproduction is, by definition, the single photon - nucleon cross-section. Hence there are no radiative corrections. Also, real longitudinal photons do not couple to matter, hence R is zero for real photoproduction (equation 2.43). Hence the photoproduction

cross-section can be simply related to F_2 (equation 2.48).

The BCDMS and NMC analyses of F_2 was performed using the radiative corrections formulated by Akhundov, Bardin and Shumeiko [10, 11]. The SLAC analyses were performed using the radiative corrections formulated by Mo and Tsai [68]. The analysis presented in this thesis uses the Mo and Tsai formulation, including τ and quark loops in the vacuum polarization diagrams, and the electroweak $\gamma - Z$ interference effects. The results obtained using these schemes have been compared [76, 77] and they differ by at most 2%. This magnitude of systematic variation in the radiative correction is similar in size to other sources of systematic uncertainty in the various F_2 measurements. Hence the radiative correction procedures may be considered to be consistent with each other.

The single photon exchange cross-section is weakly dependent on R. BCDMS used the theoretical form of R motivated by QCD, which is probably valid in the Q^2 range of the BCDMS measurement ($Q^2 > 10 GeV^2$). The E665 and the NMC analysis both use the parametrization of R obtained from a global analysis of SLAC data [78]. This parametrization includes QCD-motivated terms as well as terms motivated by higher twist effects, since the SLAC, E665 and NMC data extend to low values of Q^2 ($Q^2 > 0.3 GeV^2$). Prior SLAC measurements of F_2 have often used fixed values of R, such as $R = 0.18$. This value is consistent with the value of the SLAC parametrization (henceforth referred to as R_{SLAC}) at the typical value of Q^2 for the SLAC data.

Thus, there has been a fairly self-consistent treatment of leptoproduction and photoproduction cross-sections to extract F_2. These F_2 parametrizations can therefore be used as input for the calculation of corrections in this analysis.

Chapter 5

Muon Reconstruction Efficiency

5.1   Detector and Algorithm

One of the important corrections that one needs to make in the extraction of structure functions is the loss of muons due to reconstruction inefficiency. Briefly, to discover whether a muon-nucleon scatter occurred, we have to reconstruct the trajectories of the beam muon and the scattered muon so that the event kinematics may be calculated. Some of the scattered muon events cannot be used in the measurement because the muon tracks have not been identified. We have to understand this loss and correct for it.

The first step in the process of measuring the event kinematics is the reconstruction of the beam track. The beam spectrometer consists of four stations of multi-wire proportional chambers, the PBTs. These are used to reconstruct two straight line segments in space between the first two stations and the last two stations respectively. Between these two straight sections is a dipole magnet. By matching the two straight segments and measuring the bend angle, the beam track is completely reconstructed.

The momentum analysis of the scattered muon is done using detectors in the forward spectrometer, which consists of two dipole magnets and proportional and drift chambers. This is shown in figure 3.5. The Cern Vertex Magnet (CVM) is placed immediately downstream of the target. Further downstream is the Chicago Cyclotron Magnet (CCM), which is the main momentum analysing magnet for high momentum tracks. Between the CVM and the CCM magnets are placed two sets of multi-wire proportional chambers (MWPC), the PCV and PCN. Inside the CCM magnet are placed five stations of the PCF MWPCs, each station consisting of three chambers. Downstream of the CCM are

two stations of drift chambers, DCA and DCB. The central regions of the drift chambers are deadened by construction so that they may not be affected by the beam flux. This region is partially covered by a set of small MWPCs, the PSA, placed close to the downstream drift chamber station DCB.

A set of vertex drift chambers (VDCs) are placed inside the CVM. They form a spectrometer for low momentum particles. The VDC contribution to the forward spectrometer tracks also increases their momentum and angular resolution.

The identification of a track as a muon relies on finding track segments behind a 3m hadron absorber made of iron. The muon detector consists of four stations of proportional tube planes (PTMs) and scintillation counters (SMSs). The SMSs are used in the central region of high flux, and the PTMs outside. These four stations are separated by concrete blocks which suppress the propagation of shower particles accompanying the muon.

The event reconstruction begins with the identification of hit lists that are produced by the beam tracks, forward spectrometer tracks and the muon segments. This step is called Pattern-Recognition. The beam and forward spectrometer hit lists are called LLIN banks, and the muon detector segments are called LPRO banks.

Each hit list in the beam and forward spectrometers is then fitted with a quintic spline model of the track trajectory. Knowledge of the magnetic fields is then used to find all the track parameters of the tracks found. This step is called Track-Fitting.

The next step, Muon-Match, attempts to use the segments behind the absorber to tag one or more forward spectrometer tracks as muons.

The final step is the Vertex-Finding program. It identifies one of the forward spectrometer muons as the scattered muon, and attempts to find the intersection point of the beam and the scattered muon tracks. This vertex is used as the primary interaction vertex. Other tracks are then attached to the primary vertex if they are consistent with the hypothesis that they originate from the primary vertex. The vertex position is refitted iteratively with all such tracks contributing to the fit[1]. Finally, the beam and scattered muon track parameters at the vertex are used to calculate the event kinematics.

Using the first letter of each of these programs, the global reconstruction program is called PTMV.

---

[1]however the fitted vertex position is not used to constrain the tracks. This avoids correlated biases in the final parameters reported for different tracks.

Understanding the performance of the Pattern-Recognition program is very important in the determination of the overall reconstruction efficiency. If the pattern of chamber and hodoscope hits produced by a track cannot be seen, then one can go no further in the process of track reconstruction. The Pattern-Recognition algorithm tries to find tracks in a number of different ways. Each method uses a set of software codes called processors. In the first method, it looks for straight line segments in the PC chambers upstream of the CCM, and the DC chambers downstream of the CCM. The upstream and downstream segments are associated with each other using PCF hits inside the CCM magnet to constrain the match.

In the second method, tracks are recognized using the PC and PCF chambers only. These tracks are then projected downstream into the DC or the small aperture PSA chamber to pick up hits. In fact this is the only method that is used to pick up the PSA contribution to the track. The PC-PCF tracks needed for this can be found in two ways: PC segments can be projected forward into the PCFs, and PCF segments can be projected backwards into the PCs. Both ways are attempted and the ambiguities are resolved at a later stage in the pattern recognition algorithm.

Even if no downstream contribution is obtained from the DC or PSA, the PC-PCF track is declared valid since the curvature can be measured with the PCFs alone. The momentum resolution on such tracks is rather poor. In this analysis, downstream contribution is required in order to ensure good resolution: the loss in efficiency due to this requirement is studied using the PC-PCF tracks.

Later, the tracks are projected back from the PC into the PCV to pick up PCV hits. This increases the length of the upstream lever arm of the track and improves the resolution significantly.

Finally, the forward spectrometer tracks are linked to the vertex spectrometer tracks found by the VDCs. First, the forward spectrometer tracks are projected back into the VDCs to pick up hits directly. Then, the VDC algorithm reconstructs tracks independently using the remaining hits. These tracks are extrapolated into the forward spectrometer again to attach any remaining hits.

5.2   Pattern Recognition Efficiency

Efficiency loss at the stage of pattern recognition can result from two effects:

- chamber inefficiencies.

- inefficiencies of the pattern recognition algorithm.

The general approach is to simulate chamber efficiencies in a Monte Carlo program, the output of which is in the same format as real data. The Monte Carlo output can be reconstructed by the PTMV program in the same way as data. Then, after verification of the simulation in many different ways, the Monte Carlo can be used to calculate the pattern recognition efficiency as a function of true muon kinematics.

5.2.1 Uncorrelated Chamber Efficiencies

We will first discuss the measurement of individual chamber efficiencies, and then address the issue of correlated chamber inefficiencies. We can enumerate the following issues concerning the simulation of efficiencies of individual chambers:

- geometrical aperture.

- regions deadened by construction, due to spacers, support wires, high-flux regions etc.

- dead regions due to bad electronics etc.

- dead regions due to radiation damage.

- time dependence of overall efficiency due to high voltage or gas composition variations.

A fairly elaborate chamber simulation program has been developed that allows all of these effects to be modelled. In order to test the chamber models, many detailed comparisons between data and Monte Carlo are made. The entire data run is split into nine run periods, and each run period is sampled uniformly to produce a data set that can be used to study the chambers. These comparisons in each run period are used to check that the overall efficiency level, and various position dependences are correctly reproduced by the Monte Carlo.

The first step in this process is to define a set of events and tracks that can be used to measure the uncorrelated chamber efficiencies. Ideally one would like to have a track that is measured perfectly and independently of the chamber under consideration. This makes the track a very good reference to see if the given chamber contributes a hit that can lie on the track. For the measurement of the uncorrelated efficiencies, the event sample is defined as follows:

- -13.5m$< X_{vertex} <$-11.5m , ie. the reconstructed primary vertex is in the target region.

- There is only one beam track.

- In addition to the beam and the scattered muon, there must be at least one forward spectrometer track fitted to the primary vertex. This enriches the sample in the number of usable tracks.

Tracks used for the measurement are required to satisfy the following conditions:

- Tracks found by the VDCs alone (labelled track type 6) are not used, because these tracks may be prone to reconstruction errors.

- The track should have a properly measured curvature.

- The track must be fitted to the primary vertex.

- The PCV chamber group is required to contribute to the track. Since this group has 6 planes, there is sufficient redundancy to measure the efficiency of an individual plane.

- The track must extend past the CCM magnet and receive a contribution from the DC or PSA chambers.

- For a given detector plane, a minimum number of hits from the corresponding detector group is required to contribute to the track. This increases the probability that the track would have been found even if the given detector plane did not contribute to the track. An alternate method would be to drop the plane whose efficiency is being measured from the track-finding process. This alternative requires a lot of computing resources because all the tracks have to be reconstructed as many times as there are planes. However, since the overall track-finding efficiency in the proportional chambers tends to be in the high 80's or low 90's (in %), the per-plane method chosen here cannot be heavily biased. This is confirmed by a Monte Carlo study described below (tables 5.3 and 5.4), and the small residual bias is corrected.

For the muon detectors (PTMs and SMSs), we use the reconstructed scattered muon. The following conditions are imposed:

- The scattered muon momentum is at least 80 GeV, to suppress contamination from hadrons wrongly reconstructed or matched as muons.

- The track should extend at least as far downstream as PCF5.

- The PCV should contribute to the track.

These conditions should be fulfilled by a particle produced in the primary beam interaction if the track is properly reconstructed. Following these conditions, we expect to have a set of tracks that have a very high probability of being correctly reconstructed. In figure 5.1 the distributions of various track parameters are compared between data and Monte Carlo. In figures 5.2 and 5.3 the distributions of the track position at various chambers are compared between data and Monte Carlo. We see that the underlying distributions are reproduced adequately by the Monte Carlo. We can now proceed to make more detailed validations of the detector simulation.

5.2.2   Global Per-Plane Efficiencies

The following procedure is used to measure the overall efficiency of individual chambers. Each track is extrapolated/interpolated to each detector plane in turn, to obtain its position at that plane. Swimming routines are used that take the magnetic field maps into account. The plane is considered to be efficient if it contributes to the track according to the pattern recognition algorithm (ie. found in the LLIN bank). For the muon detectors, this means that the plane contributes to the muon projection (LPRO bank) that is matched to the scattered muon.

The plane efficiencies can now be studied as a function of position on the plane, for the different run blocks. These plots reveal the global efficiencies of the chamber planes, and also any position dependent effects. The first goal is to reproduce the global efficiencies in the Monte Carlo simulation of the chambers. The global efficiency is defined to be the maximum efficiency achieved by the chamber anywhere within its aperture. This allows the addition of code in the Monte Carlo to simulate local reductions in efficiency. Tables 5.1 and 5.2 summarize the global efficiencies measured for the chambers, for different run blocks. The statistical uncertainty in these measurements is 1-2% for most of the chambers, with the exception of certain PSA chambers. The PSA chambers with efficiencies below 40% for some run blocks, have a 3-4% uncertainty on these particular measurements.

These efficiencies can be considered the product of two factors: the probability of the chamber recording a hit, and the probability that the hit is incorporated into the track hit list by the pattern recognition program. The product is the most relevant quantity that must agree between the data and the reconstructed Monte Carlo. However, the Monte Carlo program takes as input the former, i.e. the hardware efficiency of the chamber. Therefore a pure Monte Carlo study is performed to compare the chamber efficiency that is put into the simulation and the efficiency measured from the Monte Carlo sample in the same way as the data above. This study can then be used to correct the numbers obtained from the data in a self-consistent fashion. One would then expect the measurements made from the data and the reconstructed Monte Carlo to agree.

The results of the pure Monte Carlo study are given in tables 5.3 and 5.4. We see that for the PCV, PC and PCF chambers, the difference between the input hardware efficiency and the measured efficiency is typically less than 2% and never exceeds 5%. For the small PSA chamber, the study was also performed with a monte carlo sample of straight-through (non-interacting) beams, giving the same results within a few percent. This shows that the results are insensitive to the differences between the environments of a DIS event and and a straight-through beam event.

The drift chambers suffer a loss of about 10-20% between the input hardware efficiency and the observed efficiency. In order to match the measurements, the hardware efficiencies input to the Monte Carlo for the drift chambers need to be close to 100%. The implication of the data-Monte Carlo comparison is that, while the true efficiency of the drift chambers to record a hit is close to 100%, The pattern-recognition program is not always successful in associating every hit produced by a particle with its drift chamber track. About 10-20% of the real hits are eventually left unused. This loss may be due to the effects of event-related multiplicity, smearing and the criteria used by the pattern-recognition algorithm. It would be reassuring to obtain independent confirmation that the true hardware efficiency of the drift chambers is indeed close to 100%.

A separate study was performed to measure the true efficiency of the drift chambers from the data, measured independently of the pattern recognition algorithm [79]. Special halo muon data were used for this study. The halo muon tracks were reconstructed in the PCN and PCF chambers without using the DC drift chambers at all. During data taking, both the CVM and CCM magnets were off. Hence the PCN-PCF tracks could be projected as straight lines into the drift chambers with the accuracy of about a millimeter. Generous roads were defined to look for DC hits since there was very little noise background. This method approaches the measurement of the true hardware efficiency, and gave results close to 100%. Thus we have some confidence that the apparent global efficiency loss in the drift chambers is properly reproduced in the Monte Carlo sample.

The muon proportional tubes (PTMs) are constructed such that each station in a given view consists of two planes staggered by half a wire spacing. Offline, the two planes are ORed and considered a single plane. In the Monte Carlo, each subplane is simulated separately, while the measurement is made on the combination of the two subplanes. This is the reason for the apparent contradiction that the measured efficiencies are higher than the input efficiencies. Given that the hardware efficiencies of the sub-planes is reasonably high, the apparent efficiency of any station is close to 100% and insensitive to the assumed hardware efficiencies of the two sub-planes.

5.2.3   Position-dependent Efficiency Losses

A number of effects that cause position-dependent losses of efficiency in the chambers have been identified and simulated in the Monte Carlo. These are discussed below in turn.

Geometrical aperture, support structures, spacers and deadening by construction

The bulk of these effects were known from construction and incorporated into the Monte Carlo. The simulation was checked against the data, and corrections were made wherever necessary. The simulation of the PSA aperture was corrected and code to simulate the spacers in the PCV was added. Measurements also revealed that the SMS hodoscopes did not completely cover the central dead region in the PTMs. For some stations, there are gaps approximately one centimeter wide around the perimeter of the SMSs, which are not covered by either the SMS or the PTM. These gaps could result in some loss of acceptance for the muon behind the absorber. Therefore it is important that the positions and sizes of the SMS hodoscopes and the PTM dead regions are properly tuned in the Monte Carlo. This will ensure that any acceptance loss is properly calculated.

Radiation damage

Many chambers show reduced efficiencies in the central regions that are exposed to high beam flux. These effects are especially pronounced in the PCF chambers and around the central hole in the drift chambers. The affected regions are consistent in shape and size with the beam profile at the MWPCs and the halo profile at the drift chambers. The inefficiency increases with time, as might be expected from radiation damage to the chambers. One of the PCF chambers (PCF2V) was taken apart after the run, and revealed some darkening of the wires in the beam region with no darkening elsewhere. This supports the efficiency measurements and the hypothesis of radiation

damage. The ionization of the gas molecules in the chamber causes them to polymer-ize slowly, and the layer of solid polymer builds up on the wires in the regions exposed to a lot of flux. This insulating coating causes the inefficiency and also shows up as a dark substance on the otherwise shiny wires [80].

In order to measure these losses in the PCV, PCN, PCF and PSA chambers, the efficiency studies were repeated in each of the nine run blocks with a sample of non-interacting straight-through beams (obtained using random beam triggers). Thus only the relevant region of the chambers is illuminated and the measurement is simplified. The size and depth of the 'holes' were measured as a function of time. These were coded into the Monte Carlo simulation for the PCV, PCN and PCF chambers.

A special study was made to map out the drift chamber dead regions using muon halo data as mentioned above [79]. The shape and size of the radiation-damaged regions turned out to be too irregular to be parameterized as functions. Instead, sufficient statistics were accumulated to create two-dimensional efficiency maps (as a function of position) for each drift chamber, measured using halo muon tracks reconstructed in the PC-PCF chambers. The maximum efficiency in the map was normalized to unity so that the global efficiency could be tuned independently. The entire chamber was represented in the map and variable binning was used to optimize the statistical precision and the resolution. Thus the maps incorporated not only the position-dependent losses due to the radiation damage in the center, but also intra-cell efficiency variation, inefficiencies due to broken wires or electronics, and septa in the vertical view chambers. Run91 is split into five periods, with one set of maps for each period, so that the changes with time are taken into account. Run90 is treated with one set of maps due to lack of sufficient halo data to make multiple maps.

5.2.4   Correlated Chamber Inefficiencies

At this point one expects a fairly good simulation of the uncorrelated chamber efficiencies in the Monte Carlo. The next step is to test the data for per-event correlations in chamber efficiencies. Such correlations could arise due to:

- dead time in the readout electronics at high rates.

- readout or other decoder errors.

- effects of the tracking algorithm.

It is difficult to measure correlated inefficiencies directly because most measured quantities are influenced by the uncorrelated losses as well. Hence we use an indirect method to look of correlated losses. Since the Monte Carlo does not contain any simulation for correlated losses, it makes predictions based on the appropriate coincidences of uncorrelated losses. We can use the Monte Carlo to make predictions for quantities that are also sensitive to correlations. These predictions can be compared to measurements from the data. If the losses in the data are larger than the Monte Carlo predictions, we may suspect some correlated effects.

One quantity sensitive to correlated effects is the number of hits from a given detector group that contribute to a track. This tests for correlations within a detector group. Figures 5.4 and 5.5 shows the comparison between data and Monte Carlo of the number of hits from each chamber group. The number of hits is also plotted versus Y and Z, where the error bar indicates the spread in the number. We find that there is good agreement for all detector except the drift chambers, where the Monte Carlo shows fewer drift chamber hits than the data. Another quantity sensitive to correlations is the probability that a detector group as a whole contributes to a track. The detector groups mentioned earlier are PCV, PCN, PCF1-5, DCA, DCB and PSA. The PCN chambers are required for forward spectrometer tracks, however none of the others are absolutely essential for the track to exist. Detailed plots are provided in [81, 82]. With the aid of these plots we conclude that there is sufficient redundancy in the upstream chambers (PCV and VDC) that the probability of having a long upstream lever arm is 100%. Individual PCF stations contribute to the track with efficiency above 98%, where the efficiency is defined as the contribution of two out of three hits at a station. This is the efficiency outside the beam regions and the location of the support wires, which also happen to be in the central region.

The section of the spectrometer downstream of the CCM magnet, consisting of the upstream and downstream (DCA and DCB respectively) drift chamber stations and the PSA chamber, suffers from lack of acceptance in the overlap region of the PSA-DC. This is because the drift chambers have developed enlarged central dead regions, probably due to radiation damage, that are not covered by the PSA. The dead regions and the PSA aperture are reproduced quite well by the Monte Carlo. Outside of the dead regions, the overall efficiency of the DCA-DCB-PSA combination is about 90%. The DCB contribution has some discrepancy between data and Monte Carlo, being about 67% for the data and 77% for the Monte Carlo. The DCA efficiency of 85% is reproduced by the Monte Carlo, hence the discrepancy in the overall efficiency of the DCA-DCB combination is suppressed. More precise estimates of the downstream chamber efficiencies, and the associated uncertainties, can be obtained by using the scattered muon tracks found in the PC-PCF chambers as reference. These studies are discussed below.
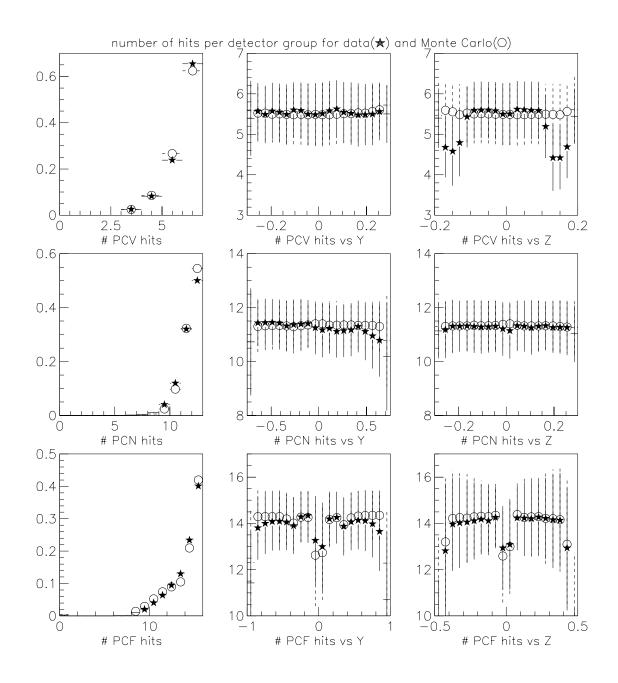

Figure 5.4: Number of detector hits on a track, for data and Monte Carlo. The sample consists of scattered muons and hadrons in inelastic scatters. In the profile histograms on the right, the 'error bar' indicates the spread (not error on the mean).
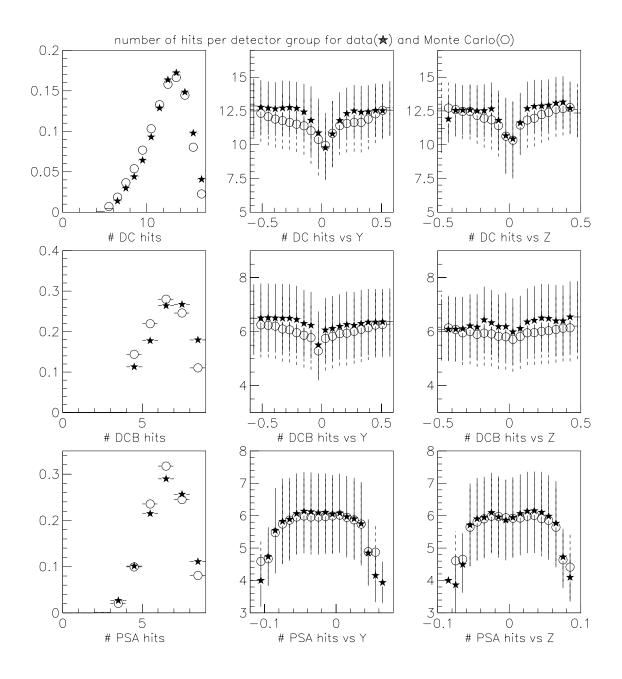

Figure 5.5: Number of detector hits on a track, for data and Monte Carlo. The sample consists of scattered muons and hadrons in inelastic scatters. In the profile histograms on the right, the 'error bar' indicates the spread (not error on the mean).

5.3 Muon Identification Efficiency

For testing correlated effects in the muon detectors, one needs an independently identified source of muons. To study the PTMs, we use the same halo data that was used for the drift chamber study. Halo muons were triggered by the large SUM hodoscope in front of the absorber and the SPM hodoscopes behind the absorber. Events with a single forward spectrometer track reaching the DCA chamber were selected, and the downstream requirement of the halo trigger was imposed in software. Tracks pointing to SUM hodoscope hits were flagged as in-time muons. The probability that these muons are matched to PTM segments is measured to be about 96.5±1%, uniformly over the entire aperture of the PTMs. This is shown in figure 5.6. This measurement was repeated for five different running periods scanning run91, and the same result was obtained. The same probability is also obtained for matching straight-through beams to segments in the SMS hodoscopes.
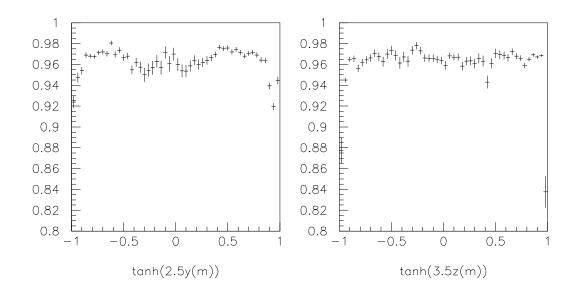

Figure 5.6: Overall efficiency of identifying single halo tracks as muons, versus horizontal and vertical coordinate.

The inefficiency of 3±1% in muon tagging could be due either to (i) inefficiency in reconstructing segments in the muon detectors, or (ii) inefficiency in the criteria for matching valid forward spectrometer muon tracks to muon segments behind the hadron absorber. These probabilities can be disentangled by obtaining a sample of true muons, requiring a reconstructed forward spectrometer track and the associated segments be-

hind the absorber, and studying the match criteria. Such a study was performed using straight-through beams and muons in the electron calorimeter calibration data. The straight-through beams provide a pure muon source illuminating the SMS hodoscopes. The electron beam data that was taken for the purpose of calibration of the calorimeter, contains some muon contamination. Muons can be identified by requiring segments in the muon detectors and using the calorimeter to veto electrons and some of the pions. A fairly clean muon sample can be isolated. These muons have low momentum compared to the beam and illuminate the PTMs, and can be used to study the momentum dependence of the match criteria. The track parameters on either side of the absorber and their expected errors are used to compute χ^2. The χ^2 probabilities (running integral of the χ^2 distribution) for the intercept and slope matches, in each view are shown in figures 5.7 and 5.8. These distributions show that about 99% of the events have χ^2 values less than about 5 in any degree of freedom. This is approximately the same as expected from variables that are normally distributed. However, we note tails in χ^2 extending to values as large as 30. These could be due to large angle single scatters of muons in the absorber, processes which are not included in the calculation of the expected error due to multiple scattering and detector resolution.

Cuts on the χ^2 were optimized to maximize the matching efficiency while keeping fake matches to a minimum. For run91, the matching criterion was set that the χ^2 of the match be less than 15 in each of the four parameters: δY, δZ, δY_{slope} and δZ_{slope}.

Figures 5.7 and 5.8 show that about 0.5% of the events will fail the match in any one parameter for a χ^2 cut of 15. This is seem to hold for both the high and low momentum muon samples. Assuming that the four parameters are independent, these studies show that a matching inefficiency of 2% (efficiency of 98%) could be expected independent of momentum. Since the same efficiency is obtained regardless of whether the segments in the muon detectors are required, we can conclude that the probability of finding segments in the PTM and SMS muon detectors must be almost 100%. This is not too surprising since individual stations have efficiencies close to 100%, and 3 out of 4 stations are required to make a segment. The measurements confirm that there are no significant correlated inefficiencies in the muon detectors.

5.4   Checking Global Efficiencies

Since we are mainly interested in the muon reconstruction efficiency, we perform some additional checks for the muon between data and Monte Carlo.
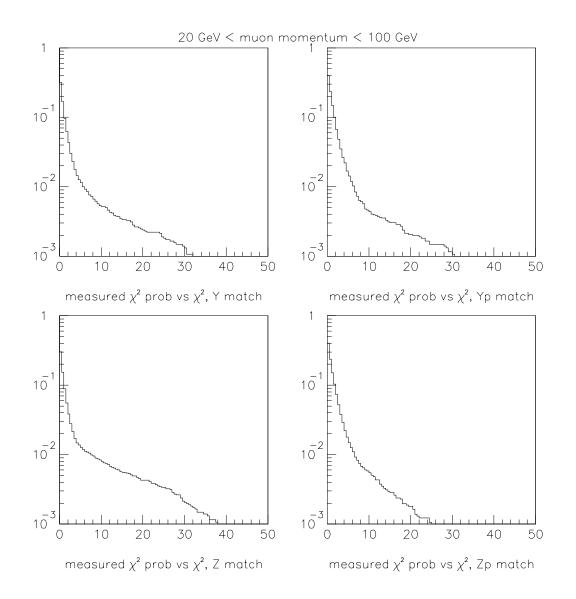

Figure 5.7: χ^2 probability vs χ^2 of match between single forward spectrometer tracks and single muon projections. The position and slope parameters in each view are shown separately. This is a low momentum muon sample.
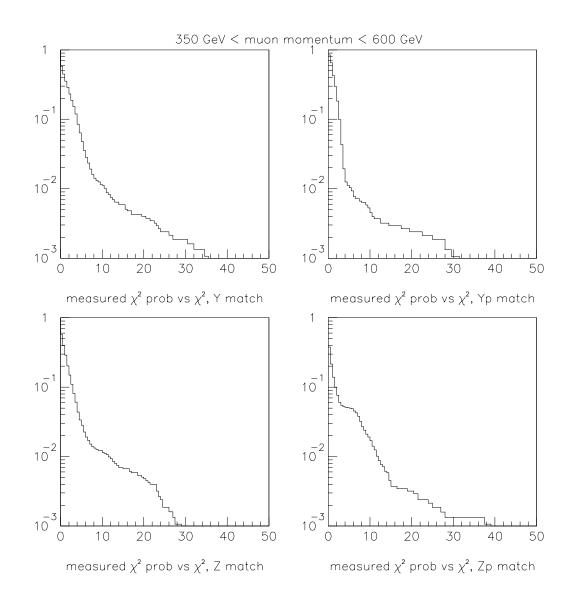

Figure 5.8: χ^2 probability vs χ^2 of match between single forward spectrometer tracks and single muon projections. The position and slope parameters in each view are shown separately. This is a high momentum muon sample.

5.4.1   Checks Using Straight-Through Beams

A very powerful check is provided by the straight-through beams. These can be independently reconstructed by the beam spectrometer, and the efficiency of finding the track in the forward spectrometer can be measured. A Monte Carlo sample of straight-through beams can be generated quite simply by turning off the generator of scatters. This comparison can be used to check that the simulation of the forward spectrometer chambers (except the drift chambers which are not illuminated by the beam) reproduces the global reconstruction efficiency.

The first step is to ensure that the uncorrelated chamber efficiencies in the beam region are properly simulated in the Monte Carlo. The same procedure discussed earlier for the entire aperture of the chambers is used for the central regions as well. The random beam triggers are used to provide a sample of straight-through beams. The same distribution is generated in the Monte Carlo by feeding it the parameters of reconstructed beam tracks obtained from the random beam triggers.

The Monte Carlo is tuned to incorporate the various non-uniformities affecting the chambers in the central regions, as a function of time. References [83, 84] show per-plane efficiencies measured from the data compared to the Monte Carlo model. The model describes the data very well. Figure 5.9 shows the probability distribution of the number of hits from the various detectors contributing to the forward spectrometer track. Again the Monte Carlo gives good agreement with the data. Comparing these distributions to those obtained from tracks going through the outer regions of the chambers (figures 5.4 and 5.5), we find that the PCV, PC and PSA chambers are not seriously affected by the beam. The PC chambers typically show a few percent reduction in efficiency in the beam region compared to the outside. However the PCF chambers are dramatically affected. There are two causes for this. Firstly, The support wires for the stereo U and V views pass through the region illuminated by the beam, producing dead strips about a half centimeter wide. Secondly, many chambers show radiation-damaged regions following the profile of the beam. The regions grow with time and the minimum efficiency in these regions also reduces with time, approaching zero near the end of the run. All of these dependencies are measured from the data and incorporated into the Monte Carlo.

At this point we are in position to test the Monte Carlo prediction of the forward spectrometer tracking efficiency for straight-through beams. For the data, we use the random SAT beam triggers (RSAT) because the same triggers were used to files of beam parameters for the Monte Carlo generation. Events with single beam tracks are used. In addition, the events are required to satisfy the RSAT criteria imposed using the latched beam hodoscope hits. This ensures that only one beam is present in the RF bucket. We measure the probability that a muon is identified in the forward spectrometer. Figure
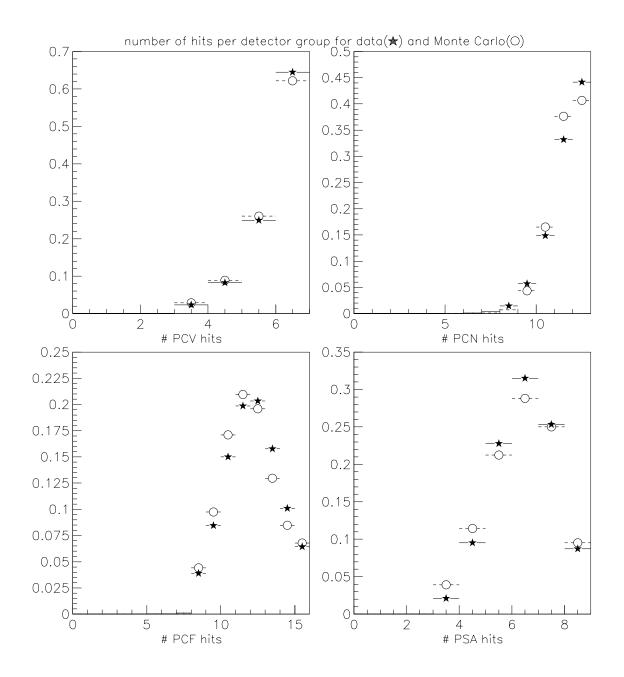

Figure 5.9: number of detector hits on a track, for data and Monte Carlo. The sample consists of straight-through beams.

5.10 shows the run dependence of the forward spectrometer muon identification efficiency using this sample. We find that the efficiency in the data hovers between 90% and 95% for most of the run. After run number 22450, it drops. This is consistent with the drop in the measured efficiencies in some of the PCF chambers, particularly in the beam region. The measured PSA efficiencies also drop in this part of the run, so the probability that the PSA will contribute to the track also reduces. Since this contribution is important to ensure high resolution, we decide to eliminate the data collected after run 22450 from the structure function measurement. There is also a temporary reduction in efficiency at run 22100, so the data between runs 22080 and 22120 is also disregarded.
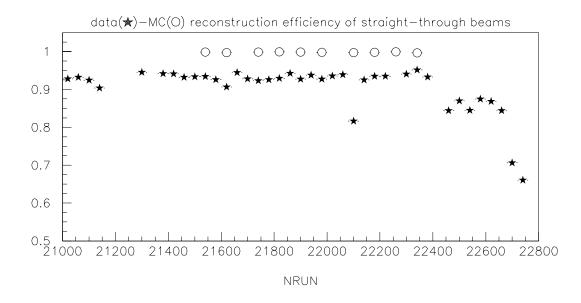

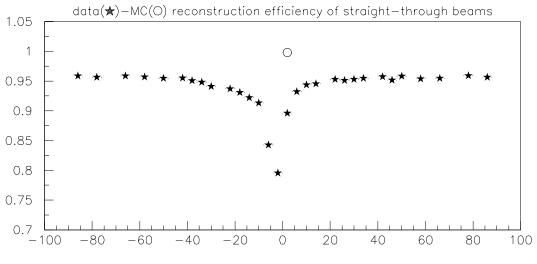

Figure 5.10: Run dependence of muon finding efficiency for data and Monte Carlo.

However, we notice that the Monte Carlo prediction for the efficiency is almost 100%. If we inspect figure 5.9, we learn that the PC and PCF chambers are somewhat less efficient in the Monte Carlo than in the data. Therefore the discrepancy in the overall muon efficiency is not due to the uncorrelated chamber efficiencies. We also do not suspect an inefficiency in the muon match stage of more than a few percent, and we know that the muon projection finding efficiency in the SMS hodoscopes is almost 100%. Hence we must look for some effect causing correlated losses.

The likely candidate is the intensity-related effects that affect the chambers, which are not simulated in the Monte Carlo. In order to test the sensitivity of the data to these effects, we use the device called the spill local rate monitor. This device is described in

[85]. In simple terms it is a long shift register that stores the bucket-by-bucket record of the beam hodoscope signals in the vicinity of the trigger time. Hence, we can look off-line at timing of the other muons coming through the beam spectrometer before or after the triggered muon.

Figure 5.11 shows the dependence of the muon finding efficiency on the time to the nearest beam muon. Negative numbers indicate buckets preceeding the trigger muon and positive numbers indicate buckets following the trigger muon. We notice a sharp drop in efficiency when there is a beam muon in the preceeding 10 buckets or in the following 5 buckets. Since each RF bucket is approximately $19ns$, this corresponds to $200ns$ and $100ns$ respectively. This could correspond to the amplifier dead times which could cause in efficiency in detecting the signal from the wire. A loss induced by a muon following the trigger muon is consistent with the hypothesis that such a muon could pass closer to the wire and induce a signal first. Since the PC and PCF chambers have $3mm$ and $2mm$ wire spacing respectively, and the charge drift time close to the wires is about $50ns/mm$, the time scale for this source of inefficiency loss is about right. Using this measurement from the spill local rate monitor, we eliminate from the structure function analysis all events in which there is a beam muon in the preceeding 10 buckets or the succeeding 5 buckets.

Figure 5.11: Forward spectrometer muon finding efficiency for data. The efficiency is shown as a function of the nearest occupied bucket in time. There are no 'out-of-time' beams in the Monte Carlo.

As additional confirmation of efficiency loss due to instantaneous rate, we look at events with two beams coming through the detector in the same bucket. We expect a large inefficiency in reconstructing both muons. This is confirmed by figure 5.12.
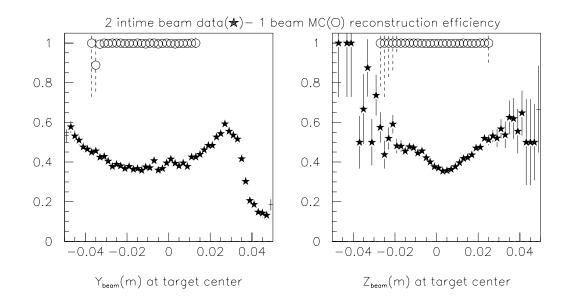

Figure 5.12: Forward spectrometer muon finding efficiency for two-beam data events, and one-beam Monte Carlo events. The efficiency is shown as a function of the position of one of the beams at the target.

The components of the forward spectrometer responsible for finding the small angle tracks are the PC and PCF chambers. In order to understand the correlated losses, we need to measure the overall efficiency of the PC and PCF chambers separately. We do this by measuring how often we get a segment independently in the PC and the PCF chambers for straight-through beams. As described in the beginning of this chapter, the PC processor constructs track segments in the PC chambers and the SF processor finds track segments in the PCF chambers. For this study, we use a sample of straight-through beam triggers, requiring one beam track in the beam spectrometer. Additional requirements are made using the SBT beam hodoscope hits and the SMS muon hodoscope hits to ensure that there is only beam muon in the event. We separately measure the fraction of events in which at least one PC segment or at least one PCF segment is found. These efficiencies are shown in figure 5.13 for the data for a few runs. We note that the PC segment efficiency is above 97% and fairly stable. The PCF segment efficiency fluctuates between 70% and 90%. The interesting point is at run 21840, where both the PC and PCF segment efficiencies are almost 100%. These data were

collected at low intensity, and provide more support for the hypothesis that the chambers and especially the PCFs are prone to intensity-induced losses. The overall forward spectrometer muon finding efficiency in the low intensity beam data is 97.7±0.2%. The residual inefficiency is consistent with the muon-match inefficiency that is expected from hard scatters in the absorber.
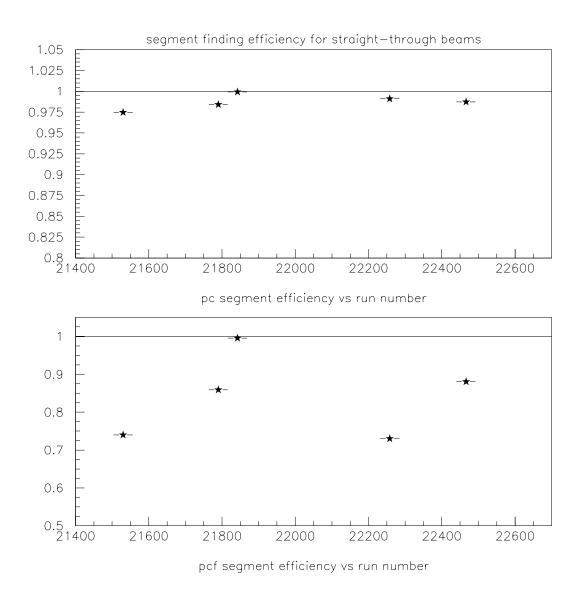

Figure 5.13: PC and PCF segment finding efficiency in straight-through beam data for various run blocks. The data at run 21840 were collected at low intensity.

To summarize the results of the checks using the straight-through beams, we conclude that the entire efficiency loss in reconstructing these tracks in the forward spectrometer is due to correlated effects. The inefficiency is about 9%, and can be decomposed into three components. The first component of this inefficiency, which is about 5%, is caused by out-of-time muons arriving within 100-200ns of the in-time muon which we are interested in reconstructing. This inefficiency is probably caused by the induced dead time in the chamber electronics, and is eliminated by removing such beams using the spill monitor information. The second component of the inefficiency, which in size is about 2%, is due to a longer-lived effect induced by the intensity. We expect this to be the space charge accumulated in the beam region of the chambers, causing a reduction in the gas amplification factor and hence an inefficiency. The positive ions causing the space charge effect typically requires hundreds of microseconds to be cleared. Finally, the third component of the inefficiency, another 2% effect, in produced in the muon-match procedure due to the large-angle scatters in the steel absorber. These 'kinks' prevent the link between the forward spectrometer track and the muon segments behind the absorber.

We suspect that the intensity-induced losses will be confined to the beam region of the chambers, hence we will not use their measurements to apply overall corrections to all the data. Rather, the purpose of this study is to understand why every straight-through beam is not reconstructed. Since the entire inefficiency is accounted for, we expect no unforseen efficiency losses that will affect the data. The one remaining issue, which is the dependence of the muon reconstruction efficiency on the final state multiplicity, is discussed in the following section.

5.4.2   Checks Using Inelastic Scatters

While the checks with the straight-through beams give confidence that the global forward spectrometer muon finding efficiency can be understood, there is an aspect that cannot be addressed by this monitoring sample. This is the multiplicity dependence of the muon reconstruction efficiency. Typically, one expects the event-related multiplicity of hits to be a source of confusion and inefficiency in the pattern recognition process.

Formally, for a given muon kinematic point (Q^2, ν), we are interested in the muon reconstruction efficiency $\epsilon(Q^2, \nu)$, averaged over the final states. In general, this efficiency may depend explicitly on the muon trajectory, as well as the final state properties which implicitly depend on (Q^2, ν). The full vector of final state parameters will be denoted by $\vec{m}$, and the probability distribution of these parameters will be denoted by the function $f(\vec{m}, Q^2, \nu)$. On an event-by-event basis, the muon reconstruction efficiency can depend on the muon trajectory and the final state, and will be denoted by $\varepsilon(\vec{m}, Q^2, \nu)$. Then

we can write the following relation:

$$\epsilon(Q^2, \nu) = \int \varepsilon(\vec{m}, Q^2, \nu) f(\vec{m}, Q^2, \nu) d\vec{m} \qquad (5.1)$$

where the integration is done over all the final state distributions.

This multidimensional integral is very difficult to do analytically, and is best performed using the Monte Carlo technique. For a given kinematic point (Q^2, ν), one generates the final state particles following known physics distributions. The LUND programs LEPTO 5.2 and JETSET 6.3 are used for the hadron generation, along with the GAMRAD program which generates radiative photons. These particles and the scattered muon are then propagated through the detector, using a simulation of materials and geometry of the detector. This task is performed by the GEANT program. The particles are used to generate hits in the chambers, which are then subjected to the track-finding algorithm. The integration described above corresponds to averaging over many Monte Carlo events in some kinematic bin (Q^2, ν), which is really the same thing that happens when one makes the muon cross-section measurement from the data.

In order to cross-check the Monte Carlo against the data, we need to collapse the full dimensionality of the final state, so that it becomes tractable. We will first focus our attention on hadronic scatters, where many particles are produced which are likely to cause confusion in the muon track-finding process. The most important parameter that describes this source of inefficiency will be the number of other tracks passing through the chambers along with the muon. The number of tracks found in the detector, apart from the muon, should be closely correlated with the true complexity of the event. Therefore, for the purpose of cross-checking the Monte Carlo against the data, we will study the muon reconstruction efficiency as a function of the number of additional tracks found in the detector. Here we have assumed that the Monte Carlo generator gives a sufficient description of the remaining aspects of the final state, such as the track momenta and angles. Prior studies [86] have shown this to be true.

The explicit dependence of the muon reconstruction efficiency $\varepsilon(\vec{m}, Q^2, \nu)$ on ν comes through the dependence of ε on the scattered muon energy E'. Averaging over the beam momentum distribution, there is a direct correlation between ν and E', since $E_{beam} - E' = \nu$. We expect that high momentum tracks are easier to find in the pattern recognition process than low momentum tracks, because they bend less in a magnetic field. High momentum tracks are 'stiff', their trajectories approaching a straight line, which is a simpler pattern to identify as compared to a curve. Hence we expect ε to reduce as E' reduces. However, in the final analysis, we impose a restriction on the scattered muon that $E' > 80$ GeV, so we are interested only in the 'stiff' muon tracks. Since the bend angle $\vartheta \sim 1/E'$, $d\vartheta \sim -dE'/E'^2$ so that the change of the bend angle with E' is small for large E'. Hence we expect the explicit dependence of ε on E' (or

ν) to be small for the 'stiff' muons, and we assume that the Monte Carlo is able to reproduce it correctly.

Following these assumptions, we will collapse equation 5.1 to a simpler form, thus:

$$\epsilon(Q^2,\nu) = \int \varepsilon(m,Q^2)f(m,Q^2,\nu)dm \tag{5.2}$$

where the variable m is the found multiplicity of the event and is assumed to be the most relevant parameter from the set of final state parameters $\vec{m}$. Compared to equation 5.1, some of the dependences and underlying distributions have been integrated out. $\varepsilon(m,Q^2)$ and $f(m,Q^2,\nu)$ must now be interpreted as the effective muon reconstruction efficiency and multiplicity distribution respectively.

Producing the Study Sample

Turning to the implementation of this scheme, we must first devise a way to identify inelastic scatters in the target without requiring the scattered muon. The target requirement is important because the pattern recognition algorithm is tuned to look for tracks coming from the target region. In the data, there is a large fraction of out-of-target scatters which may have a lower probability of being reconstructed. Therefore these events must not be included in the study sample.

The Vertex processor program has the capability of searching for vertices of the beam track with any forward spectrometer track. In the normal mode of usage, the Vertex processor searches for a vertex between a beam track and any of the forward spectrometer muons. If such a vertex is not found, the event reconstruction is normally terminated. For our purposes, we instruct the processor to continue the vertex search between the beam track and any forward spectrometer track. If a vertex is found, then we know that the beam interacted in the target. We can then ask if we have a reconstructed muon attached to the vertex.

For the measurement of this muon vertex reconstruction efficiency, we further select events to have one beam track and at least one negative forward spectrometer track fitted to it in the target region $-13.5m < X_{vtx} < -11.5m$. Since we are using positive muons, we know that the negative fitted track is not the muon track. This gives us a sample not biased by the muon track, which we can use for the muon efficiency measurement.

In order to identify hadronic scatters, we use the topology of particle and energy flow as measured by the electromagnetic calorimeter. This detector and its associated offline analysis proceeds independently of the spectrometer chambers and track-finding. In order to distinguish hadronic scatters from electromagnetic backgrounds, i.e. $\mu - e$

scatters and bremsstrahlung, we use the properties that the electromagnetic processes typically produce particles at smaller angles than the hadronic scatters. The spectrometer magnet can spread out any charged particles in the horizontal plane, however, the spread in the vertical direction is restricted by the original production angles. Hence we construct the quantity Z_{flow} using the calorimeter [49], which is defined as:

$$Z_{flow} = \frac{\sum Z_{Clus}^2 E_{Clus}}{\sum E_{Clus}} \qquad (5.3)$$

for each event, where the sum is over all the clusters in the EM Calorimeter, Z_{Clus} is the vertical distance (in meters) of the center of the cluster from the center of the Calorimeter and E_{Clus} is the energy of the cluster. This quantity is just the mean squared vertical dispersion of the energy flow, since the incoming beam is centered on the center of the calorimeter. We expect $\mu - e$ scatters and bremsstrahlung events to produce small Z_{flow}, while hadronic scatters will produce large Z_{flow}.

Figure 5.14 shows the distributions of $log_{10} Z_{flow}$ for Monte Carlo samples of $\mu - e$, bremsstrahlung and hadronic scatters, and an inclusive data sample. All data and Monte Carlo events are required to satisfy the SAT trigger. We see that the electromagnetic background events are confined to $Z_{flow} < 0.01 m^2$, while hadronic scatters produce Z_{flow} mostly above $0.01 m^2$. In the data, we see clear evidence for both kinds of events. We make the cut $Z_{flow} > 0.01 m^2$ to isolate hadronic scatters.

Checking the Underlying Final State

Next, we compare the final state multiplicity distributions $f(m, Q^2, \nu)$ between the data and the Monte Carlo. We will use the SATPS and SVS triggers for making the comparisons, because together they give us data over the entire kinematic range of interest to us, and they have no final state bias.

We make the same quality and kinematic cuts on the beam and the scattered muon as we make in the final structure function analysis. In addition, if there is any energy detected in the Calorimeter and $Z_{flow} < 0.01 m^2$, the event tagged as an electromagnetic event and removed. Using the remaining sample of hadronic scatters, we study the multiplicity distributions $f(m, Q^2, \nu)$ as a function of Q^2 and W. The multiplicity is defined as the total number of tracks with defined momentum found in the event, excluding the beam and the scattered muon tracks.

Figure 5.15 shows the Q^2 dependence of the average multiplicity, in bins of W. The data show that there is little variation of the average multiplicity with Q^2, for all W. This trend is reproduced by the Monte Carlo over a substantial range of Q^2 and W.
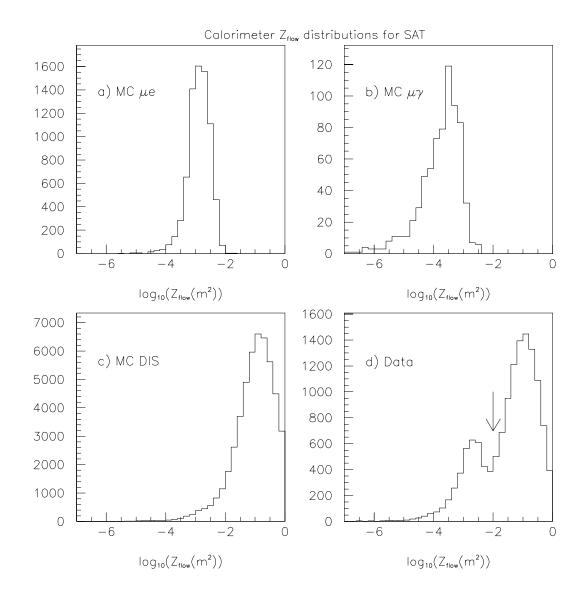

Figure 5.14: Small Angle Trigger event distributions of Calorimeter Z_{flow}. (a) Monte Carlo $\mu - e$ sample. (b) Monte Carlo bremsstrahlung sample. (c) Monte Carlo sample of hadronic scatters. (d) Inclusive data sample. The arrow indicates the cut used to isolate hadronic scatters from the electromagnetic events.

86
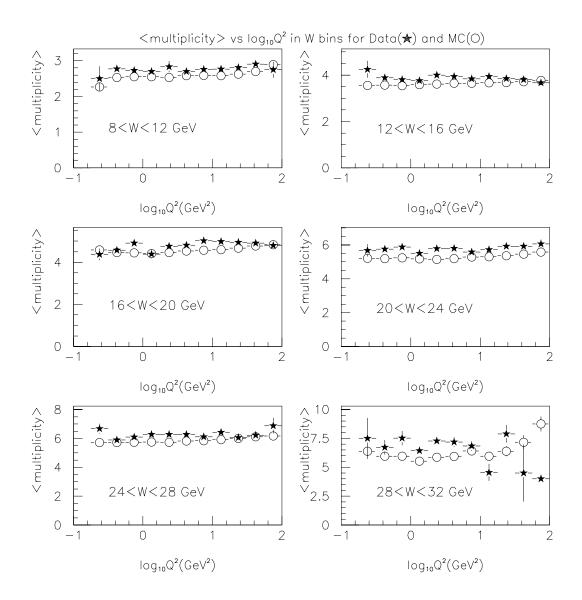

Figure 5.15: Average multiplicity vs $log_{10}Q^2$ in W bins, for Data and Monte Carlo. Hadronic scatters selected using the calorimeter are used. Only SATPS and SVS triggers are included. The average multiplicity is seen to be nearly independent of Q^2.

Figure 5.16 shows the dependence of the average multiplicity on $log_{10}W$, in bins of Q^2. Measurements ([60] and references therein) have shown that the multiplicity depends logarithmically on the hadronic center-of-mass energy. This behavior has also been motivated by the LUND String model [70]. The linear dependence on $log_{10}W$ is confirmed by the plots in figure 5.16. The Monte Carlo reproduces the trends very well.

We notice that the average multiplicity in the data is systematically higher than in the Monte Carlo. We use the property that multiplicity is nearly independent of Q^2, to combine all Q^2 bins, and study the W dependence of the multiplicity alone. This dependence is compared between data and Monte Carlo in figure 5.17a. We find that the average multiplicity in the data is higher by 8% than in the Monte Carlo, for any W. In order to tune the Monte Carlo to match the data, we multiply the found multiplicity in a Monte Carlo event by 1.08.

To test that this correction to the Monte Carlo achieves the desired result, we compare the Monte Carlo corrected multiplicity distributions with the multiplicity distributions measured from the data. These comparisons, in bins of W, are shown in figure 5.18. They show that scaling the Monte Carlo multiplicity by 1.08 gives us fair agreement between the multiplicity distributions, in all bins of W. With this correction the Monte Carlo also reproduces the W dependence of the average multiplicity, as shown in figure 5.17b.

To summarize, we find that the multiplicity distributions $f(m, Q^2, W)$ are nearly independent of Q^2, and the average multiplicity shows the expected linear dependence on $logW$. The Monte Carlo is able to match these trends. When the found multiplicity in any Monte Carlo event is scaled by 1.08, there is excellent agreement in the multiplicity distributions between the data and the Monte Carlo. This allows us to use the Monte Carlo to integrate over the underlying multiplicity distribution to obtain the average muon reconstruction efficiency, using equation 5.2. We now turn to the remaining component of the integrand, which is $\varepsilon(m, Q^2)$.

Checking the Multiplicity Dependence of the Muon-Finding Efficiency

Since the Q^2 dependence of $f(m, Q^2, W)$ is very weak, we will approximate equation 5.2 by the following:

$$\epsilon(Q^2, \nu) = \int \varepsilon(m, Q^2) f(m, W) dm \qquad (5.4)$$

where the muon-finding efficiency $\varepsilon(m, Q^2)$ can depend on the multiplicity and Q^2 explicitly. The Q^2 dependence is allowed because Q^2 is strongly correlated with the muon
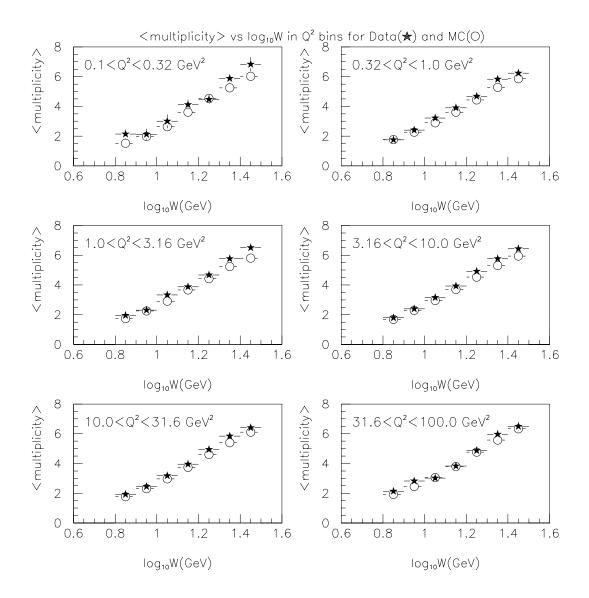

Figure 5.16: Average multiplicity vs $log_{10}W$ in Q^2 bins, for Data and Monte Carlo. Hadronic scatters selected using the calorimeter are used. Only SATPS and SVS triggers are included. The average multiplicity has a linear dependence on $log_{10}W$.

Only SATPS and SVS triggers are included. a) The average multiplicity in the data is higher by 8% than in the Monte Carlo, for any W. b) Monte Carlo corrected by scaling multiplicity by 1.08.
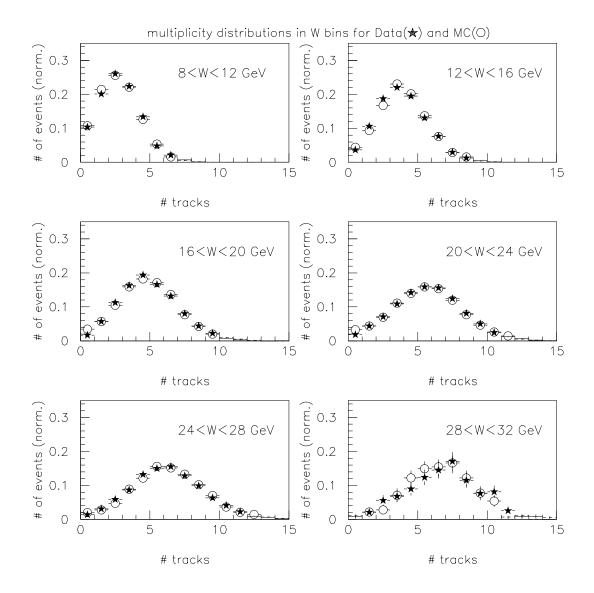

Figure 5.18: Normalized multiplicity distributions in W bins, for Data and Monte Carlo. Each distribution has been normalized to integrate to unity. Hadronic scatters selected using the calorimeter are used. Only SATPS and SVS triggers are included. The Monte Carlo multiplicity has been multiplied by 1.08, giving a good match with the data.

scattering angle. At small scattering angles, the muon traverses the radiation-damaged regions of many chambers, while at large scattering angles the muon sees all the chambers operating at high efficiency. Using the straight-through beams, we have shown that the efficiency at very small scattering angles is lower due to long-lived intensity effects. It is also possible that, in the presence of additional hadron multiplicity, the radiation-damaged regions do not provide enough hits to always find the muon. That is to say, the minimum number of hits required to find the muon may depend on whether there is additional multiplicity to cause confusion. Since the chamber efficiencies are varying with scattering angle, we have to allow $\varepsilon(m, Q^2)$ to depend on both the hadron multiplicity and Q^2.

In the absence of a reconstructed muon-muon vertex, we have to use the hardware directly to estimate Q^2. Figure 5.19 shows the $log_{10}Q^2$ distributions for the CALorimeter, SATPS, SAT and SVS triggers. The various triggers have different Q^2 acceptances, so we may use different trigger samples to estimate the variation of $\varepsilon(m, Q^2)$ with Q^2. The distributions in muon scattering angle are shown in 5.20.

The multiplicity dependence of the muon reconstruction efficiency measured for the different triggers is shown in figures 5.21 and 5.22. The measurements are made both on data and on the Monte Carlo. The comparisons between the corresponding data and Monte Carlo plots is shown in 5.23 and 5.24. Each of the plots is fitted with a second order polynomial in the multiplicity m, of the form:

$$\varepsilon(m, \overline{\theta}) = A_0 + A_1.m + A_2.m^2 \qquad (5.5)$$

where $\overline{\theta}$ is the representative scattering angle for a given trigger sample. The coefficients A_0, A_1 and A_2 with the associated errors, and the χ^2 of the fits are indicated on the plots.

We note that the efficiencies approach unity for null multiplicity for all triggers. This is just what we would expect based on the studies with the straight-through beams. Apart from a 2% loss due to muon matching inefficiency in the data, the scattered muons are always found in the absence of additional multiplicity. The inefficiencies caused by the intensity-related effects in the beam region do not affect the muons scattering through some non-zero angle.

As the multiplicity increases, there is a significant reduction in muon-finding efficiency due to increasing event complexity. In E665, it is conceivable that this effect in enhanced due to the reversed-polarity, double-dipole magnet geometry. This magnetic field configuration refocuses the hadron tracks towards the central region of the spectrometer, thereby increasing the local density of tracks. We find that the Monte Carlo is able to reproduce the bulk of this inefficiency. The data and Monte Carlo comparisons show that the difference between the data measurement and the Monte Carlo predictions

92

are typically smaller than 5%. The difference is larger for high multiplicities in the large angle SVS trigger.

We have a handle on the variation of the multiplicity dependence of the efficiency with the muon scattering angle by comparing the CAL, SATPS and SVS trigger samples. As shown in figures 5.19 and 5.20, the typical Q^2 and scattering angles for the CAL and SVS triggers span the range of the same quantities for the SAT trigger. In figures 5.25 and 5.26, the difference between the efficiencies measured with the three trigger samples is shown. We find that CAL and SAT measurements differ by at most a few percent, while the SVS and SAT measurements differ by less than 10%. This is consistent with the measurements shown in figure 5.20 that the mean scattering angles for CAL and SAT are about $1mrad$ and $2.5mrad$ respectively, while the same for the SVS is about $8mrad$. Thus we can see that a linear interpolation in scattering angle between the CAL and SVS efficiency parametrizations gives a good approximation for the θ^{scat} dependence.

We use these measurements to correct the Monte Carlo for the residual differences between its predictions and the data measurements. For a given Monte Carlo event, we use the reconstructed multiplicity and the scattering angle to evaluate the reconstruction efficiency using the Monte Carlo parametrizations shown above. This is the efficiency with which the Monte Carlo event would be reconstructed on average. The same event in the real data would have a slightly different efficiency, as our measurements show. To evaluate the corresponding efficiency for a similar data event, we first scale the multiplicity in the Monte Carlo event by 1.08, as discussed in the preceeding section. This makes the multiplicity in the Monte Carlo match the data. Then we use the scaled multiplicity and the scattering angle to evaluate the reconstruction efficiency using the data parametrizations shown above. This gives the reconstruction efficiency, on average, that the Monte Carlo event would have if it had occurred in the real data.

We have seen that the reconstruction efficiency in the Monte Carlo is always higher than in the data. Therefore it is a simple matter to adjust the Monte Carlo so that it would match the data. Using the evaluated data and Monte Carlo efficiencies, a given Monte Carlo event is randomly declared unreconstructed with the appropriate probability. This gives us a Monte Carlo sample that incorporates the correct muon reconstruction efficiency.

As a final test of the Monte Carlo in this respect, the multiplicity dependence of the reconstruction efficiency is extracted from the "corrected" Monte Carlo, and compared with the data again in figures 5.27 and 5.28. There is now fair agreement between the data and the final Monte Carlo.

5.4.3   Downstream Chamber Efficiency

So far we have dealt with the efficiency of finding the muon track and fitting it to the beam track in order to obtain the muon-muon vertex. In the structure function analysis we also require high resolution. This implies that one wants muon tracks with long arm lengths on either side of the main momentum analysing magnet CCM. As mentioned before, the upstream arm length is always long because the PCV contribute to the track about 98% of the time, and the combined PCV-VDC contribution is 100% efficient. But the efficiency of the downstream chamber combination DCA-DCB-PSA is not so high, so it must be studied carefully.

The track finding program is able to find forward spectrometer tracks using the PC-PCF chambers alone. These tracks can be projected to the drift chambers and the PSA with an accuracy of a few millimeters. For the muon, this translates into a resolution on the energy loss ν of 30-40 GeV, which is rather poor. However, this position resolution is good enough to study the position dependence of the downstream chamber efficiencies.

Figure 5.29 shows the two-dimensional position dependence of the efficiency for DCA, DCB or PSA to contribute to a PC-PCF muon track. The efficiency is shown as a function of the extrapolated position of the track at DCA and DCB respectively. The minimum and maximum is set at 0.8 and 1.0 respectively, and the size of the boxes is proportional to level of the efficiency above 0.8. The small circular chamber at the center is the PSA, with the drift chambers covering the wider aperture. We notice that over most of the area of the drift chambers and the PSA, the efficiencies are high and fairly independent of position. Between the left and right halves of the Z view drift chambers, there are vertical septa that cause reductions in the overall efficiency. We also note an oval shaped region at the center of the drift chambers where there is a large efficiency loss. This is due to the fact that all the drift chambers are radiation-damaged in this region, as mentioned earlier in this chapter.

All these effects have been incorporated into the Monte Carlo simulation. Figure 5.30 shows the DC-PSA efficiency measured from the Monte carlo output the same way as it was measured from the data. Qualitatively, the Monte Carlo simulation agrees with the data. The various geometrical effects, apertures and the drift chamber dead regions are reproduced reasonably well by the simulation. Quantitatively, there may be some room for improvement. In order to compare efficiency levels outside the dead regions, we cut away the region of the drift chamber septa and the central dead regions, for each of the set of chambers DCA and DCB. We also cut within the high efficiency active area of the PSA chamber. Following these cuts, we should be in the high efficiency regions of these chambers, and we can look at the efficiency as a function of the horizontal and vertical coordinates Y and Z separately to make quantitative comparisons between the

data and the Monte Carlo. These plots are shown in figures 5.31, 5.32, 5.33 and 5.34. Again, there may be some room for improvement.

As a final adjustment to the Monte Carlo, the lower histograms in figures 5.29 and 5.30 are used as look-up tables for the efficiency of the DC-PSA chambers. The coordinates at the DCB station are chosen because the PSA is situated close to this station. Each Monte Carlo event is re-weighted by the ratio of the efficiencies for the data and the original Monte Carlo, as a function of position. This technique corrects the Monte Carlo for the difference between its DC-PSA model and the actual chambers. The final corrections for inefficiency in the data are extracted from the re-weighted Monte Carlo. The systematic uncertainty in the DC-PSA efficiency is estimated as the full size of this final adjustment to the Monte Carlo.

5.4.4   Effects of Field Non-uniformity at Large Displacements

At large displacements from the center of the CCM magnet, the magnetic field becomes non-uniform. In particular, the field does not point in the vertical direction. This causes the track to bend even in the nominally 'non-bend' view. However, the track-finding program does not take this into account, causing loss of efficiency when the muon makes a large excursion from the center of the magnet. We expect this to influence the reconstruction of scattered muons at large scattering angles. Therefore we check the Monte Carlo against the data to see if the Monte Carlo is able to match the data.

The large scattering angle regime corresponds to the high Q^2, high x part of the kinematic space, where the structure function is constrained by measurements from SLAC, BCDMS and NMC experiments. Therefore it is fair to use the parametrization (described in appendix A) of F_2 fitted to these data to generate events in the Monte Carlo. In figure 5.35 we show the comparisons between self-normalized (integrating to unity) distributions of $log_{10}\theta$ (scattering angle), and scattered muon Y and Z coordinates at $X = 4m$. The $X = 4m$ position is immediately downstream of the downstream CCM edge. The comparisons show that the Monte Carlo is able to reproduce the data at small scattering angles. But at large angles, corresponding to large displacements from the center of the magnet (roughly at $Y = Z = 0$), the rate of reconstructed muons is significantly lower in the data than in the Monte Carlo. Furthermore, the discrepancy gets worse as the displacement and the scattering angle increases. It is rather surprising that the Monte Carlo does not reproduce the data in this region. At these distances we have high efficiency for the small angle trigger, and chamber efficiencies have recovered from the radiation damage in the central region. Therefore the non-uniformity of the magnetic field is the only candidate theory for this data-Monte Carlo discrepancy. This is not fully understood, since the Monte Carlo uses the full CCM field map for the

generation of track trajectories.

As there is some question about the validity of the Monte Carlo simulation at large scattering angles, we avoid those regions in this measurement. In the final analysis we will impose the following cuts: $-0.3m < Y_\mu < 0.3m$ and $-0.2m < Z_\mu < 0.2m$, where these scattered muon coordinates are measured at $X = 4m$, and $\theta_{scat} < 20mrad$.

5.5 Reconstruction Efficiency Predicted by Monte Carlo

We now show the muon reconstruction efficiency predicted by the Monte Carlo. The efficiency is shown as a function of individual kinematic variables in figures 5.36 and 5.37, and in 2-dimensional 'box' format vs various combinations of kinematic variables in figures 5.38 and 5.39. The efficiency is proportional to the area of the boxes.

The beam selection criteria listed in section 10.1 are imposed on the Monte Carlo events before the efficiency is computed. No trigger-related cuts or explicit kinematics cuts are made on the sample.

We have shown the efficiency defined in two different ways. In figures 5.36 and 5.38, the efficiency is defined as the probability of finding the beam muon-scattered muon vertex. In figures 5.37 and 5.39, additional requirements are made on the scattered muon. The drift chamber or PSA contribution to the muon track is required, and the geometrical cuts to exclude the muon from the poorly understood regions of the DC-PSA are made. Also, the X_{vtx} cut is made (see section 10.2 for the explanation of these requirements). Thus the latter definition of efficiency is the one ultimately relevant for the correction applied to the data. As we saw in section 5.4.3, the low efficiency regions of the drift chambers which do not overlap the PSA are largely responsible for the loss of acceptance seen in figures 5.37 and 5.39, compared to figures 5.36 and 5.38.

Chapter 6

Trigger Efficiency

6.1 The Detector

There were three kinds of hard or energetic interaction triggers operating during run91. These were the Small Angle Trigger (SAT), the set of Large Angle Triggers (LATs) and the Calorimeter Trigger (CAL). These triggers are differentiated by their beam muon requirements and in some ways by their construction and triggering philosophies.

The bulk of the physics results presented in this thesis are based on the data collected by the Small Angle Trigger. The SAT is described in [45]. A cartoon of the SAT construction is shown in figure 6.1. Briefly, the SAT is a pure veto trigger that senses the absence of the unscattered muon in coincidence with an incoming beam muon. The beam muon is defined by the appropriate coincidence (i.e. roads) of hits in the beam hodoscopes. These signals are provided to a fast pre-programmed memory module which predicts the position of the unscattered muon at the muon detectors downstream of the forward spectrometer. At the downstream end, additional hodoscopes are located. If these hodoscopes signal hits in the predicted muon position, then no scatter is expected and the event is vetoed. On the other hand, the beam signal and the absence of the corresponding unscattered muon veto indicates a scatter and the trigger fires.

The special feature of this construction is that the veto window for any detected beam muon moves according to the position and slope of the incoming muon. This allows the veto window to be smaller than the beam profile, permitting the detection of interactions where the scattered muon remains within the beam phase space. This means that the trigger can fire on small angle scatters (down to ~ 1 mrad.).

116
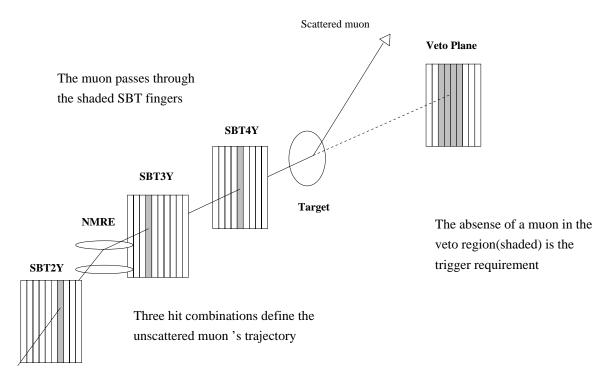

Figure 6.1: Schematic diagram of the SAT.

The first two stations of the SMS hodoscopes placed downstream of the hadron absorber were used to produced the veto signal. It was recognized that this arrangement produces a large number of fake triggers due to scatters in the absorber. Since the veto hodoscopes are very close to the absorber (about 1 m) compared to the target (about 30 m), a scatter through a much larger angle in the absorber is required to fool the trigger. However, the absorber corresponds to about 18 interaction lengths while the target is 1/6 (hydrogen) or 1/3 (deuterium) of an interaction length. Therefore scatters in the absorber can produce a significant fake trigger rate that increases the experiment dead-time due to the rate limitations of the data acquisition system.

To alleviate this problem, a small hodoscope, the SSA, was placed upstream of the absorber and its signal was incorporated into the veto. The muon position at this hodoscope is of course not affected by any subsequent scatter. While this solves the problem of fake triggers due to absorber scatters, it makes the trigger sensitive to vetoes caused by other particles produced in an inelastic muon interaction.

A monitoring trigger called the SATPS is constructed to be the same as the SAT except that the SSA veto is not included. This allows the SSA veto to be studied. This trigger is pre-scaled by a factor of 32 due to the large fake trigger rate.

6.2 SAT Efficiency

The SAT efficiency is computed using a Monte Carlo simulation of muon scatters in the detector. We can identify the following issues that need to be understood in order to calculate the trigger efficiency correctly:

- efficiencies of the trigger hodoscopes.

- the trigger logic that was implemented in the hardware.

- the geometry of the trigger system, i.e. the positions and sizes of the trigger hodoscopes.

- the magnetic fields and materials that affect the muon trajectory.

- the effects on the SMS veto of other particles which emerge from the absorber due to muon interactions in the absorber.

- the effects on the SSA veto due to all other particles that are produced in the forward spectrometer in addition to the scattered muon. These include the particles produced in the primary muon interaction in the target, and the particles produced by their subsequent reinteractions.

6.2.1 Trigger Hodoscope Efficiencies

As mentioned above, the trigger can be decomposed into the beam requirement and the veto requirement. It is not necessary to know the absolute efficiency of the beam hodoscopes. This is because the same beam signal is randomly pre-scaled by a measured factor to form a random beam trigger called the RSAT. The number of RSATs recorded gives the measure of flux that is used to normalize the number of SAT events. Hence the efficiency of the beam hodoscopes cancels in the cross-section measurement.

The SAT event rate itself gives us a measurement of the efficiency of the veto elements. The trigger rate is suppressed by five orders of magnitude compared to the beam rate. This must be so for the trigger to be viable since the scattering rate is of the order of 10^{-6}. Any inefficiency in the veto elements would swamp the trigger rate with straight-through beams. Therefore we know that the efficiency of the veto elements is practically 100%.

6.2.2 Trigger Logic Simulation

All individual counter signals from the trigger hodoscopes are latched and read out with any recorded event. The SAT hardware logic has been emulated in software [87] using the latched counter bits in lieu of the electronic pulses. Using the software and the latched bits, we can compare the predictions with the actual hardware trigger bits for RSAT, SAT and non-SAT events. This allows us to estimate the latching efficiencies of the hodoscopes and test the software logic simulation.

We use RSAT events with one reconstructed beam track to measure the probability that the software simulation also predicts an RSAT. We can do the same test with SAT events, however in this case additional restrictions have to be placed on the events. This is because there is a small rate of spurious signals that confuse the trigger into firing. But the true scattering rate is also small, hence the spurious triggers form a significant fraction of the SAT events. Since we do not expect the spurious triggers to conform to the designed logic, we use the reconstructed kinematics to select only good scatters for the test. The following conditions are imposed: $Q^2 > 0.05\ GeV^2$, $\nu > 20\ GeV$, $-13.5m < X_{vtx} < -11.5m$, and $\theta > 0.0002$. The results are shown in figure 6.2. We find that both RSAT and SAT triggers satisfy the RSAT simulation requirements with an efficiency in excess of 98% over the entire run. The difference in the efficiencies for the two triggers is about 0.2%, which contributes a small uncertainty in the normalization of the SAT trigger. We conclude that the beam definition of the SAT trigger is well-understood.

Next, we try to test our understanding of the SAT trigger hardware. We take good scatters from the SAT and non-SAT event sample, require the beam simulation to be valid, and predict whether the SAT should or should not have fired according to the latched counter signals. This should always agree with the presence or absence of the SAT hardware bit. Any disagreements are an indication of (i) latching inefficiencies or (ii) a mistake in the logic simulation. They represent systematic uncertainties in our ability to fully understand the hardware as it was when the event occured.

We use events with one reconstructed beam track, and impose kinematic cuts: $\nu > 20\ GeV$ or $\theta > 0.0003$. In addition, a resolution cut of $\delta\nu/\nu < 0.5$ is imposed. Table 6.1 shows the results using different trigger samples for the test. The processed data from the entire run91 are used.

The underlying distributions provided by the large angle triggers (SVS, CVT and SVSWAM2), the SATPS and the CAL have different biases in scattering angle and scattered muon energy. This leads to different overlaps between these triggers and the SAT. However, Table 6.1 shows that the discrepancies between the SAT hardware and
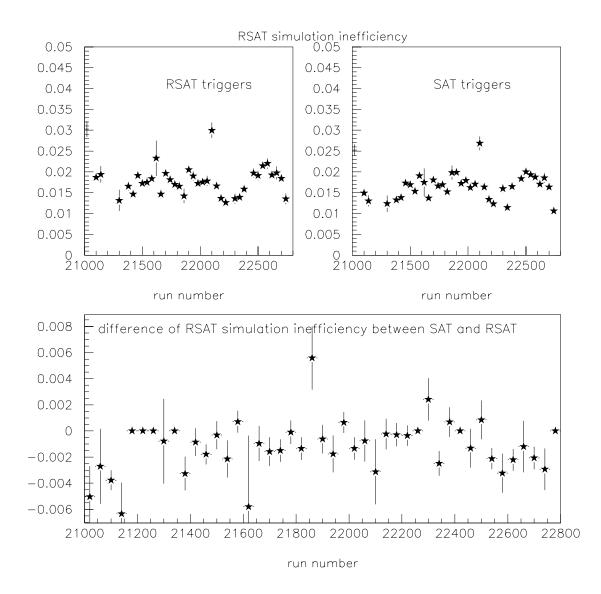

Figure 6.2: Inefficiency of RSAT simulation applied to RSAT and SAT triggers, as a function of run number. The lower histogram shows the difference in the inefficiencies for the two triggers.

software simulation are all at the level of 1% or less for the different samples. This suggests that the discrepancies are independent of the scattering kinematics, and are instead due to a steady rate of timing or latching inefficiency or spurious pulses or latches. We may conservatively assign a systematic uncertainty of 1.3% on the accuracy of the trigger logic simulation.

The RSAT and SAT logic simulation tests reported above are repeated with cuts on the beam tracks. These are the same cuts that are imposed in the final analysis of the data. They require the beam to completely traverse the liquid target, and remove beams with too low or too high an energy. The effect of the beam phase space cuts is to change the RSAT and SAT simulation efficiencies by 0.1% or less.

SAT simulation inefficiency vs run number

We can also combine the trigger samples and study the time dependence of the probability of the simulation to disagree with the hardware bit. This is shown in figure 6.3. This shows that the conditions over the run are fairly stable. We use the results from table tef:satsim to assign a systematic uncertainty of 1.3% in the trigger acceptance calculation, due to lack of complete knowledge of the trigger hardware.

6.2.3   Geometry of the Trigger System

In order to simulate the trigger in the Monte Carlo program from first principles, we have to know the positions of all the trigger elements. The longitudinal positions are determined by survey. The transverse positions are determined to good approximation by survey, followed by measurements using reconstructed forward spectrometer muon tracks. The forward spectrometer has been aligned using beam tracks [59] which set the transverse position reference for the experiment.

The positions of the edges of the veto windows are the most important geometrical measurements concerning the trigger. The probability of a hit in the veto window for the SSA and the SMS is plotted as a function of the distance from the edge in each view. These measurements are used to determine that the positions of the veto window edges are known to within 1 mm.

6.2.4   Absolute Probability of SMS Veto

The SMS veto is constructed in the two views separately. The two upstream stations of the SMS hodoscopes in the Y view are ORed to produce the SMSY veto. Similarly the Z view hodoscopes are used to construct the SMSZ veto signal. The SMS veto signal is then constructed by taking the coincidence of the SMSY and SMSZ veto signals. In other words,

$$SMSV = (SMS1Y + SMS2Y).(SMS1Z + SMS2Z) \qquad (6.1)$$

In order to understand the probability that an SMS veto pulse is produced, we need to consider the scenarios that lead to a particle hitting these counters. These are enumerated below.

- In the simplest situation, the scattered muon travels in a straight line through the absorber and hits the veto counters. The knowledge of the geometry of the veto counters enables this process to be simulated trivially.

- If there is more than one incoming muon in the same RF bucket, the SAT beam logic is unable to make an unambiguous prediction for the position of the unscattered muon. To guard against this situation, when there are hits in multiple beam counters, the SAT beam signal is vetoed by an electronic device called the cluster module. This feature protects the SAT trigger against events with multiple muon in the same bucket. The effect of the cluster module has been simulated using

the latched hits, and included in the simulation of the SAT beam. Therefore the requirement of the SAT beam in software provides an additional level of protection against multiple beams. The probability of multiple occupancy depends on instantaneous intensity, but is typically 1-2% which is not very large provided we are protected against it.

The presence of beam muons in preceeding or succeeding buckets is a somewhat different issue. Muons in preceeding buckets have the possibility of creating veto pulses that overflow into the bucket containing the scattered muon. The SAT beam definition includes a no-neighbour requirement for the preceeding bucket; in addition, the requirement of a single reconstructed beam track removes some of these cases to the extent that the out-of-time muon can also be reconstructed in the beam spectrometer chambers.

We can actually detect and measure the timing of the out-of-time beam muons. The spill local rate monitor [85] records the beam muon occupancy of every bucket in the vicinity of the trigger time. As discussed in the chapter on reconstruction efficiency, events are eliminated in which there is a beam muon in the preceeding 10 buckets or the succeeding 5 buckets with respect to the trigger time. This corresponds to about $200ns$ before and $100ns$ after the trigger time. This is much longer than the timing resolution of the trigger veto hodoscopes, so that we expect the deleterious effects of the out-of-time beams to be completely eliminated by making this requirement.

- The scattered muon gets deflected in the absorber through multiple coulomb scattering or otherwise. This means that a muon that would have projected into the veto window can avoid it and vice versa. While multiple coulomb scattering can be calculated using a simple formula, single large angle scatters are harder to calculate. This effect gets larger as the muon momentum reduces. Empirically, it was found that this was not a severe problem for muons above 80 GeV in momentum. Reconstructed muons below 80 GeV, when projected to the veto counters, gave a substantially weaker correlation with the presence of hits in the counters. This is one of the reasons that a cut of 80 GeV is made on the momentum of the reconstructed scattered muon in the entire analysis.

- The muon emerges from the absorber accompanied by other particles. This may be due to delta ray emission or a hard electromagnetic or hadronic interaction. While the muon may not hit the veto counters, one of the other particles might do so and veto the event. It is difficult to calculate these processes reliably, and it is necessary to measure these effects so that the loss of events due to such 'suicides' can be corrected for.

The absolute probability of an SMS veto can be measured from the data by using a sample of events obtained with the Calorimeter (CAL) trigger. The CAL trigger is

described in chapter 3. There are two salient features of this trigger that make it ideal for this measurement. Firstly, the CAL trigger uses only the calorimeter signals to trigger on the event. In particular, no detector downstream of the hadron absorber is used. This makes the trigger completely insensitive to any muon activity in the absorber. Secondly, the CAL trigger is completely positive with no veto components. Therefore we get a sample of events unbiased with respect to muon vetos behind the absorber, which can be used to measure the veto probability in the muon veto hodoscopes.

In order to make this measurement, we isolate from the reconstructed CAL triggers a sample of events in which we have a very well-reconstructed scattered muon track. We need to have confidence that the track used for the measurement is actually the scattered muon track. In addition, we need high resolution on the track parameters so that the measurement has the minimum of smearing. Hence we make the following selection on the muon track:

- One beam track in the beam spectrometer.

- The RSAT conditions are satisfied by the beam hodoscopes. This eliminates the possibility of multiple beams in the bucket.

- $\nu >$25 GeV and $Q^2 >$0.2 GeV^2. This gives roughly the same kinematic range as the structure function analysis. The loss in statistics is small because the calorimeter trigger does not fire if the muon energy loss is small, and the lower Q^2 events have most of the muons projecting inside the veto counters so that they are not useful for studying the showering.

- Energy of the scattered muon greater than 80 GeV.

- The muon track extends upto the DCB or the PSA chamber. This ensures good resolution on the muon position extrapolated to the veto counter.

- The muon track is well-constrained by contributions from the PCV, PC, PCF4 and PCF5 chambers.

- the muon-muon vertex probability is greater than 1%. This ensures that the scattered muon track connects well with the beam track and no large mistake was made in its reconstruction.

All the muon activity in the absorber can only depend on the five muon parameters measured just before it enters the absorber. These are the vertical and horizontal positions and slopes, and the energy. The longitudinal position of the veto hodoscope is the most natural plane at which to report the position of the scattered muon. We take the muon parameters at the most downstream chamber and extrapolate in a straight line

to the hodoscope. This gives us the predicted position of the scattered muon if all its interactions in the absorber could be ignored.

Our physical model for the actual muon at the veto counter is shown in figure 6.4. Instead of a single particle at its predicted position, the muon is instead represented by a continuum of co-axial cones. These cones represent surfaces on which there is a certain probability of finding any particle. This particle may be the muon itself if it undergoes scattering in the absorber, or it may be one of the particles that constitutes the shower produced by the muon. These particles may emanate from any point along the muon's trajectory.

We have assumed that the various materials in this region are arranged in sheets of uniform thickness perpendicular to the direction of the muon. Since the muon slope is always less than about 30 mrad when it is close to the veto counters, it is almost perpendicular to the various detectors and absorber materials. Hence we can assume an azimuthal symmetry in the particle distribution around the predicted muon path.
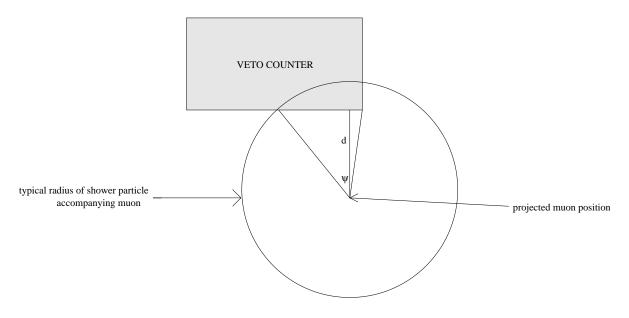

Figure 6.4: Model of the muon as it emerges from the hadron absorber and intersects the plane of the veto counter.

The intersection of these equal particle density surfaces with the plane of the veto counter gives concentric rings, an example of which is shown in figure 6.4. It is clear that the probability that a particle will hit the veto counter depends on two coordinates. One is the minimum distance of the any point on the veto hodoscope from the projected muon position. The closer the muon is to the veto counter, the larger is the overlap

of the ring with the hodoscope. This distance is labelled in figure 6.4 as d. Thus one expects the veto probability to increase as d decreases. However, this probability cannot depend on d alone. For any given d, the hodoscope subtends an angle ψ at the center of the ring. As ψ increases, a larger fraction of the ring overlaps with the hodoscope, so again we expect the veto probability to increase.

Hence we have chosen d and ψ as our variables in terms of which we will parametrize the veto probability. Figure 6.5 shows contours of equal d and equal ψ. These contours illustrate that these variables are motivated. For any given d, as ones moves the projected muon position along a d counter, the veto probability intially increases as one moves from one of the corners towards the adjacent corner. One would cut counters of increasing ψ, as confirmed by the figure. When one reaches the half-way point, the veto probability reaches a stationary point before falling again. Again the figure shows that the ψ counters become parallel to the d counters at the midway point. Near one of the corners, the variation with lateral movement would be largest, and this is where the ψ contours intersect the d contours at large angles. Far from the veto hodoscope, the azimuthal position makes little difference, so that there is again only one relevant coordinate which is d. In this case one notices that the ψ contours would become the same as the d contours. Thus these variables span the relevant two-dimensional space very efficiently. Each one of them is capable of describing a large part of the relevant geometry, and together they compensate for the deficiencies in each other. An additional advantage of these variables is that the veto probability is expected to be a monotonic function of them. This simplifies the process of parametrizing the veto probability.

The measurements of the veto probability as a function of d and ψ obtained from the CAL trigger data are shown in figure 6.6. Let us first study the veto probability as a function of the distance from the veto window d. Negative d implies the muon projects inside the veto window. Since the veto hodoscopes are very efficient the veto probability for these muons is 100%. If the muon projects very close to the edge of the veto window, then the multiple scattering in the absorber smears the apparent edge of the veto window. We see the multiple scattering effects extending to about 1 cm from the edge of the hodoscope, at which point the veto probability has dropped to about 20%. Beyond this the veto probability reduces slowly until it becomes less than about 1% more than 10 cm from the hodoscope. This long tail can be attributed to hard large angle scatters of the muon and shower particles accompanying the muon. The dependence of the veto probability on the angle subtended ψ also shows the reduction as the angle reduces. As the angle becomes large the muon is typically close to the veto edge, and the veto probability becomes large due to multiple scattering. The small bump at $\psi \sim 1.5$ i.e. 90 degrees, is a reflection of the two-dimensional nature of the geometry. For this value the contours of constant ψ makes large excursions in the distance d, as shown in figure 6.5, and get contributions from small d. Contours of ψ greater than 90 degrees are always removed from the edge of the counter by some minimum distance.

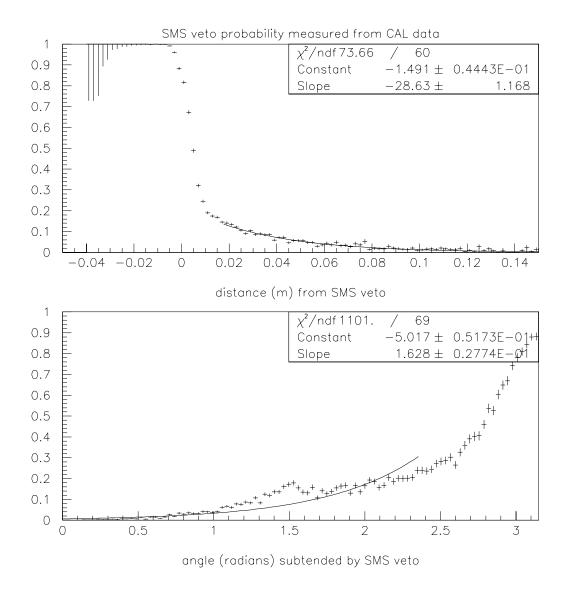

Figure 6.6: SMS veto probability measured using Calorimeter trigger data.

The standard E665 Monte Carlo simulation of the detector includes the calculation of the multiple scattering, but makes no attempt to reproduce the large angle scatters or the showering. Hence we implant the measurements of these effects into the Monte Carlo. The measurements are shown in figure 6.6. We first fit the dependence of the veto probability on d, in the region $d > 0.01m$. This probability, which we call $f(d)$, is fitted very well by the function

$$f(d) = exp(-1.49 - 28.6d) \qquad (6.2)$$

where d is in meters. If the geometry were one-dimensional we could simply use $f(d)$ as the veto probability due to showering and hard scattering in the absorber. However, we also expect some dependence on ψ, as shown in figure 6.6. We find a rapid increase in the veto probability as ψ exceeds about 2.5 radians, which we expect is the reflection of the behavior for $d < 0.01m$. Barring this region, we find that the function

$$g(\psi) = exp(-5.0 + 1.63\psi) \qquad (6.3)$$

gives an approximate description of the ψ dependence. While this function does not incorporate some of the subtle variations in the ψ dependence, our hypothesis is that these subtleties are a reflection of the d dependence.

In order to test this hypothesis, we must construct a joint veto probability distribution which is a function of both d and ψ. The simplest guess is that it is a linear combination of $f(d)$ and $g(\psi)$, i.e.

$$P(SMSveto) = af(d) + bg(\psi) + c \qquad (6.4)$$

Since this is a linear equation if we treat f and g as the independent variables, we can use the regression technique to calculate the coefficients a, b, c. the result of the calculation is the following:

$$P(SMSveto) = 0.19exp(-28.6d) + 0.235exp(1.63(\psi - \pi)) + 0.0009 \qquad (6.5)$$

It is reassuring that the constant term is small as expected.

This parametric function for the SMS veto probability is used is used to generate hits in the SMS veto in the Monte Carlo. We use the true muon coordinates to calculate d and ψ. If the muon projects outside the veto counter, we evaluate the veto probability using the measured function above, and generate a hit in the veto counter with this probability. Note that we have used the true muon coordinate even though the measurement was made with reconstructed muon from the data. We argue that the muons used from the data are expected to have a position resolution of about 0.5 mm, which should result in a negligible smearing correction for the slowly varying component of veto probability.

In order to test this simulation, we would like to 'measure' the veto probability from the tuned Monte Carlo in the same way that the measurement was made from the data.
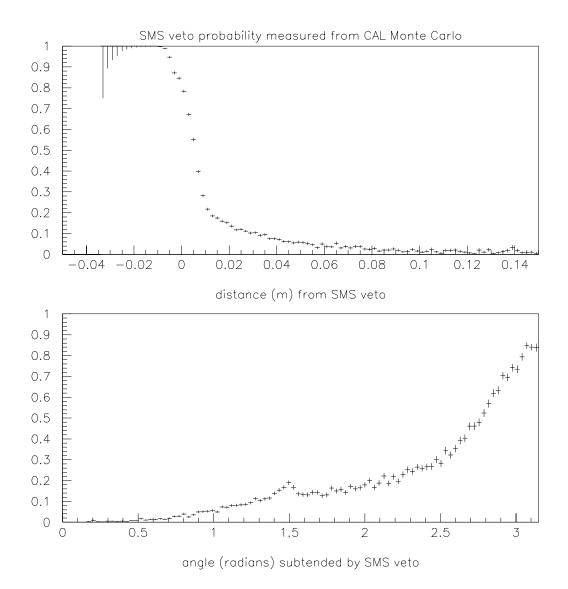

Figure 6.7: SMS veto probability for Monte Carlo events satisfying Calorimeter trigger simulation.

Since we will be comparing one-dimensional measurements, we will be projecting over the dependence in either d or ψ. hence it is important that the underlying muon position distributions be approximately the same in the test sample of the Monte Carlo as in the data. For this purpose, we obtain a simple parametrization of the Calorimeter trigger efficiency from the data, using the muon triggers to study it. We apply this Calorimeter trigger simulation to select CAL triggers from the Monte Carlo. The underlying cross-section is generated using the trial structure functions that fit the existing data, and the calculated radiative corrections. In this way we create a sample of monte Carlo events that can be used for a fair test of the SMS veto probability simulation. Figure 6.7 shows the results of the SMS veto probability 'measurement' on the monte Carlo. We note that the monte Carlo reproduces the dependence of d and ψ, including the subtle variations with ψ which were not forced in $g(\psi)$. They are really the manifestions of the d dependence integrated over the underlying distribution.

In figure 6.8 we show the difference between the veto probabilities measured from the data and the Monte Carlo. The agreement is quite good except in the region $\mid d \mid$ < 1 cm, where the veto probability is changing rapidly. In order to be insensitive to the exact understanding of the veto probability close to the counter, we will impose a requirement $d > 0.015m$ in all the analyses. This also makes us insensitive to our ignorance of the position of the veto hodoscope to better than 1 mm.
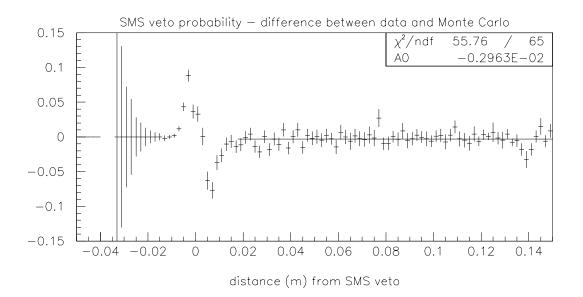

Figure 6.8: Difference beween SMS veto probability measured from data and Monte Carlo.

Figure 6.9 shows the difference in the ψ dependence of the SMS veto probability measured from the data and the Monte Carlo. The events at large ψ have been eliminated by the cut on $d > 0.015m$. In general the agreement between the data and the Monte Carlo is quite good, although over some range in ψ there can be about 1% difference.
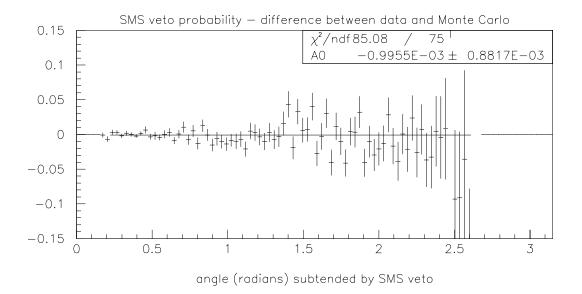

Figure 6.9: Difference beween SMS veto probability measured from data and Monte Carlo.

At this point we examine the simple fit that $P(SMSveto) = af(d) + bg(\psi) + c$. We add more terms in the expression to incorporate correlations between the d and ψ dependences. The regression analysis is repeated to find the contribution of such terms. In all cases the extra terms are found to contribute less than 1% to the veto probability. We also examine the possibility that the veto probability depends on the muon energy. We add terms in the expression that are energy dependent, and we try linear, logarithmic, and inverse energy dependences. Again, in all cases, such terms are found to contribute less than 1% to the veto probability. We conclude that the parameterization for the SMS veto probability as a linear combination of $f(d)$ and $g(\psi)$ is adequate.

6.2.5 Absolute Probability of SSA Veto

We now turn our attention to the other component of the SAT veto, the SSA hodoscope. Since this hodoscope is in front of the absorber, it is sensitive to hits from the scattered muon as well as any other particle produced in the event final state. The final state includes all the other particles produced from the muon interaction in the spectrometer, upstream of the absorber.

We start by separating the SSA veto probability into the scattered muon component and the final state component. Figure 6.10 shows the measured dependence of the SSA veto probability on d, the distance of the projected muon position at the SSA from the edge of the veto region. The triggers which do not include the SSA veto, i.e. the SATPS, CAL and the large angle triggers, were used to make the measurement. The same quality cuts are made on the data that were made for the measurements of the SMS veto probability. In addition, calorimeter based cuts were used to remove muon-electron elastic scatters from the sample, because in these events the electron has a high probability of hitting the SSA hodoscope. The d dependence of the veto probability allows us to separate the vetoes caused by the muon and the vetoes caused by the final state particles. When the muon projects into the veto region ($d < 0$), the veto probability is essentially unity. At the edge ($d=0$) there is a sharp reduction in the veto probability, and for $d > 0$ there is little dependence on d. In contrast to the smeared edge seen for the SMS veto, the sharp edge of the SSA is to be expected since there is not much multiple scattering of the muon before the hadron absorber. The lack of dependence of the SSA veto probability on d for $d > 0$ suggests that this component of the veto probability is due to the final state and not the muon itself. The ψ dependence is examined and also shows lack of ψ dependence when the muon projects outside the veto region.

We isolate the events with $d > 0.0025m$ in order to study the dependence of the veto rate on final state quantities. Compared to the study of the SMS veto, this is in principle a much more involved problem because the final state has many more degrees of freedom. However, we want to measure the total muon cross-section and not the final state characteristics. Hence it suffices to study the veto rate as a function of the muon kinematics and we do not need to characterize the final state in great detail. Since the final state is produced by the collision of the nucleon and the apparent virtual photon emitted by the muon, the kinematics of the apparent virtual photon would be the best variables in terms of which to parametrize the final state activity. Figure 6.11 depicts the relevant geometry for the SSA veto caused by the final state. The muon radiates the apparent virtual photon γ^*, carrying energy ν and emerging at an angle θ_γ with respect to the incoming muon direction. The apparent virtual photon fragments into some final state X, which on average can be represented by a cone about the direction of γ^*. The
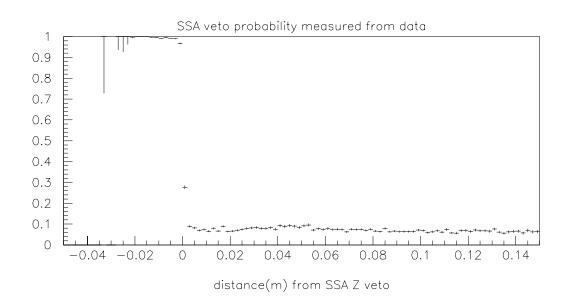

Figure 6.10: SSA Z hodoscope veto rate measured from the data, excluding μe elastic scatters.

probability that one of the final state particles hits the SSA veto depends on two things: (i) the number of final state particles, which depends on ν, and (ii) the angle with which they emerge, which is θ_γ. For small θ_γ the particles are directed towards the SSA and are more likely to hit it, while for large θ_γ they are directed away from the SSA and are likely to miss it. θ_γ is also inversely correlated with ν since, for a given scattered muon energy and angle, $\theta_\gamma \sim \nu^{-1}$. Hence the variation of the SSA veto probability with θ_γ also reflects some of the ν dependence.
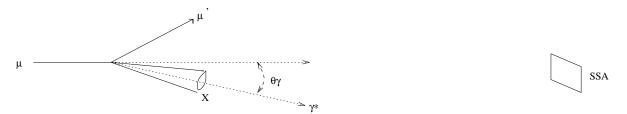

Figure 6.11: A cartoon depicting the final state particles produced by the apparent virtual photon, in relation to the SSA veto hodoscope.

On the basis of the final state, events can be classified into one of three categories: hadronic scatters, hard muon bremsstrahlung, and elastic μe scatters. The former two constitute the total muon cross-section, so that the SSA veto rate measurement made from the data makes the correct weighted average of the veto probability for these two

kinds of events. This is important because for a given γ^*, the final state topologies for hadronic scatters and hard muon bremsstrahlung are quite different and one expects to have different SSA veto probabilities. However, the average extracted from the data suffices to measure the total cross-section. On the other hand, elastic μe scatters do not contribute to the muon-nucleon cross-section, hence they must not be included in the data sample used to make the measurement. This is especially important because the electron tends to get focussed back onto the SSA and has an enhanced probability of vetoing the event.

For a given beam muon, the γ^* energy ν and angle θ_γ completely specify the event. Hence we choose to parametrize the SSA veto probability in terms of these variables in the following manner:

$$
\begin{aligned}
P(SSA\,veto) = \quad & a + b(\nu/100) + c(log_{10}\theta_\gamma) + d(\nu/100)^2 \\
& + e(\nu/100)(log_{10}\theta_\gamma) + f(log_{10}\theta_\gamma)^2
\end{aligned}
\tag{6.6}
$$

We use the SATPS and the large angle triggers to provide a data sample that is unbiased with respect to the final state, because these triggers do not include any veto component upstream of the absorber. We also impose the requirement that the muon scatter in the target region, i.e. -13.5 m $< X_{vtx} <$ -11.5 m, because these are the events of interest, and the veto probability may depend on the point of origin of the final state particles. We also require $x_{Bj} > 0.0008$ which removes the μe scatters appearing at $x_{Bj} \sim 0.000545$. A regression analysis is performed on the data to calculate the coefficients a, b, c, d, e and f. The results obtained are as follows:

$a = 0.2241E - 01, b = -0.6924E - 01, c = -0.1792E - 01,$
$d = -0.2800E - 02, e = -0.4980E - 01, f = -0.8484E - 02$

This parametrization is then used to simulate hits in the Monte Carlo. The true muon position at the SSA hodoscope is used to determine if the muon projects into the SSA veto region. If it does, a hit is simulated in the SSA. If the muon projects outside the SSA veto region, a hit is generated with a probability given by the parametrization above.

We can now test the accuracy of the parametrization by comparing the Monte Carlo results with the data. We compare the SSA veto probability measured from the data, using separate SATPS and LAT trigger samples, to the same 'measurements' made from the Monte Carlo. We do the test separately for SATPS and LAT samples because this gives different underlying distributions. The SATPS has acceptance down to muon scattering angles of about 0.5 mrad, while the LAT has acceptance above about 3 mrad. If the SSA veto has been understood properly, then the Monte Carlo should be able to correctly integrate over the underlying distribution and match the data measurement in terms of any kinematic variable. Hence we compare the dependence of the SSA veto

probability on the apparent virtual photon kinematics ν and θ_γ, the scattered muon variables θ^{scat} and ϕ^{scat}, and Q^2. These comparisons are shown in figures 6.12, 6.13, 6.14, 6.15 and 6.16. We find that the Monte Carlo reproduces the data measurements very well, for both the SATPS and LAT samples. We examine the differences between the data measurements and the Monte Carlo predictions, and find that the level differences are less than 1%. Point-to- point systematic differences are less than 2%. We take 2% as a conservative estimate of the systematic uncertainty in the measurement of the SSA veto probability.

6.3   SAT Efficiency Predicted by Monte Carlo

Having incorporated all the detector-related effects into the Monte Carlo simulation, we can now use the Monte Carlo to predict the SAT efficiency as a function of kinematic variables. The one-dimensional plots are shown in figures 6.17 and 6.18. The efficiency is shown in two-dimensional 'box' format in figures 6.19 and 6.20, where the efficiency is proportional to the area of the boxes.

The SAT efficiency is computed twice with two different underlying distributions. In the first case, the underlying muon distributions are selected after all the analysis cuts described in chapter 10, except the geometrical cuts on the muon position with respect to the SSA and SMS edges. This sample gives the absolute efficiency of the SAT, shown in figures 6.17 and 6.19. The bulk of the efficiency loss at small θ and Q^2 is due to loss of geometrical acceptance (i.e. the muon hits one of the veto hodoscopes).

In the second case, we include the geometrical cut on the muon position to be outside the SSA and SMS edges (see chapter 10) in the selection of the underlying distribution. This selection absorbs the geometrical acceptance loss into the underlying distribution. The SAT efficiency recomputed with this selection is shown in figures 6.18 and 6.20. Here we see the inefficiency due to the combined effects of the vetoes induced in the SMS by the muon shower in the absorber and the vetoes induced in the SSA by the final state particles.

Chapter 7

Detector Calibration and Resolution

Having understood the trigger and reconstruction efficiencies, we know the fraction of the muon scatters that occur that we are able to study offline. Since we are trying to measure the double differential cross-section for muon-nucleon scattering, we need to measure the kinematics of the muon-nucleon scatter. As with any measurement, there can be errors in this measurement on an event-by-event basis. These errors can be classified into two categories: (i) systematic biases, and (ii) errors due to the finite resolution of the detector.

7.1 Detector Calibration

A magnetic tracking spectrometer works on the principle that the trajectory of a charged particle in a magnetic field can be calculated. The detector measures the position of the charged particle at various points along the trajectory as it passes through a region of known magnetic field. The position measurements are made in E665 using multi-wire proportional chambers (MWPCs) and drift chambers. The particle position and direction information is derived from the reconstructed trajectory, while the momentum information induced from the measured curvature in the magnetic field and the knowledge of the field.

7.1.1   Chamber Alignment and Calibration

The first step in the calibration of the detector is to determine the relative positions of all the chambers in the detector. The details of this procedure can be found in [59]. First, the longitudinal positions of all the detectors, i.e. positions along the direction of the muon beam, are determined by optical survey. In order to measure the relative transverse positions, straight-line tracks are used from the data as reference. In E665, the straight-through beam and halo muons provide an abundant supply of particles that illuminate a large number of chambers simultaneously. Special triggers, using scintillation hodoscopes, are designed to trigger on the passage of beam and halo muons. Dedicated runs are performed periodically with these triggers and a large number of these straight-through muons are recorded. The various magnets in the spectrometers are turned off so that the particles are expected to travel in straight lines in the field-free regions. Using the tracking detectors, the tracks produced by the straight-through muons are reconstructed and fitted with a straight-line model in three dimensions. The transverse position and angles of all the chambers were adjusted until the residues between the hits and the track coordinates were minimized. For the drift chambers and the vertex drift chambers (VDC), the same procedure is used to calibrate the relationship between the measured time of the hit and its position. This procedure results in all the chambers being aligned with respect to each other. It also yields information on the relative wire spacing of all the chambers, which is used to confirm the design parameters. A brief description of the chamber alignment and calibration procedure is given below.

First, stations 2 and 4 of the beam spectrometer were determined to be the best reference chambers. With the beam spectrometer NMRE magnet turned off, a straight-through beam muon track was fitted using these chambers. This track was then extrapolated in a straight line to each of the other chambers in the beam spectrometer.

Second, the straight-through beam track was extrapolated into the multi-wire proportional chambers of the forward spectrometer. Since the forward spectrometer magnets CVM and CCM were off, a straight-line projection was used. The reference track was then used to align the PCN, PCF, PSA chambers and the SMS hodoscopes. The PCV was not aligned using this procedure because it was attached to the CVM magnet and moved when the magnet was powered on.

Third, straight-through halo muons were used to align the large drift chambers with respect to the PCN-PCF chambers. Again, the CCM magnet was turned off and straight line projections were used. The same data was used to internally align the various planes of the drift chambers with respect to each other.

Finally, The VDC and PCV chambers were aligned using the beam and halo tracks,

with the forward spectrometer magnets on. The VDC were designed to operate in the magnetic field of the CVM magnet, hence they can only be aligned and calibrated in the presence of the field.

7.1.2   Magnetic Field Measurements

There are three magnets in the E665 detector. These are the beam spectrometer dipole magnet NMRE, and the two forward spectrometer dipoles CVM and CCM. Since the beam is confined to a small central region of the NMRE magnet, it suffices to characterize it with one number, which is the transverse momentum kick it imparts to a typical beam muon. On the other hand, complete three-dimensional field maps are maintained for the CVM and CCM magnets, since particles traverse them over different regions of their large apertures.

7.2   Checks of the Detector Calibration

There are various physics measurements that can be made in order to test the calibration of the spectrometer. We will discuss each one of these in turn.

7.2.1   Primary Protons from the Tevatron

The Tevatron provides a very stable beam of protons that are almost mono-energetic. Using a modified beam-line, E665 took data where the primary protons were brought into the muon lab. The momentum measurement of the protons in the beam spectrometer and the forward spectrometer provided the absolute energy calibration for the E665 detector.

Using the current values of the Tevatron magnet settings, the momentum of the primary protons was independently determined to be 800.6 ± 2 GeV [88]. The error in the proton momentum comes mainly from the inaccuracy in the current readback of the Tevatron magnets. The transverse momentum kick of the beam spectrometer NMRE magnet was tuned such that the beam spectrometer measurement agreed with the measurement from the Tevatron. The transverse momentum kick was determined to be 1.515±0.004 GeV. This gives an error estimate of 0.3% on the absolute momentum calibration using this method. The error comes mainly from the uncertainty in the

primary proton momentum, but it also includes the error in the NMRE current readback [88]. The primary protons can also be used to check the measurement obtained from the forward spectrometer. The forward spectrometer measurement is 800.5±0.14 GeV, where the error is statistical only [59]. This is consistent with the primary proton momentum measurement.

7.2.2 Relative Momentum Calibration of Beam and Forward spectrometers

The relative momentum calibration of the beam and forward spectrometers can also be checked using the straight-through muons triggered by a beam trigger. The difference in the momentum measurements from the two spectrometers should be zero. Figure 7.1 shows the run dependence of ν (difference between beam and forward spectrometer momentum measurements) for straight-through beams. These events are selected by using random SAT beam triggers, requiring one in-time beam track and one forward spectrometer muon, and removing events with a beam in the preceeding 10 buckets or the succeeding 5 buckets. The PSA is required to contribute to the forward spectrometer muon. The assumption is that the beam and the forward spectrometers are measuring the same particle. According to figure 7.1, this quantity ν for straight-through beams varies rather randomly between 0.5 GeV and 2 GeV over the run. The ν distribution for straight-through beams integrating over all runs is shown in the top half of figure 7.2. A Gaussian fit is performed, yielding a good description of the distribution. We see that the beam spectrometer measurement is systematically larger than the forward spectrometer measurement by about 1.3 GeV. We repeat the same procedure on the Monte Carlo, where the detector alignment and calibration is perfect. The reconstructed Monte Carlo yields a positive ν offset of about 0.6 GeV, indicating a bias in the track fitting procedure. We take the difference of 0.7 GeV (corresponding to 0.15% at the mean beam energy of 465 GeV), between the data and the Monte Carlo measurements as a systematic uncertainty in the relative calibration of the beam and forward spectrometers. Since we use the Monte Carlo to make the final corrections to the data in order to extract the cross-section, the track-fitting bias is automatically compensated for.

7.2.3 Calibration Check using Muon-Electron Scatters

The muon-electron scatters detected by the experiment offer another way to check the calibration of the spectrometer. Due to the elasticity of the event, the kinematics are constrained to give $x_{Bj} = m_e/m_p$ (up to radiative corrections).

ν (GeV) vs Run Number
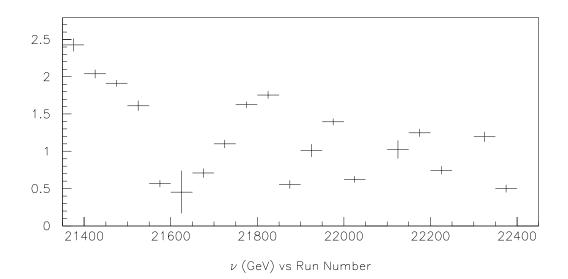

Figure 7.1: Difference (ν) between momenta of straight-through beams as measured by the beam and forward spectrometers. The mean difference is shown for different run blocks, with the errors on the mean values.

The following criteria are used to select useful events:

- One beam track is required.

- The event is required to satisfy the Small Angle Trigger (SAT) software simulation.

- The muon energy loss ν must be greater than 100 GeV. Through the elasticity condition, this translates into the requirement $Q^2 > 0.1$ GeV^2 for the μe events. The SAT has very little acceptance for $Q^2 < 0.1$ GeV^2.

- The scattered muon track must receive contributions from the PCV and PSA chambers. This ensures a long lever arm and hence good resolution.

- The scatter should originate in the target region, $-11.5m > X_{vtx} > -13.5m$.

Further cuts are applied to select clean μe events using their characteristic topology:

- One and only one cluster is required in the electromagnetic calorimeter.

- One negative track should be fitted to the muon-muon vertex, and no other tracks should be detected.
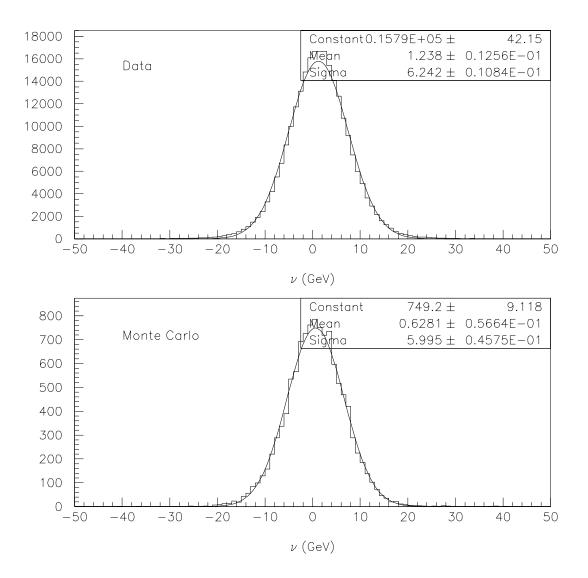

Figure 7.2: Difference (ν) between momenta of straight-through beams as measured by the beam and forward spectrometers. The upper plot is obtained from the data and the lower from the Monte Carlo. The curves are Gaussian fits to the distributions.

- The negative fitted track should impact on the calorimeter face within 5 cm of the cluster position. This enhances the probability that the negative track is an electron.

- The negative track should carry more than 85% of the energy lost by the muon.

- The calorimeter cluster should have a vertical displacement of less than 10 cm from the central horizontal plane of the detector. This uses the property that the energy flow is confined to small angles in electromagnetic events.

The $log_{10}x_{Bj}$ distribution of events surviving these cuts is shown in figure 7.3. The characteristic μe peak is observed with little background. There is a tail extending to lower values of x_{Bj}, which may be due to radiative corrections to the elastic μe peak, or μN scatters not rejected by the cuts. The histogram is fitted with a sum of two Gaussians, one for the main μe peak and one to accommodate the tail. The parameters P_1,P_2,P_3 and P_4,P_5,P_6 are the normalization, mean and r.m.s. of the two Gaussians respectively. Using the main peak, we find the mean is -3.2643 $\pm$0.0003, and the r.m.s. is 0.0241$\pm$0.0003. This can be compared with the value calculated using the elastic μe scattering condition, $log_{10}x_{Bj} = log_{10}(m_e/m_p) = -3.2639$. The measured x_{Bj} differs from the calculated value by 0.1%.
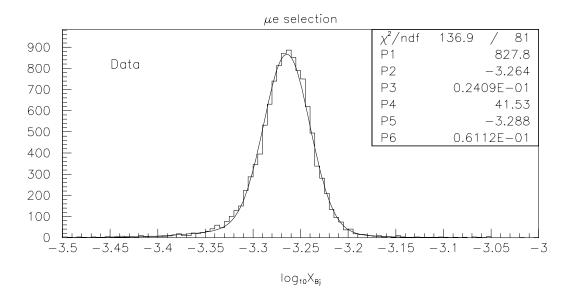

Figure 7.3: $log_{10}x_{Bj}$ for data events passing the μe selection. The curve is a sum of two Gaussians fitted to the data. The fit parameters are described in the text.

7.2.4 Calibration Check using the K_s^0 Mass Measurement

The neutral kaon can be used to check the calibration of the forward spectrometer. The mass of the neutral kaon is 497.67 ± 0.03 MeV, and the mean lifetime τ of the short-lived neutral kaon K_s^0 is $0.8926 \pm 0.0012 \times 10^{-10}s$, corresponding to $c\tau = 2.676$ cm. The K_s^0 decays into two charged pions with a branching ratio of $\sim 68\%$ [89].

Experimentally, the K_s^0 is detected by reconstructing a vertex of two oppositely charged tracks, which is detached from the primary muon-muon vertex. Such a vertex has a V^0 topology, i.e. the topology of a neutral particle decaying to two charged particles of opposite sign. The sample of reconstructed V^0 candidates contains true V^0's such as K_s^0, Λ^0, $\bar{\Lambda}^0$ and photon conversions $\gamma \to e^+e^-$, and also backgrounds due to small errors in the reconstructed track parameters.

In order to isolate a clean K_s^0 sample for the mass measurements, the following cuts are made.

- Both tracks contributing to the V^0 are required to have forward spectrometer contributions.

- The invariant mass of the V^0 is required to be greater than 0.1 GeV, when the charged particles are assigned electron masses. This cut $m_{e^+e^-} > 0.1$ GeV eliminates photon conversions.

- The position vector of the V^0 is computed by using the reconstructed position of the V^0 vertex and treating the primary muon-muon vertex as the origin. The 3-momentum vector of the V^0 is computed by using the parameters of the two tracks at their respective points of minimum distance of approach to the V^0 vertex. If the V^0 vertex is truly caused by the decay of a neutral particle, the position and momentum vectors would be collinear. Representing the position and momentum vectors in polar coordinates as (θ_r, ϕ_r) and (θ_p, ϕ_p) respectively, we make the following requirements:

$$\left| \frac{\theta_r - \theta_p}{(\theta_r + \theta_p)/2} \right| < 0.2$$
$$| \phi_r - \phi_p | < 0.3 \qquad (7.1)$$

Following these cuts, we plot the invariant mass of the V^0 assigning charged pion masses to the two tracks. The resulting invariant mass distribution is shown in figure 7.4. The distribution shows a sharp peak and a broad peak, both centered near the K_s^0 mass, and a fairly flat background. Superposed on the distribution is a fit to the sum of

two Gaussians and a second order polynomial. The parameters P_1, P_2, P_3 and P_4, P_5, P_6 show the normalization, mean and sigma of the two fitted Gaussians respectively, while the parameters P_7, P_8, P_9 are the coefficients of the polynomial describing the background. The narrow peak is clearly due to the K_s^0 signal, and we take the fitted mean of 496.6 ± 0.2 MeV to be the measured K_s^0 mass.
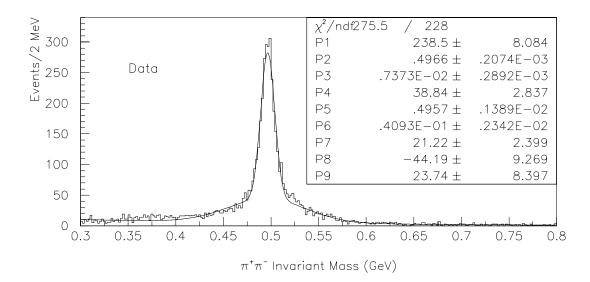

Figure 7.4: The $\pi\pi$ invariant mass distribution for V^0 vertices that pass the K_s^0 selection. The curve is the sum of two Gaussians and a polynomial fitted to the data. The fit parameters are described in the text.

The measured value is about 1 MeV lower than the value published by the PDG [89]. To use the measurement as a calibration check, we make the conservative assumption that the entire difference is due to a momentum scale error in the forward spectrometer. We scale up the momenta of both tracks by a factor of 1.003, and repeat the analysis of the K_s^0 mass measurement. This yields a value of 497.5 ± 0.2 MeV, in good agreement with the PDG value. Finally, we repeat the analysis once more with a scale factor of 1.005, yielding a K_s^0 mass of 498.1 ± 0.2 MeV which overshoots the PDG value. Hence we estimate an uncertainty of 0.35% in the momentum calibration of the forward spectrometer.

7.3   Detector Resolution

The resolution of a tracking device in free space is governed by three factors, the length of the track, the resolution of the individual hits contributing to the track, and the number of hits. With good knowledge of these quantities, the expected resolution on the track parameters can be calculated. In a realistic detector, the particle traverses some amount of material and this degrades the resolution due to scattering and energy loss. In practice, a Monte Carlo simulation of the tracking spectrometer is used to calculate the resolution.

The following relevant features of the spectrometers must be simulated. One is the longitudinal position of the proportional and drift chambers that make the spatial measurements of the track. The second is the wire spacing that governs the transverse resolution of proportional chambers, or the resolution of the drift chambers. These characteristics of the spectrometer are known by construction and also measured during the calibration process as described earlier. These measurements are used to model the detector in the Monte Carlo simulation. The probability with which various chambers contribute hits to a track must also be simulated. As described in the chapter on reconstruction efficiency, the efficiencies of various chambers have been measured and incorporated into the simulation. Finally, the GEANT program is used to model the presence of various materials at the appropriate locations in the spectrometer. Thus we expect that we have a good model of the tracking detector, and we expect to be able to calculate reliably the resolution of the detector.

The smearing of the muon kinematics due to the resolution is in general dependent on the kinematics. At some specific kinematic points, we can check the calculated smearing from the Monte Carlo against the data. We will use two such points, provided by the straight-through beams and the muon-electron scatters.

7.3.1   Resolution Checks using Straight-through Beams

For a non-interacting muon passing through the beam and forward spectrometers, we expect the measured energy loss ν, scattering angle θ_{scat} and the squared 4-momentum transfer Q^2 to all be zero. However, a finite value will be measured due to the chamber resolution and multiple scattering. In figure 7.2, we see that the ν resolution at 465 GeV is about 6 GeV. The Monte Carlo reproduces the resolution measured from the data quite well. As a test of the track-fitting calculation, we may normalize the measured ν to the calculated error on this quantity $\delta\nu$. If the calculation is correct, the result should be a Gaussian with a width of unity. As figure 7.5 shows, the calculated error

is somewhat of an overestimate, however the results for the data and Monte Carlo are similar.
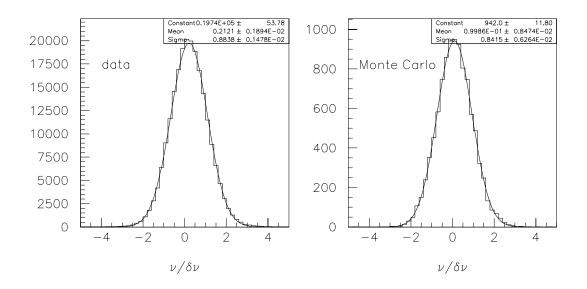

Figure 7.5: ν for straight-through beams normalized to the calculated error $\delta\nu$. The data and Monte Carlo results are shown

Figure 7.6 shows the Q^2 and scattering angle event distributions for straight-through beams obtained from Data and Monte Carlo respectively. We note that the typical reconstructed values are similar for Data and Monte Carlo, however there is a shoulder in the Monte Carlo distributions at the upper edge of the distributions. Since we will be making the structure function measurements in the range $Q^2 > 0.2$ GeV^2, the Q^2 resolution is a few percent or better. Hence we expect the smearing correction due to the angular resolution to be quite small.

7.3.2 Resolution Check using Muon-Electron Scatters

The muon-electron scatters mentioned earlier can also be used to check the resolution of the spectrometer. The width of the μe peak in the $log_{10}x_{Bj}$ distribution can be used for this purpose. As shown in figure 7.3, the width is $\delta log_{10}x_{Bj}$=0.0241±0.0003. This corresponds to $\delta \ln x_{Bj} = \delta x_{Bj}/x_{Bj} = 0.055$, i.e. a fractional resolution on x_{Bj} of 5.5%.
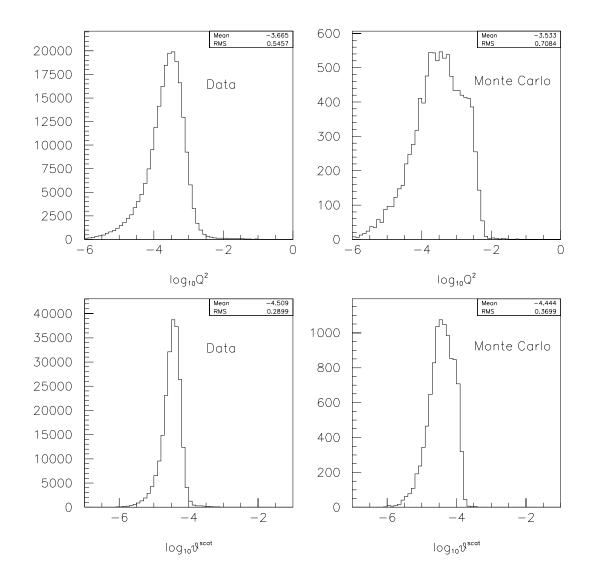

Figure 7.6: $log_{10}Q^2$ and $log_{10}\theta^{scat}$ event distributions for straight-through beams, for Data and Monte Carlo.

Figure 7.7 shows the deviation of the reconstructed x_{Bj} from the nominal value of m_e/m_p, normalized to the expected error calculated by the track-fitting program. If the error is correctly calculated, the r.m.s. would be unity. The distribution is fitted with two Gaussians to accommodate the backgrounds. The parameter P_3 is the r.m.s. of the main peak. We obtain an r.m.s. of 1.09 for data and 1.02 for the Monte Carlo, both of which are close to unity taking into consideration the larger background observed in the data under the μe peak.

7.3.3 Estimating the Resolution Smearing Corrections

In the structure function analysis, a fully binned Monte Carlo method is used to combine all the corrections due to the detector, including the resolution smearing. It is instructive to compute separately the correction to the measured cross-section due to resolution smearing. This gives us a feel for this aspect of the detector.

Using Monte Carlo events, one can study the differences between the generated and reconstructed kinematics as a function of the kinematic variables. We select the muon scattering angle θ and the muon energy loss ν as the two kinematics whose errors on average are uncorrelated with each other. On an event-by-event basis, an error in the reconstruction of a track slope affects the curvature and the scattering angle measurement. However, the track always bends in the same direction in the dipole field, while the scattering angle is distributed symmetrically in azimuth. The event-by-event correlations are expected to be wiped out by integrating over the symmetric distribution in the azimuthal angle ϕ. This is confirmed by the Monte Carlo.

Figure 7.8 shows the difference between the generated (true) and the reconstructed kinematics, as a function of kinematics. The size of the 'error bar' shows the r.m.s. in the quantities $\nu_{true} - \nu_{reconstructed}$ and $\ln\theta_{true} - \ln\theta_{reconstructed}$. $\ln\theta$ is chosen so that we can directly extract the fractional resolution $\delta\theta/\theta$. We see that the ν resolution is about 6 GeV at low ν, which is consistent with the straight-through beam studies, and improves to about 3 GeV at high ν, where it is dominated by the error on the beam track. The fractional resolution on θ is about 2.5% and is only weakly dependent on θ.

The envelopes of the plots in figure 7.8 is used to extract a smearing kernel for the variables $\ln\theta$ and ν. The smearing kernel is parametrized as follows:

$$\begin{aligned}
\sigma_{ln\theta} &= 0.03, log_{10}\theta < -2.4 \\
\sigma_{ln\theta} &= 0.015 - (log_{10}\theta + 2.0)/100.0, log_{10}\theta > -2.4
\end{aligned} \tag{7.2}$$

and

$$\sigma_\nu = \sqrt{9.0 + 0.000025 E'^2} \tag{7.3}$$

where E' is the scattered muon energy in GeV for a given ν in GeV. $\sigma_{ln\theta}$ and σ_ν are used as the r.m.s. of independent Gaussian random number generators.

In order to estimate the smearing correction, a fast Monte Carlo technique is used to generate about 200 million events. The parametrizations of F_2 and R structure functions, and the calculated radiative corrections are used to compute the total muon cross-section. This cross-section is modified by the computed detector acceptance so that events can be generated according to the distribution of the triggered and reconstructed events. The kinematics of the generated event are randomly smeared in ν and $\ln\theta$, according to the parametrized smearing kernel.

The true and smeared distributions for hydrogen are shown in figure 7.9. The smearing correction is defined as the ratio of the number of smeared events to the number of generated events in a bin. The smearing corrections for hydrogen and deuterium are shown in figure 7.10. At low ν there is a significant smearing correction, but it falls below 10% for $\nu > 25 GeV$. The angular resolution is good enough that the true and smeared $log_{10}Q^2$ distributions are very similar, and the smearing correction in Q^2 is less than 1%. Since the smearing corrections are small, the corrections made to the measured cross-section using the fully binned Monte Carlo should be quite accurate.

The cross-section for elastic scattering was not included in arriving at these estimates. Since the ν resolution is about 6 GeV, the contribution above $\nu_{smeared}$ of 25 GeV is negligible from the elastic events occurring at low ν and Q^2. At high ν and Q^2 the elastic cross-section itself is highly suppressed. Hence the omission of the elastic cross-section does not affect the estimates of the smearing correction in the region of interest.
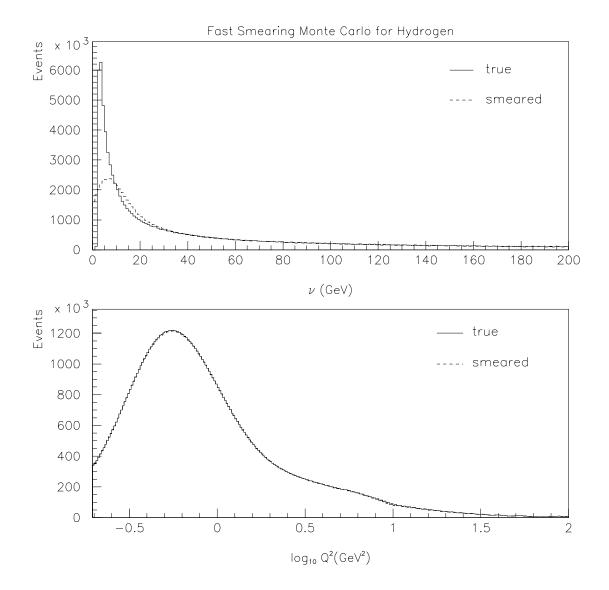

Figure 7.9: Distributions of generated (true) and resolution-smeared kinematics for hydrogen. The distributions are very similar for high ν and all Q^2.
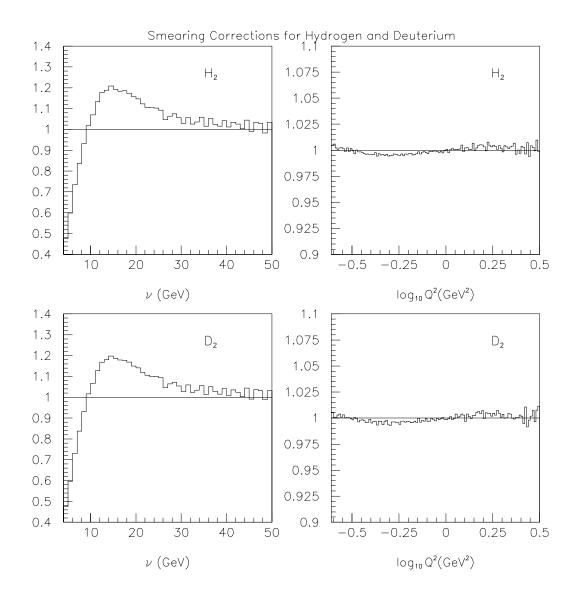

Figure 7.10: Smearing correction for hydrogen and deuterium.

Chapter 8

Radiative Corrections

In this analysis, the measurement is made of the inclusive muon-nucleon cross-section. However, the structure functions are related to the calculated cross-section in the Born approximation. In this sense, the structure functions are not directly measurable quantities in an inclusive cross-section experiment. They must be extracted from the measurement by using the calculated Born cross-section and the higher order QED effects, which are called radiative corrections.

8.1 Formulation

The higher order diagrams may be classified as follows:

- single virtual photon exchange between the lepton vertex and the hadron vertex.

- multiple virtual photon exchange between the lepton vertex and the hadron vertex.

We refer to the formulation of Mo and Tsai [68] and Tsai [69] of the radiative corrections to lepton-nucleon scattering. According to Appendix B of [68], the radiative tails from an unpolarized target to inclusive lepton scattering can be calculated exactly to order α_{em} if

1. The single virtual photon exchange mechanism is assumed.

2. The interference terms between real photon emission off the lepton and the hadron are ignored.

3. The measurement is sensitive only to the scattered lepton.

The virtue of the diagrams where there is only one virtual photon connecting the hadron with the lepton, is that these diagrams can be factorized into a lepton tensor and a hadron tensor. The hadron vertex has the same form as in the Born diagram, and therefore can be expressed in terms of the same structure functions. Therefore, this subset of diagrams can be calculated using the known physics for the lepton and the hadron structure functions. While the structure functions are *a priori* unknown, they can be extracted using an iterative procedure.

This factorization property does not hold for diagrams where two or more virtual photons are exchanged between the lepton and the hadron (figure 8.3c). The effect of the double virtual photon exchange can be estimated by comparing e^+p and e^-p scattering, because the interference of this diagram with the Born diagram is odd in the sign of the lepton. The difference between e^+p and e^-p scattering indicates that the effect of double virtual photon exchange is small. Model-dependent calculations (see discussion in [17]) show that the double photon exchange terms are typically logs or dilogs with argument Q^2/xs. At low x the argument is of order unity, giving small values for the log. The further suppression by a power of α_{em} justifies the neglect of these terms.

Henceforth we will make the assumption that the single virtual photon exchange mechanism is dominant. Furthermore, in the formulation of Mo and Tsai, all electromagnetic corrections to the hadron vertex (figure 8.3a, b) are absorbed into the definitions of the nucleon structure functions. Hence we are left with the following subset of diagrams:

- real photon emission off the incoming and outgoing leptons (figure 8.1).

- virtual Z^0 exchange and interference between virtual photon and virtual Z^0 exchange (figure 8.2a).

- loop correction to the lepton vertex (figure 8.2b).

- loop correction to the photon propagator, including e, μ, τ and quark loops (figure 8.2c).

The propagator loop diagrams have ultraviolet divergences, which are removed by renormalization of the electromagnetic coupling. The finite remainder is momentum-dependent and leads to the "running" of the electromagnetic coupling. The vertex

loop and the real photon emission both have divergences when the photon (virtual photon in the loop or real photon in the case of emission) becomes soft. The reason is that the electron propagators in the diagrams become very close to on-shell. It was shown by Bloch and Nordsieck [90] that the scattering of a charged particle is always accompanied by the emission of an infinite number of soft photons. One can understand this by observing that every photon emission involves an additional power of α_{em}, and an additional electron propagator. As the emitted photon becomes soft, the electron propagator diverges, which overwhelms the suppression due to the additional power of α_{em}. Fortunately, the theory rescues itself by the fact that the infrared divergences in the real photon emission diagrams, are cancelled by the infrared divergences in the virtual photon vertex loops, order-by-order in perturbation theory.

In the method of Mo and Tsai, an energy cutoff parameter Δ is introduced to define a soft photon. At lowest order, the cancellation of the infrared divergence in the emission and vertex loop diagrams gives a finite remainder δ, which is a function of the cutoff parameter Δ. It has been shown [91] that δ can be calculated for kinematical purposes by assuming a single real photon emitted, and the emission of an infinite number of soft photons can be incorporated into the calculation by replacing $1 + \delta \rightarrow e^{\delta}$. For the emission of hard photons more energetic than Δ, the lowest order calculation is used. This piece is finite and higher order contributions should be suppressed by powers of α_{em}.

In a robust calculation, the sum of the infrared piece and the hard photon piece should be independent of Δ. Studies [77] show this to be true to a very good approximation when $\Delta \sim 0.001 E_{beam}$. Hence, in this analysis, Δ is chosen to be 465 MeV.

The real photon emission off the incoming or outgoing leptons is sometimes referred to as internal bremsstrahlung. In addition to this, there is energy loss of the lepton in the target material before or after the scatter of interest (straggling). This energy loss may be due to the bremsstrahlung off other nuclei in the target (external bremsstrahlung) or ionization losses. At relativistic energies muons behave like minimum-ionizing particles so the ionization losses are small compared to the total energy. The external bremsstrahlung for muons is usually negligible since it is suppressed by a factor m_e^2/m_μ^2 compared to electrons.

8.2   Results

The radiative correction is calculated by the FERRAD program [61] using the Mo and Tsai scheme. The inputs to the program are described in chapter 3 (Structure Function
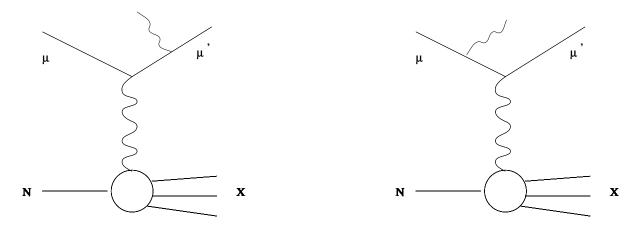

Figure 8.1: Lowest order diagrams for real photon emission off the incoming and outgoing lepton legs. These are included in the calculated radiative correction. For soft photon emission, higher order diagrams are also summed.
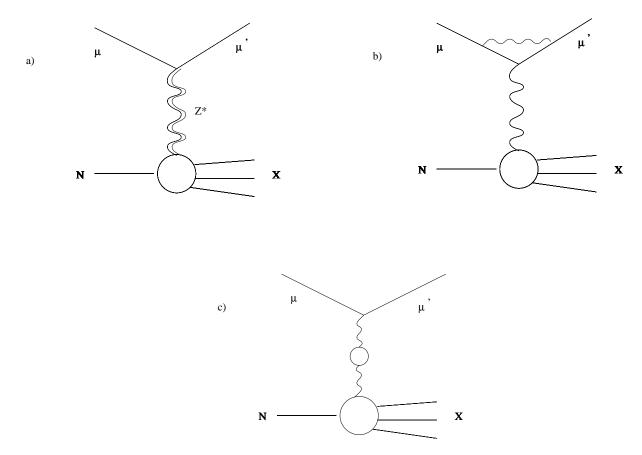

Figure 8.2: Lowest order corrections to the Born diagram included in the calculated radiative correction. a) Virtual Z^0 exchange and γZ interference is included in the radiative correction. b) Lepton vertex correction. c) Vacuum polarization, including e, μ, τ and quark loops.
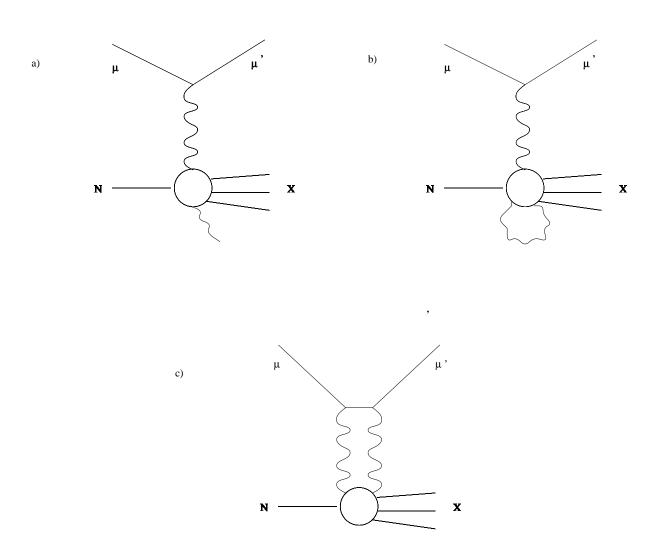

Figure 8.3: Diagrams not included in the calculated radiative corrections. a) & b) hadron corrections, which by definition are part of the hadron structure functions. c) Two photon exchange.

Analysis chapter). The internal integrations in FERRAD are performed using 280 steps in hadronic W, and 8 unequal intervals in the radiated photon angle optimized for speed and accuracy. Each of the 8 intervals are integrated using 35 equal steps. Further increase in the number of integration steps produced a negligible change in the result.

The radiative correction is defined by $\sigma_{tot}/\sigma_{1\gamma}$, where σ_{tot} is the inclusive muon cross-section and $\sigma_{1\gamma}$ is the Born cross-section. The measured σ_{tot} is divided by this ratio to extract the Born cross-section, which is then related to the structure function F_2. The correction is calculated on a 30×30 grid in x_{Bj} and y_{Bj}. The correction at any kinematic point is obtained by interpolating in a local 3×3 grid around the point of interest.

The total cross-section is given by

$$\sigma_{tot} = \sigma_{1\gamma} \times K \times (1 + vacpol + vertex + weak + small) + \sigma_{coher} + \sigma_{quasi} + \sigma_{inel} \quad (8.1)$$

where

- $K = e^{\delta}$ is the soft photon part of the radiative correction mentioned earlier. It varies between 0.9 at the low x range of the data to 0.8 at the high x range. Being less than unity indicates that in this range of x, soft photon radiation is causing more events to leak out of a bin of width Δ than leak in. It is similar for proton and deuteron because the inelastic structure functions for proton and deuteron have similar shapes over the x range of the E665 data.

- $vacpol$ is the correction due to vacuum polarization effects. It varies between 2% and 7% from low to high Q^2 range of the data. Again it is similar for proton and deuteron.

- $vertex$ is the correction due to the lepton vertex loop. It varies between 0.5% at low Q^2 and 3% at high Q^2.

- $weak$ is the effect of the Z^0 exchange. It increases with Q^2 but is typically smaller than 1% for $Q^2 < 100 GeV^2$. It is negative.

- $small$ contains small corrections to the infrared non-divergent part and the soft photon part. It is negative and less than 1%.

The bulk of the radiative correction comes from real photon emission. σ_{coher}, σ_{quasi} and σ_{inel} are the radiative tails due to hard photon radiation from other kinematic points. σ_{coher} is the tail from coherent nuclear scattering (zero for proton), σ_{quasi} is the tail from quasi-elastic muon-nucleon scattering, and σ_{inel} is the tail from inelastic scattering outside of the bin width Δ. At low x and high y, there is a large radiative correction from σ_{coher} and σ_{quasi}. This is because, for elastic scattering there is no minimum energy

transfer at small Q^2. Then there is a divergence in the muon propagator when it radiates away all its energy as a collinear high energy photon, and scatters elastically as a low energy muon. This divergence is regulated only by the muon mass. In contrast, inelastic scattering always involves some energy transfer, which serves to cut off the divergence in the cross-section. At low x, the sum of σ_{coher} and σ_{quasi} increases upto about 30% at the highest y of the data, while at high x it is small. Since the elastic form factors are different for proton and deuteron, the difference between the coherent and quasi-elastic tails for the two targets accounts for the bulk of the difference between the radiative corrections. σ_{inel} varies between about 15% and 25% from low to high x. σ_{inel} corresponds to events migrating into the bin from adjacent inelastic scattering bins. The positive contribution from σ_{inel} and the negative contribution from the K factor cancel each other to some extent.

The total radiative correction applied to the data, as a function of x_{Bj} and Q^2, is shown in figures 8.4, 8.5, 8.6 and 8.7. The correction is plotted for $y_{Bj} < 0.8$ because a similar cut is applied to the data sample used in this analysis. The correction is larger for the proton than the deuteron mainly because of the larger radiative tail from the elastic peak. This component increases with y, causing the radiative correction to reach a maximum at low x and high Q^2. There it is about 40% for the proton and about 25% for the deuteron.

8.3 Uncertainties

The calculated radiative corrections depend on the input $\sigma_{1\gamma}$ and the approximations made in the calculation. The dependence on the input $\sigma_{1\gamma}$ is investigated by varying the inputs by their respective measurement errors. This is discussed further in a later chapter in conjunction with the discussion of other systematic uncertainties. The accuracy of the Mo and Tsai formulation is estimated by comparison with the formulation of Bardin *et al.* This comparison [76, 77] shows that, when the radiative correction is as large as 50% at low x and high y, the difference between the two calculations is less than 2%. We therefore assign the systematic uncertainty on the radiative correction to be 4% of itself, originating from calculational inaccuracy.

Chapter 9

Luminosity

The absolute normalization for the muon scattering events is provided by the luminosity. As indicated in chapter 4, the luminosity measurement requires the understanding of the beam and the target. In addition, the response kernel of the detector can depend on the beam profile. For this reason, understanding the beam implies that the total number of useable beams and the beam distributions be known. We shall first discuss the beam and then the target.

9.1 Understanding the Beam

The normalization procedure involves the following strategy. Individual beam muons are tagged and reconstructed in the beam spectrometer. The hodoscopes in the beam spectrometer are used to provide a fast electronic signal to indicate the incoming beam muon. This signal serves three purposes. Firstly, it is used in coincidence with other signals indicating a muon scatter to form the trigger. Secondly, a randomly pre-scaled version of the beam signal is used to form a random beam trigger. Thirdly, the total number of beam pulses is counted by using two different scaler schemes that provide a cross-check on each other.

If the beam spectrometer response is the same for the random beam trigger and the physics trigger, then the number of usable beams can be accurately determined by counting the number of random beam triggers and multiplying this number by the pre-scale factor. The pre-scale factor is determined independently by comparing the number of random beam triggers with the number of actual beam signals counted by the scalers. This method has the advantage that the absolute beam spectrometer tagging

efficiency need not be known. This efficiency includes the hodoscope and beam track reconstruction efficiencies as well as the experimental dead times and loss of events during off-line processing. In addition, it includes the loss of beams due to off-line cuts that are used to define the usable beams. As long as the beams in the physics triggers are subjected to the same requirements as the beams in the random beam triggers, the effect cancels in the ratio of physics triggers to random beam triggers.

9.1.1   Beam Spectrometer Response

As mentioned above, the experiment is designed so that the beam spectrometer response will be the same for all triggers. The only reason for the response to be different is differences in the trigger timing. This can cause changes in the latching efficiencies of electronic signals and hence change the efficiencies of various on-line and off-line requirements.

A detailed study of the trigger timing is provided in [92, 93]. These results showed that all the triggers have similar timing to better than $0.5ns$, with the exception of the SVSWAM2 trigger (which is not used in this analysis). The jitter in the trigger time is about $1ns$, and the trigger time for all triggers is stable within $2ns$ over the entire run (again with the exception of the SVSWAM2 trigger). The run dependence of the average trigger times is shown in figure 9.1.

In order to test the sensitivity of hodoscope latching efficiencies to variations in trigger time, we study the probability that the simulation of various elements of the trigger logic is satisfied. The simulation requires that there be latched hits in the appropriate beam hodoscopes, and the SSA and SMS hodoscopes in the Y and Z views. We expect all of these hodoscopes to have latched hits for RSAT triggers, because these events are triggered on straight-through beams which will pass through all these hodoscopes. The probability that RSAT events satisfy the beam hodoscope requirements was shown in figure 6.2. Figure 9.2 shows the run dependence of the probability that the SSA and SMS hodoscopes record a hit. These plots show no run dependence, and in particular no correlation with the $2ns$ trigger time shifts seen in figure 9.1. Therefore we conclude that the detector response is not very sensitive to any difference between triggers. As mentioned in the chapter describing the trigger efficiency, the difference in the beam spectrometer response contributes an uncertainty of 0.2% to the calculated luminosity.
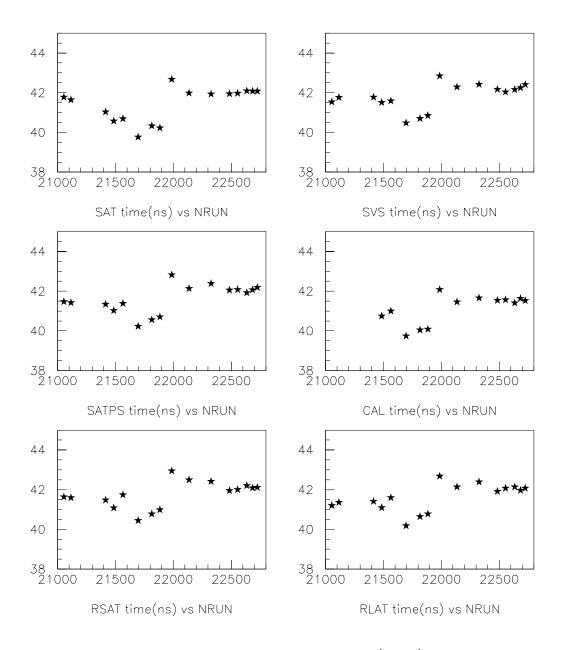

Figure 9.1: Run dependence of the average trigger time (in ns) for various triggers. The time measurement involves an arbitrary offset. The CAL trigger was not installed in the early part of the run.
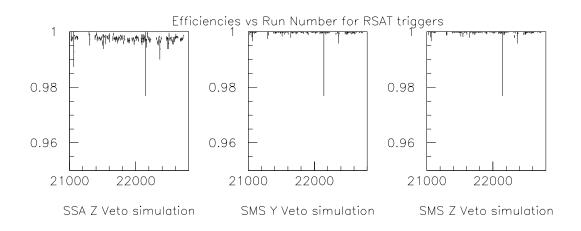

Figure 9.2: Run dependence of the SSA and SMS latching efficiencies, as measured by the trigger element simulation software applied to RSAT triggers. For these events these elements should always be hit by the beam muon.

9.1.2 Beam Counting

The issue of counting the total number of beams is now reduced to measuring the prescale factor for the random beam trigger. The function of pre-scaling the electronic beam signal is performed by special hardware circuits that provide pseudo-random pre-scaling. These modules are programmed to provide a prescale factor of 2^{19}. To guard against small deviations from the preset value, the prescale factor is measured using beam scalers.

Details of the scaler schemes and the prescale factor measurement are provided in [59]. Two sets of scalers are used, one being read out and reset after each spill, and the other being read out and reset after each event. The run dependence of the prescale factor is examined, and no significant deviation from the average value is found. The measurement is performed separately with the hydrogen and deuterium target in place, and with the event scalers and spill scalers. All measurements are consistent with each other within the statistical uncertainty. The prescale factor used in this analysis for RSAT triggers is 526718±800, corresponding to 0.0015% uncertainty in the beam counting. The base 2 logarithm of the measured prescale factor is 19.007.

9.1.3 Beam Distributions

The final aspect of understanding the beams is the correct reproduction of the beam distributions in the Monte Carlo. This ensures that the acceptance corrections extracted from the Monte Carlo have used the correct underlying distributions to average over (equation 4.5). Detailed studies of the beam distributions are provided in [62], and the procedure used to include them in the Monte Carlo generation is discussed in chapter 4. Here we provide comparisons between the beam distributions measured from the data and the Monte Carlo (figures 9.3 and 9.4). The events are RSAT that satisfy the final beam phase space cuts used in the analysis. The position distributions are shown at the PBT3 beam station (X=-36.8m), the target (X=-12.5m), and the PCF5 chamber (X=0.218m). The beam parameters reported at PBT4 are used to make straight-line extrapolations to PBT3 and the target since the magnetic fields are nominally zero in this region. The beam track is swum through the CVM and CCM fields using the measured momentum to report the position at PCF5. The distribution in energy and the error in the curvature of the beam track is also shown. The Monte Carlo is able to reproduce the distributions.

9.2 Understanding the Target

The relevant properties of the target are the length, composition and density. These will be discussed in turn.

9.2.1 Target Length

The cryogenic liquid target vessels are cylindrical and made of mylar, surrounded by an insulating Rohacell jacket. A vacuum was maintained between the mylar vessel and the Rohacell jacket for insulation purposes. The targets are nominally one meter long and have a diameter of 10 cm. In order to measure the lengths of the targets, the temperature and pressure conditions existing during running have to be reproduced. The cryogenic hydrogen and deuterium targets are operated at a pressure of $\sim$15 p.s.i. and a temperature of $\sim$20K. In order to compute the length of the target under these conditions, the target length is measured [94] using a precision scale under three sets of conditions: room temperature at normal pressure, room temperature at 15 p.s.i., and liquid nitrogen temperature at 15 p.s.i. The precision of the length scale is about 0.01 inch. The temperature coefficient at 15 p.s.i. is calculated to be $1.3 \times 10^{-5}/degreeC$, which can be compared with the published value of $1.7 \times 10^{-5}/degreeC$. Using these

180
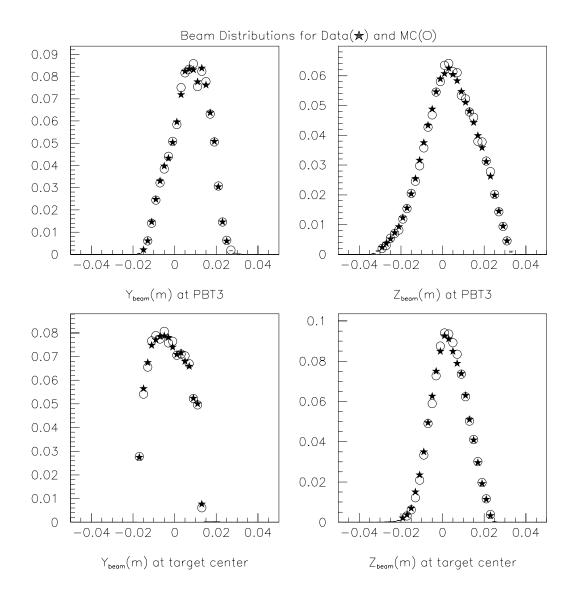

Figure 9.3: Position distributions of RSAT beam tracks, compared for Data and Monte Carlo.
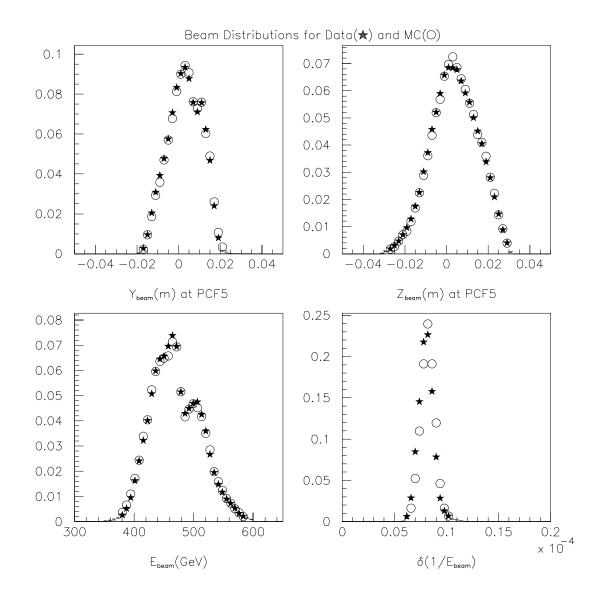

Figure 9.4: Position, energy and curvature error distributions of RSAT beam tracks, compared for Data and Monte Carlo.

measurements, the following target lengths are computed for the cold targets:

$$Hydrogen: \quad length = 99.1 \pm 0.035cm$$
$$Deuterium: \quad length = 98.9 \pm 0.035cm \tag{9.1}$$

The uncertainty includes the error in the temperature coefficient and the accuracy of the length scale.

The length measurement is performed along the axis of the cylindrical target vessel. The vessel end caps are made semi-circular so that they do not deform under pressure. The geometry of the target vessel is shown in figure 9.5. Due to the curvature of the end caps, the length of target material traversed by each beam depends on the transverse position of the beam relative of the target axis. To take into account this effect, we must first determine the transverse position of the target. We use the reconstructed vertex position in the transverse dimensions to measure the position of the target. The Y and Z positions of the target axis are determined to be

$$Hydrogen: \quad y_c = 0.028m, z_c = -0.006m$$
$$Deuterium: \quad y_c = 0.028m, z_c = 0.0m \tag{9.2}$$
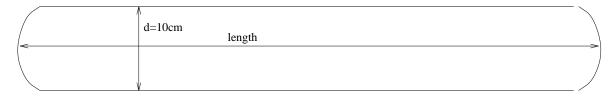

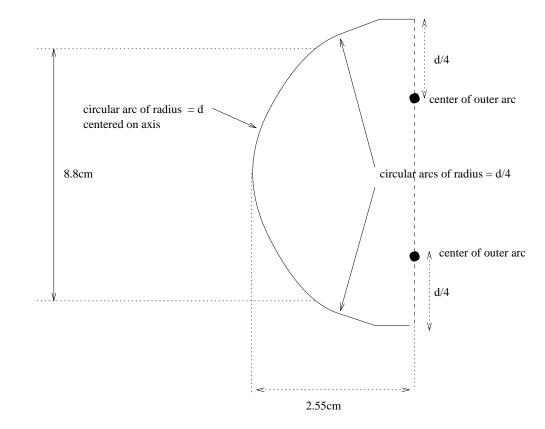

Using the coordinates of the beam in each reconstructed random beam event, the actual target length traversed by the beam is computed, using the shape indicated in figure 9.5. The luminosity contributed by each beam muon is then weighted by the actual target length for that beam relative to the nominal target length. In run91, the beam profile intersected the edge of the target, where the target length changes due to the curvature of the end caps. The uncertainty in the transverse position of the target contributes an uncertainty of 0.5% to the luminosity.

9.2.2 Target Density

The saturated vapour pressures in the targets are continuously monitored and used to calculate the target temperatures and therefore the densities [59]. The density of the liquid target is fairly insensitive to the pressure. The molar density of molecular hydrogen is measured to be 0.035022 moles/cc. Due to changes in the hydrogen deuteride (HD) contamination in the D_2 between different running periods, the molar density of D_2 is measured to be 0.040346 moles/cc for the period prior to run number 21601, and 0.040487 moles/cc in the latter period.

9.2.3   Target Composition

The chemical composition of the targets were measured using a boil-off test [59]. The deuterium target was found to be contaminated with hydrogen deuteride (HD). The HD contamination has two effects on the molar density of nucleons. Firstly, the physical properties of HD are slightly different from D_2, so at the same temperature and pressure the molecular density of the target changes due to the contamination. This is a relatively small effect. The main effect is that in a molecule of HD there is one nucleon (neutron) less than a molecule of D_2. Therefore, even though the molecular density does not change very much, the nucleon density changes substantially when D_2 is replaced by HD. Furthermore, the change in the scattering rate depends on the neutron-to-proton cross-section ratio.

In order to correct the deuterium scattering rate for the HD contamination, we define the neutron cross-section as the difference between the deuteron and the proton cross-sections. The measured scattering rate on the deuterium target is

$$R_{measured} \propto (\alpha \sigma_n + \beta \sigma_p) \qquad (9.3)$$

while the "true" scattering rate in the absence of HD contamination would be

$$R_{true} \propto (\sigma_n + \sigma_p) \qquad (9.4)$$

β differs from unity because of the change in the molecular density (each molecule of HD contains the same number of protons as a molecule of D_2). α differs from unity due to the change in the molecular density as well as the absence of one neutron in an HD molecule. The α and β values are extracted using the measured HD contamination [59] and quoted here

$$run < 21601 : \quad \alpha = 0.98372, \beta = 0.99944$$
$$run > 21601 : \quad \alpha = 0.95219, \beta = 0.99838 \qquad (9.5)$$

Each scatter on the deuteron target is re-weighted by the ratio $R_{true}/R_{measured}$ in order to estimate the scattering rate that would occur if the target had been pure deuterium. The correction requires the knowledge of σ_n/σ_p, for which we use the E665 measurement [59] at low x and Q^2 and the parametrization of data from previous measurements (Appendix B) over the rest of the kinematic range. The correction is about 2.2% at low x where σ_n/σ_p is close to unity, and is smaller at larger x.

The uncertainty in the density measurement amounts to 0.05% for hydrogen and 0.6% for deuterium. The uncertainty in the density for hydrogen comes from the uncertainty in the pressure readout accuracy and the pressure-to-density relationship. The uncertainty in the deuterium density includes this, and the uncertainty in the correction for the HD contamination.

Chapter 10

Structure Function Results

All of the information obtained and discussed in the previous chapters is used in the extraction of the structure function. The flow of the analysis program used to obtain the results is now discussed. This will include the cuts made on the data to define the final sample. The motivation and the efficiency of the various selection criteria have already been described in the preceeding chapters. The results and the determination of the systematic uncertainties will be discussed.

10.1   Beam Selection

The first step in the structure function measurement procedure is the selection of the usable beam muons. The measurement is performed by counting the scattered muon events selected by the Small Angle Trigger (SAT), and the luminosity is measured by counting the random beam triggers (RSAT) defined in conjunction with the SAT. The same selection is applied to the RSAT and the SAT events, which are randomly mixed with each other in the data stream. This ensures that the efficiency of the beam selection cuts cancels in the normalization of SAT to RSAT events.

The following criteria are imposed:

- The run number $NRUN$ must lie in the range $21350 < NRUN < 22080$ or $22120 < NRUN < 22450$. During these running periods the chamber efficiencies are high. The very early running period shows some loss of efficiency in the drift chambers. The very late running period shows loss of efficiency in many of the

forward spectrometer chambers.

- One and only one beam track should be reconstructed in the beam spectrometer. This simplifies the counting of usable beams and also removes any ambiguities in the reconstruction of the beam-scattered muon vertex. Approximately 10% of the events contain multiple beam tracks, most of which are stale tracks.

- The latched hits in the beam hodoscopes are required to satisfy the SAT beam logic. This ensures that the beam track occurred in the proper time window of the trigger.

- The spill monitor is used to identify events where a second beam muon traversed the spectrometer within the time window specified by eleven radio-frequency (RF) buckets preceeding and six RF buckets succeeding the trigger bucket. These events are removed from the sample. This cut eliminates the trigger vetoes due to the out-of-time beams and improves the reconstruction efficiency in the forward spectrometer in the beam region.

- The beam track is extrapolated in a straight line from the most downstream beam station (PBT4) to the upstream and downstream face of the target (-13m and -12m respectively). At each face a cut is made on the transverse coordinate of the beam, to ensure that the beam traverses the full length of the target material. The transverse position of the beam is required to be within 4.6cm of the longitudinal axis of the target. Approximately 30% of the beams are removed by this cut, because the beam was hitting the edge of the target.

- The reconstructed beam momentum is required to be with the range of 350 GeV and 600 GeV. A very small fraction of the events lie in the tails of the beam momentum distribution outside this range.

Following this selection, the surviving RSAT events are used to measure the luminosity, while the SAT events are subjected to further selection as discussed below. The RSAT events are weighted to correct for target length effects as discussed in chapter 9. For nominal 1m targets, the final number of weighted RSAT events is 159853 for hydrogen, 100648 for deuterium and 31796 for the empty liquid target.

10.2   Scattered Muon Selection

The following cuts are made on the reconstructed parameters and the scattered muon track:

- The scattered muon momentum must be greater than 100 GeV. This makes the muon mismatch probability negligible, reduces the radiative corrections and the correction due to R, and also reduces the muon multiple scattering in the hadron absorber, making the trigger easier to understand.

- The muon energy loss ν must be greater than 35 GeV. This eliminates the contamination from straight-through beams and restricts the data to the region where the smearing corrections are small.

- The calculated fractional error on the reconstructed ν must be less than 0.5, i.e. $\delta\nu/\nu < 0.5$. This cut was embedded in the output filter during data reconstruction. It had a minimal effect given the cut on ν.

- The transverse position of the scattered muon, when projected to the SMS hodoscopes defining the SAT veto window, must be at least 1.5cm outside the edge of the window.

- Similarly, the transverse position of the scattered muon, when projected to the SSA hodoscope, must be at least 2.5mm outside the edge of the SSA veto window.

- The longitudinal position of the reconstructed vertex must be within the range $-13.5m < X_{vtx} < -11.5m$. The nominal target position is between -13m and -12m. Due to resolution smearing in X_{vtx}, in-target scatters can be reconstructed outside this range. About 3% of the in-target scatters are lost by the requirement $-13.5m < X_{vtx} < -11.5m$. This loss is corrected by Monte Carlo. The off-target scatters included by the cut are statistically subtracted using empty target data.

- The scattered muon track is required to receive a contribution from the PSA or drift chambers. This ensures good resolution on the scattered muon. This requirement is made by asking that the last detector plane contributing to the track be downstream of the 2m mark, in the E665 coordinate system.

- Reconstructed scattered muons extrapolating into certain regions of the drift chambers or PSA are excluded from the sample. These are in certain low efficiency regions which are straight-forward to define geometrically. For the PSA, the acceptable region is defined as:

$$(Y_{PSA} + 0.024)^2 + (Z_{PSA} - 0.005)^2 < 0.065^2$$

where the coordinates are defined at the PSA in meters. This defines a circular region where all PSA chambers overlap and the efficiency is high. For the drift chambers, the muons passing through the septum region of either drift chamber station are removed. The septum regions are defined as:

$$-0.005m < Y_{DCA} < 0.035m$$
$$-0.045m < Y_{DCB} < -0.005m$$

- $-0.3m < Y_\mu < 0.3m$ and $-0.2m < Z_\mu < 0.2m$, where these scattered muon coordinates are measured at $X = 4m$, and $\theta_{scat} < 20mrad$. The motivation for these cuts is discussed in chapter 5, where it is shown that at large distances from the center of the CCM, there is a loss of scattered muon rate in the data which is not reproduced by the Monte Carlo. Since the reasons for this are not yet fully understood, we do not use the data from these outer regions of the detector in the structure function analysis.

10.3 Estimation of Systematic Uncertainties

The Monte Carlo sample of events is subjected to the same selection criteria as the data, in order to derive the corrections due to the detector response. The quality of the Monte Carlo has been discussed extensively in the preceeding chapters. The studies mentioned therein are used to estimate the uncertainties in various aspects pertaining to this measurement. The systematic uncertainties that depend on the scattering kinematics are grouped in six categories: trigger efficiency, reconstruction efficiency, absolute energy scale, relative energy scale between the beam and forward spectrometers, radiative correction, and variation in R. There is also an overall normalization uncertainty which does not depend on the scattering kinematics. These sources of uncertainty will be discussed in turn.

10.3.1 Trigger Efficiency

The kinematics-dependent systematic uncertainty in the Small Angle Trigger (SAT) efficiency comes from three sources: ignorance of hodoscope geometry, SMS veto probability and SSA veto probability.

Geometry

There is some uncertainty in the position of the various hodoscope elements that participate in the SAT. This limits the accuracy with which the Monte Carlo model simulates the geometrical acceptance of the SAT. To evaluate the sensitivity to the hodoscope positions, the SSA veto window is enlarged by $1mm$ on each edge, and the SMS veto window is enlarged by $2mm$ on each edge using the reconstructed muon track, both in the data and the Monte Carlo. The acceptance correction is re-evaluated from the Monte Carlo and applied to the data. The fractional change in the measured F_2 ($(F_2^{new} - F_2^{standard})/F_2^{standard}$) is given in the column marked **G** in tables A.1, A.2 and

A.3. The absolute magnitude of the change is used as the systematic error estimate.

SMS veto probability

Even if the muon were to fall outside the geometrical acceptance of the SMS veto, the trigger may still be vetoed by shower particles etc. accompanying the muon as it passes through the hadron absorber. The probability of this sort of veto has been measured, and the uncertainty on the probability is estimated at 15% of itself. In order to estimate the effect of this uncertainty on each bin, the Monte Carlo parametrizations of this probability are varied in both directions by 15%. The acceptance correction is re-evaluated in both cases and applied to the data. The resulting change in the measured F_2 in quoted in the columns marked **M+** and **M-** (for an increase and decrease in the SMS veto probability) in tables A.1, A.2 and A.3. Half of the difference is used as the systematic uncertainty in each bin.

SSA veto probability

Even if the muon were to fall outside the geometrical acceptance of the SSA veto, the trigger may still be vetoed by hadrons or other particles produced by the muon interaction in the forward spectrometer. The probability of this sort of veto has been measured, and the uncertainty on the probability is estimated at 10% of itself. In order to estimate the effect of this uncertainty on each bin, the Monte Carlo parametrizations of this probability are varied in both directions by 10%. The acceptance correction is re-evaluated in both cases and applied to the data. The resulting change in the measured F_2 in quoted in the columns marked **A+** and **A-** (for an increase and decrease in the SSA veto probability) in tables A.1, A.2 and A.3. Half of the difference is used as the systematic uncertainty in each bin.

Combined uncertainty in trigger efficiency

Since the three sources of uncertainty mentioned above are independent, they are combined in quadrature to arrive at the uncertainty in F_2. This is quoted in the column marked **TR** in tables A.13-A.18.

10.3.2   Reconstruction Efficiency

We include in this category the efficiency of reconstructing the scattered muon vertex (which depends on the multiplicity and the scattering angle), and the DC-PSA efficiency. These three effects are kinematics-dependent.

Multiplicity dependence

The uncertainty in the inefficiency is estimated at 10% of the inefficiency itself, when plotted as a function of event multiplicity. The inefficiency is adjusted in the Monte Carlo by 10% of itself in both directions, and the data is corrected with the adjusted Monte Carlo. The percent change in the measured F_2 is given in the columns marked **N+** and **N-** respectively in tables A.4, A.5 and A.6. Half of the difference is assigned as the systematic uncertainty in F_2 due to the uncertainty in the multiplicity dependence of the efficiency.

Scattering angle dependence

The reconstruction efficiency can depend on scattering angle, but the Monte Carlo cannot be validated by comparing with data directly, because the scattering angle cannot be measured unless the muon is already reconstructed. We used the different triggers to obtain event distributions biased towards small and large angles respectively. An adjustment was made to the Monte Carlo to match the data by interpolating in scattering angle. This procedure used all available information, hence it was used in quoting the measured F_2. The uncertainty in this procedure is estimated by ignoring the angular dependence of the Monte Carlo adjustment, and redoing the F_2 measurement. The fractional change in F_2 is quoted in the column marked **A** in tables A.4, A.5 and A.6. It is assigned as the systematic uncertainty due to the possibility that the angular dependence of the efficiency is not completely understood.

DC-PSA efficiency

While the DC and PSA chambers are not essential for reconstructing the event, they are required to contribute to the scattered muon track to ensure good resolution. The efficiency of this requirement is measured from data and Monte Carlo, and a final adjustment is made to make the Monte Carlo match the data in this respect. The change in F_2 when this adjustment is removed is given in the column marked **DS** in tables A.4, A.5 and A.6. The uncertainty in the DC-PSA efficiency is estimated to be the full size of this change.

Combined uncertainty in reconstruction efficiency

Since the three sources of uncertainty mentioned above are independent, they are combined in quadrature to arrive at the uncertainty in F_2. This is quoted in the column marked **RE** in tables A.13-A.18.

10.3.3   Absolute Energy Scale Error

The uncertainty in the absolute energy scale is estimated at 0.35%. The kinematics of each event in the data are re-evaluated after the beam and scattered muon momenta are scaled up by a factor of 1.0035 while preserving the scattering angle. The events are then subjected to the standard structure function analysis. The procedure is then repeated while all energies are scaled down by the same factor. Half of the difference between the F_2 obtained from these procedures is quoted as the systematic uncertainty due to the energy scale error (tables A.13-A.18, column **EA**). The sign gives the direction of the change in F_2 if the true energy scale were higher than what we nominally use.

10.3.4   Relative Energy Scale Error

The uncertainty in the relative energy scale between the beam and forward spectrometers is estimated at 0.3%. The kinematics of each event in the data are re-evaluated after the beam momentum is increased by a factor of 1.0015 and the scattered muon momentum is decreased by the same factor, while preserving the scattering angle. The events are then subjected to the standard structure function analysis. The procedure is then repeated while the direction of the change is reversed for each track. Half of the difference between the F_2 obtained from these procedures is quoted as the systematic uncertainty due to the relative energy scale error (tables A.13-A.18, column **ER**). The sign gives the direction of the change in F_2 if the true muon energy loss were higher than what we nominally measure.

10.3.5   Radiative Corrections

The uncertainty in the calculated radiative corrections arises from approximations in the calculational technique itself, and the uncertainty in the input F_2. The uncertainty in the calculation is taken as 4% of itself as discussed in chapter 8. This corresponds to an uncertainty in F_2 of less than 2%.

The kinematic plane in $Q^2 - W$ is divided into three regions: the low W region including the elastic, the high W-low Q^2 region including photoproduction, and the high W-high Q^2 region. The low W region is defined by $W < 5GeV$. For the high W region, the low and high Q^2 regions are demarcated by $Q^2 = 3GeV^2$. The input F_2 is varied independently in each of the three kinematic regions by the measurement errors. The elastic cross-sections and the low W structure functions are varied together

in both directions by 5% and 10% respectively [95, 73, 74]. In each case, the high W-low Q^2 and the high W-high Q^2 structure functions are varied in opposite directions by 10%. It was found that this variation pattern maximizes the change in the calculated radiative corrections. This procedure allows for a change in the overall magnitude of F_2 as well as a change in the slope with respect to Q^2 and W. The uncertainties in the photoproduction cross-section ($\sim$5% [35]), the high W inelastic structure functions, and the interpolation between them at very low Q^2 are taken into account.

Following this procedure, four sets of calculated radiative corrections are obtained, each of which is used to re-evaluate the measured F_2. The fractional change in each case from the standard measurement is shown in tables A.7, A.8 and A.9. The columns are labelled at the top of the table, with an explanation of the change made in each kinematic region. As described in appendix B, the low W parametrization is called F2LOWW, F2DOLA is the high W, low Q^2 parametrization including photoproduction, and F2NMC is the high W, high Q^2 parametrization. "*1.1" indicates scaling up the structure function by 10% while "/1.1" indicates reduction by 10%.

The systematic uncertainty in the measured F_2 in each bin, is taken as half of the maximum variation between any two of the four measurements. It is added in quadrature with the uncertainty in the calculational technique, to quote the total systematic uncertainty due to radiative corrections (column **RC**, tables A.13-A.18).

10.3.6 Variation in R

The extraction of F_2 from $\sigma_{1\gamma}$ requires the knowledge of $R = \sigma_L/\sigma_T$. We have used R_{slac}, which is obtained from a global analysis of SLAC data [78]. The details are provided in appendix C. The systematic uncertainty in F_2 is quoted by varying R_{slac} in both directions by the error on it. The fractional change in F_2 due to either variation in R_{slac} is given in the columns marked R_s+ and R_s- in tables A.10, A.11 and A.12. Half of the difference is quoted as the systematic uncertainty in F_2 due to variation in R_{slac} (under the column marked **RS** in tables A.13-A.18). In tables A.10, A.11 and A.12 we have also quoted the fractional change in F_2 when we assume $R = 0$, and $R = R_{QCD}$. The parametric expression for R_{QCD} that was used is given in appendix C. In the column marked R_A of tables A.10, A.11 and A.12, we quote the fractional change in F_2 when we use R calculated using the modified MRS(A) set of parton distributions in the $\overline{MS}$ scheme [96].

10.3.7 Bin Edges and Bin Centering

The kinematic boundaries in ν and E_{scat} cut through the bins in x and Q^2, making the bins at the edges of the kinematic phase space difficult to understand. In order to select the usable bins, the F_2 measurement is performed with the set of cuts $\nu > 25 GeV, E_{scat} > 80 GeV$ and again with the cuts $\nu > 50 GeV, E_{scat} > 120 GeV$. In each case the acceptance in each bin is recomputed from the Monte Carlo using the same cuts. The measurements are compared bin-to-bin, and any bin in which the measurement changes by more than 5% is removed. This method only removes the edge bins. The final F_2 measurements are quoted in the remaining bins. To measure the residual uncertainty due to the kinematic cuts, the measurement is repeated using the cuts $\nu > 25 GeV, E_{scat} > 90 GeV$ and $\nu > 45 GeV, E_{scat} > 110 GeV$. Half of the difference in each bin is included in the systematic uncertainty. A similar procedure is applied for understanding the effect of the cuts on the Y and Z positions of the scattered muon at $X = 4m$, and the maximum scattering angle cut. The F_2 measurement is repeated after removing the maximum scattering angle cut, while maintaining the Y and Z position cuts. The measurement changes only at the high Q^2 edge bins, and always less than 10% except in two bins. These two bins are removed. In the remaining bins the change is used as an estimate of systematic uncertainty due to the combination of bin edge effects and the the detector modelling at large scattering angles.

The structure function is defined at kinematic points, however the measurement is performed in bins. This means the measurement produces a bin-integrated average. In order to quote a value at bin center, an estimate of the derivatives of F_2 beyond the first derivative is required (for a linear function, the bin-integrated average is equal to the value at bin center). We have used the parametrization of F_2 described in appendix B to estimate the correction due to the derivatives beyond first order. We have chosen to quote F_2 at the center of the bin in $log x$ and $log Q^2$. The bin-centering correction is performed by weighting each event in the data by the ratio $F_2(log x_c, log Q_c^2)/F_2(log x, log Q^2)$, where F_2 is obtained from the parametrization and the subscript "c" denotes bin center. The bin-centering correction is small except at the lowest x, where it is about 5%, and above x of 0.1 (where the bins are wide), where it is about 10%. The systematic uncertainty is estimated by using instead a parametrization fitted to our data. The difference is negligible except at the highest and lowest x of the data. It is included in quadrature as the systematic uncertainty in the bin-centering correction. The column marked **BN** in tables A.13-A.18 shows the quadrature-combined uncertainty from all the bin edge and bin centering effects discussed above.

10.3.8 Systematic Uncertainty Independent of Kinematics

Certain sources of error are independent of the scattering kinematics, hence they lead to an uncertainty in the overall normalization of F_2.

The contributions from the uncertainty in luminosity-related measurements are as follows:
beam spectrometer response 0.2%, random beam prescale factor 0.15%, nominal target length 0.035%, uncertainty in target length due to target wall curvature 0.5%, effective density for pure targets hydrogen 0.05% and deuterium 0.6%. The statistical uncertainty on the final number of random beam events is 0.34% for hydrogen and 0.53% for deuterium (following empty target subtraction). Adding in quadrature, these amount to an total uncertainty in the luminosity of 0.7% for hydrogen and 1.0% for deuterium.

The uncertainty in the trigger logic simulation is 1.3%, and it was shown that this is not sensitive to scattering kinematics. Hence we include it in the overall normalization uncertainty. Finally, the muon match efficiency was shown to be fairly independent of momentum and position of the muon, within about 1%. We include an uncertainty of 1% from this source. Therefore the total uncertainty in the overall normalization of F_2 is 1.8% for hydrogen and 1.9% for deuterium, obtaining by adding the contributions in quadrature.

10.4 Fitting the Measured F_2

In order to fit F_2 over our kinematic range, we use a parametric function that is motivated in part by the function used by NMC [11], and in part by the parametrization of Donnachie and Landshoff [35]. We define the following functions:

$$
\begin{aligned}
A(x) &= x^{a_1}(1-x)^{a_2}[a_3 + a_4(1-x) + a_5(1-x)^2 + a_6(1-x)^3 + a_7(1-x)^4] \\
B(x) &= b_1 + b_2 x + b_3/(x + b_4) \\
f_{hiQ^2} &= A(x)[\frac{ln(Q^2/\Lambda^2)}{ln(Q_0^2/\Lambda^2)}]^{B(x)} \\
Q_0^2 &= 20\,GeV^2 \\
\Lambda &= 250\,MeV \\
f_{loQ^2} &= c_1 x^{-0.0808}(\frac{Q^2}{Q^2 + (c_1/0.604)^{0.9252}})^{1.0808}[1 + c_2(W - 20)] \\
g &= \frac{1}{1 + e^{(Q^2-3)/1.5}}
\end{aligned}
$$

$$F_2^{fit} = f_{loQ^2}.g + f_{hiQ^2}.(1-g) \tag{10.1}$$

The function f_{hiQ^2} is motivated by QCD evolution, while f_{loQ^2} follows a form approaching the photoproduction limit. The function g is used to make a smooth transition with Q^2 between the two functions. Except for the c_2 term, f_{loQ^2} is constrained to match the real photoproduction cross-section. The c_2 term is introduced to fit the observed departure of the W dependence of the virtual photoproduction cross-section from the real photoproduction cross-section.

As we showed in chapter 4, the acceptance and the radiative corrections made to the raw event count to extract F_2 in fact depend on the structure function. Hence we use the results of the fit in an iterative process to force consistency between the input and the output structure function. However, we have to be careful not to extend the fit beyond the range of the data. We find that the strength of the E665 data lies at low x and low Q^2, while the high x, high Q^2 regime has been measured extensively by NMC and BCDMS, connecting smoothly with the high x, low Q^2 data from SLAC. Hence we use the parametrization of those data described in appendix B for $x > 0.05$, and the fit to the E665 data described above for $x < 0.05$. In addition, we do not measure the structure function at very low Q^2, i.e. $Q^2 < 0.2 GeV^2$. Hence we connect our fit smoothly with the Donnachie-Landshoff parametrization at lower Q^2 which matches the real photoproduction cross-section at $Q^2 = 0$. Denoting the global F_2 function of appendix B as F_2^{global} (which includes the Donnachie-Landshoff parametrization at low Q^2 and the SLAC-NMC-BCDMS fit at high x), we use the following function in the range $x < 0.05, W > 8 GeV$ to iterate the extraction of the corrections:

$$F_2^{iterate} = F_2^{fit}\Theta(log_{10}Q^2 + 1.0) +$$
$$[1 - \Theta(log_{10}Q^2 + 1.0)].[F_2^{global} + \frac{F_2^{fit} - F_2^{global}}{(log_{10}Q^2)^2}] \tag{10.2}$$

where Θ is the step function which is unity when the argument is positive and zero when it is negative. Outside the range $x < 0.05, W > 8 GeV$, we maintain the use of F_2^{global}. This new F_2 is used to recalculate the radiative corrections, and reweight the events in the Monte Carlo used to calculate the acceptance corrections. Since the F_2^{global} function roughly describes our data, the typical change in the measured F_2 after the first iteration is only about 1%. After four iterations the change in F_2 is less than 0.05%, and we stop iterating. It should be mentioned that the variables used in this context for the Monte Carlo re-weighting are the hadronic variables, i.e. they describe the kinematics of the true single virtual photon that interacts with the nucleon. They are not the true or the reconstructed kinematics of the muon vertex.

The fit is performed and iterated after all systematic effects have been investigated. The error on each point used in the fit is the quadrature sum of the statistical error from the data, the statistical error on the Monte Carlo correction, and the kinematics-dependent systematic uncertainty. The uncertainty in the overall normalization is not

included. The fitted parameters and their respective errors are given below in table 10.1. It should be noted that the errors on some of these parameters are correlated. For each target there are 91 data points. The fit to the proton F_2 gives $\chi^2/DoF = 0.88$, while the fit to the deuteron F_2 gives $\chi^2/DoF = 0.93$.

Table 10.1: Fitted parameters for F_2 function.

parameter	proton	deuteron
a_1	-0.0604 $\pm$ 0.0074	-0.1612 $\pm$ 0.0044
a_2	0.1962 $\pm$ 0.2497	3.1043 $\pm$ 0.2797
a_3	0.0527 $\pm$ 0.0074	0.3437 $\pm$ 0.0139
a_4	-0.7423 $\pm$ 0.0078	-0.5676 $\pm$ 0.0100
a_5	6.0061 $\pm$ 0.0083	5.9451 $\pm$ 0.0051
a_6	-9.9770 $\pm$ 0.0087	-10.1843 $\pm$ 0.0068

c_1	0.3677 $\pm$ 0.0256	0.4118 $\pm$ 0.0259
c_2	0.0123 $\pm$ 0.0028	0.0112 $\pm$ 0.0022

10.5 Final Data-Monte Carlo Comparisons

The Monte Carlo obtained after the final iteration is used to make comparisons of inclusive distributions with the data. All the analysis cuts made for the F_2 measurement are made both on the data and the Monte Carlo. The inclusive distributions are self-normalized (i.e. integrate to unity) before the comparison. The distributions from the data and the Monte Carlo are superposed on the left side in figures 10.1, 10.2 and 10.3, and the corresponding data/MC ratio is shown on the right side. The distributions agree to within 10% or better over most of the kinematic range.

10.6 Results

The results on the structure function F_2 are given in tables A.19, A.20 and A.21 for the proton and the deuteron. The statistical and kinematics-dependent systematic uncertainties are also quoted in percent of F_2. The systematic uncertainty is the quadrature
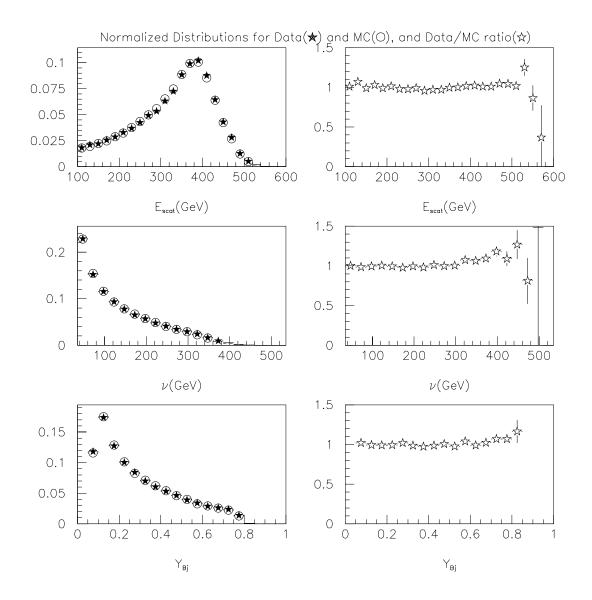

Figure 10.1: Final Data-Monte Carlo comparisons of inclusive distributions. The distributions are normalized to integrate to unity before the comparison. The data and Monte Carlo distributions are superimposed on the left, and the data/MC ratio is shown on the right. E_{scat} is the scattered muon energy, the other variables have their usual meaning.

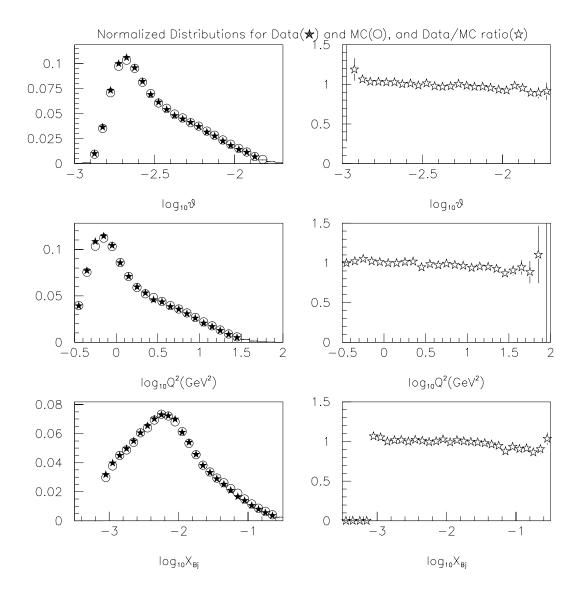

Figure 10.2: Final Data-Monte Carlo comparisons of inclusive distributions. The distributions are normalized to integrate to unity before the comparison. The data and Monte Carlo distributions are superimposed on the left, and the data/MC ratio is shown on the right. θ is the muon scattering angle in radians, the other variables have their usual meaning.
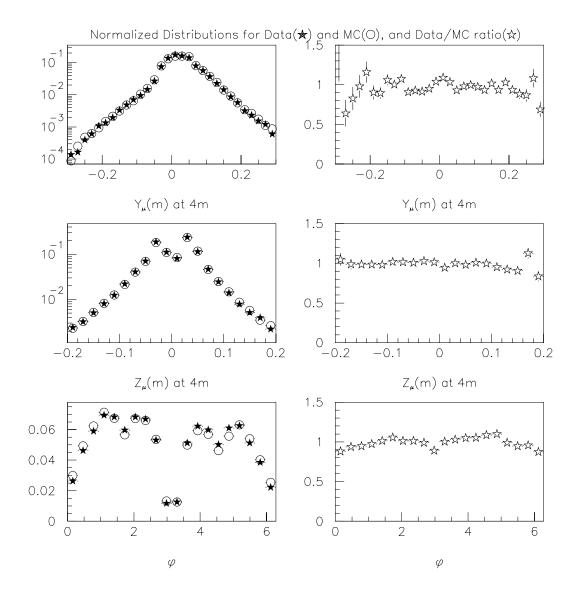

Figure 10.3: Final Data-Monte Carlo comparisons of inclusive distributions. The distributions are normalized to integrate to unity before the comparison. The data and Monte Carlo distributions are superimposed on the left, and the data/MC ratio is shown on the right. Y_μ and Z_μ are the transverse coordinates of the reconstructed scattered muon at the longitudinal position $X = 4m$, which is just downstream of the CCM magnet. ϕ is the azimuthal angle of the muon scatter in radians.

sum of the seven different uncertainties quoted in tables A.13-A.18 for each bin. The overall normalization uncertainty discussed in section 10.3.8 is not included in the quoted systematic uncertainty.

Tables A.22-A.24 show the total acceptance for the muon cross-section computed for each bin from the Monte Carlo. The statistical uncertainty in the computed acceptance, due to the Monte Carlo statistics, is also given in percent of the acceptance. The statistical uncertainty in the acceptance correction is included in quadrature with the statistical uncertainty on the data, in the quoted statistical error on F_2. The bin acceptance, as denoted by ϵ in equation 4.7, includes all the detector-related effects affecting the measurement of the total muon cross-section. These include the trigger and reconstruction efficiencies as well as the multiple scattering and resolution smearing effects indicated in figure 4.1.

The structure function F_2 is plotted against Q^2, in x bins in figures 10.4 and 10.5. In these and all subsequent plots of E665 and other data, the error bars represent the quadrature sum of the statistical and systematic uncertainties. However the overall normalization uncertainty will not be included in any of the errors shown. Figures 10.6 and 10.7 show F_2 plotted against x at fixed Q^2. In figures 10.8-10.11, the data are compared with the F_2 parametrization described in appendix B, as well as the fit described in section 10.4. While the F_2 parametrization of appendix B gives a good qualitative description of the data at low x and Q^2, the fit gives a better description of the slope of F_2 with respect to Q^2 at fixed x and the slope of F_2 with respect to x at fixed Q^2.

Figures 10.12-10.17 show linear fits to lnF_2 vs lnQ^2 in different x bins. The purpose of these fits is to extract the logarithmic derivative of F_2 with respect to Q^2 as a function of x. In each fit the parameter P_1 is the intercept at $Q^2 = 1GeV^2$ and P_2 is the slope $\partial lnF_2/\partial lnQ^2$. The slopes and the associated errors are extracted from the fits and plotted vs x in figure 10.18. Also shown on figure 10.18 is the value of the slope of 1.0808 in the photoproduction limit, extracted from the high energy behavior of the real photoproduction cross-section (equations 2.52 and 2.51).

Figures 10.19-10.24 show linear fits to lnF_2 vs lnx in different Q^2 bins. As with the Q^2 slopes, the derivative $\partial lnF_2/\partial lnx$ at fixed Q^2 is a concise way of showing certain aspects of the data. The logarithmic derivative of F_2 with respect to x is shown in figure 10.25. The high energy photoproduction limit derived from equations 2.52 and 2.51 is shown, as is the typical slope of ~ -0.3 derived from the high Q^2 HERA data ($F_2 \sim x^{-0.3}$ [96]).

In this analysis the proton and deuteron structure functions are measured separately. We use linear fits similar to those shown in figures 10.12-10.17 to extract the value of the proton and deuteron F_2 at the central Q^2 in each x bin. The deuteron-to-proton

structure function ratio extracted in this way is shown as a function of x in figure 10.26. An independent analysis of the E665 data has been performed [59, 98] with the goal of measuring the deuteron-to-proton structure function ratio directly, by exploiting the cancellation of acceptance corrections. The results on the ratio from the "direct" analysis [59, 98] are also shown in figure 10.26. Within the uncertainties, the results on F_2^d/F_2^p from the two analyses are in good agreement. The "direct" analysis uses the data from the calorimeter trigger in addition to the SAT to extend the range of the F_2^d/F_2^p measurement to lower x.

Chapter 11

Comparisons and Conclusions

In this chapter we compare our structure function results with measurements from other experiments, and with theoretical models. As discussed in chapter 2, the structure function F_2 can be analysed using the perturbative QCD formalism at high Q^2, or in terms of the non-perturbative hadronic photon picture which is usually applied at low Q^2. We will briefly review some of the current models that use these techniques and compare them with the data. We will also compare the data with the F_2 results from NMC and HERA.

11.1   Comparisons with Other Experiments

The high Q^2, large x range of the E665 data overlaps with the NMC structure function measurements [11]. The comparison between the two measurements is shown in figures 11.1 and 11.2. The two measurements are in good agreement. The E665 data also overlaps significantly with the HERA data in x, though the HERA data is at higher Q^2. In figure 11.3 we show the E665 data and the ZEUS data [99] as a function of Q^2 in bins of x. All the E665 data are not shown; only those E665 x bins which contain the corresponding x value of the ZEUS data are shown. In one plot the different x bins are scaled by powers of 10 for clarity; in the other plot the data in the different x bins are shown without any scale factors. The same symbols are used for the different x bins in the two plots. We see that the two experiments together cover a very large dynamic range in x and Q^2. In each x bin we expect a smooth connection in Q^2 between the two data sets. We have superimposed F_2 model calculations from Badelek and Kwiecinski (discussed below) to guide the eye in this regard. We see that the two data sets do indeed connect with each other quite smoothly as a function of Q^2.

The comparison with the HERA data shows the pattern of F_2 scaling and scaling violations over a very large range of x and Q^2. It also shows that the x dependence of F_2 is different at low and high Q^2. The rise in F_2 with decreasing x is weaker in the lower Q^2 E665 data than it is in the higher Q^2 HERA data. This difference is quantified in figure 10.25 which shows the logarithmic derivative of F_2 with respect to x.

11.2 QCD-evolved Leading-Twist Structure Functions

In section 2.2.2 we discussed how the QCD radiation from quarks and gluons causes the apparent quark and gluon density, and hence the structure functions, to change with the momentum scale of the photon. At high Q^2, where the multi-parton or "higher-twist" effects are expected to be small, the photon dominantly scatters off individual partons. The accompanying QCD radiative effects can be calculated in field theory. Hence an analysis of the structure function data based on QCD evolution can be used to obtain a set of universal parton distributions. The usefulness of these universal parton distributions is that they can then be used to calculate any hard scattering cross-section.

We compare the data with three F_2 models/fits based on perturbative QCD evolution. The CTEQ collaboration [97] and the group of Martin, Roberts and Stirling (MRS) [96], have performed QCD fits to world data including F_2 data. The group of Glück, Reya and Vogt (GRV) [71] have used a somewhat different approach of performing QCD evolution up from a low momentum scale ($\mu_0^2 = 0.3 GeV^2$). They have used an *ansatz* that the parton distributions have valence-like behavior (approach zero as $x \rightarrow 0$) at the low momentum scale.

In the figures 11.4, 11.5, 11.8 and 11.9, the measured F_2 is compared with the F_2 calculated from the CTEQ version 3 and the MRS(A) sets of parton distributions. Also shown is the F_2 obtained from the GRV HO set. The QCD evolution in the CTEQ3 set is performed down to $Q = 1.6 GeV$. For lower Q^2, we perform a linear extrapolation of $ln F_2$ as a function of $ln Q^2$ at fixed x by using the logarithmic derivative $\partial ln F_2 / \partial ln Q^2$ evaluated at $Q = 1.6 GeV$. The QCD evolution in the MRS(A) set is performed both up and down in Q^2 from $Q_0^2 = 4 GeV^2$ using the GLAP QCD evolution equations (see section 2.2.2). The GRV set breaks down below $Q^2 = 0.3 GeV^2$ hence we do not show the calculation below this scale. The CTEQ3, MRS(A) and the GRV distributions are all based on next-to-leading order (NLO) QCD calculations with no higher twist contributions. The Fortran code to calculate the CTEQ3 and the MRS(A) F_2 is obtained from [97] and [96] respectively. The GRV HO parton distributions are evaluated using $PDFLIB$ [100] and the relation in the $\overline{MS}$ scheme between F_2 and the parton

distributions is obtained from [71].

The comparisons show that the CTEQ3 and the MRS(A) F_2 are able to describe the data at high x and Q^2. This is to be expected since the E665 F_2 data are consistent with the other F_2 data used in these QCD fits in this range. At low x and Q^2, the CTEQ3 and the MRS(A) F_2 are in disagreement with the data. The comparison with the MRS(A) F_2 shows that the data lie below the NLO QCD-evolved calculation. This implies that the higher twist terms in the structure function are negative in the range of the low x, low Q^2 E665 data. The difference between the calculation and the data can be interpreted as a measurement of the higher twist effects in this range.

The comparison with the GRV F_2 shows that the calculation lies below the data at the lowest x and Q^2. This is merely a reflection of the *ansatz* that the parton distributions are valence-like at low Q^2, implying that the GRV $F_2 \to 0$ as $x \to 0$ at low Q^2, while the measured F_2 does not follow this behavior. Since we expect a pure twist-2 description of F_2 to be insufficient at low Q^2, the GRV approach was not intended to describe the data at low Q^2. Instead, it shows that the shape of the structure function at high Q^2 can be explained through the QCD evolution of the twist-2 component alone. The GRV F_2 has been able to reproduce the rise in the structure function with reducing x as seen in the high Q^2 HERA data. It is in fair agreement with the high Q^2 E665 data. What is perhaps more surprising is that the GRV F_2 is able to describe the E665 data down to Q^2 as low as $0.7 GeV^2$ and x as low as 0.003, before the agreement breaks down.

11.3 Low Q^2 Structure Functions

We will now discuss three models/fits that explicitly attempt to describe the structure function at low Q^2. These models typically combine information from the high Q^2 perturbative region and low Q^2 phenomenology to describe the transition to low Q^2. They are the Donnachie-Landshoff model, the Badelek-Kwiecinski model and the modified parton distributions of Martin, Roberts and Sterling.

The gist of the Donnachie-Landshoff model [35] is provided by equation 2.52. It is a phenomenological interpolation between the real photoproduction data and the data in the perturbative region of Q^2. In [35] the authors describe further refinements to the F_2 given by equation 2.52, made by incorporating the contribution of heavy flavors and invoking counting-rule arguments to describe the large x behavior. In the following comparisons with our data we compute the Donnachie-Landshoff F_2 in its full form with the Fortran code obtained from [35]. This model has the correct photoproduction limit (see equation 2.48) because the real photoproduction data is included in the fit.

The Badelek-Kwiecinski model [34] is based on the idea of Generalized Vector Meson Dominance (GVMD) that was discussed in section 2.3.6. In the Badelek-Kwiecinski model, the sum over all the hadronic fluctuations of the photon is split into two pieces:

$$F_2 = F_2^{(v)} + F_2^{(p)} \tag{11.1}$$

$F_2^{(v)}$ denotes the contribution from the low mass vector mesons ρ, ω and ϕ, and is given in equation 2.38. Since this contribution vanishes at high Q^2, the measured structure function at high Q^2 must be due to the contribution of the high mass states beyond the ϕ. The contribution of the high mass states is represented by $F_2^{(p)}$, and is obtained from the conventional QCD-evolved parton distributions by using dispersion relations. The authors have simplified the dispersion relations to obtain a simple expression for $F_2^{(p)}$ in terms of the high Q^2 asymptotic structure function F_2^{AS}:

$$F_2^{(p)}(s, Q^2) = \frac{Q^2}{Q^2 + Q_0^2} F_2^{AS}(s, Q^2 + Q_0^2) \tag{11.2}$$

$F_2^{(p)}$ represents the contribution of vector meson states heavier than Q_0. By choosing Q_0 to be greater than the mass of the heaviest vector meson included in $F_2^{(v)}$, double counting is avoided.

It is evident that $F_2 \to F_2^{AS}$ for large Q^2. As Q^2 reduces the model makes a smooth transition by combining the non-perturbative contribution of the low mass vector mesons and the residual contribution of the high mass states. The singularities in F_2^{AS} at low Q^2 are removed by the shift of the variable $Q^2 \to Q^2 + Q_0^2$. At very low Q^2 the model qualitatively approaches the photoproduction limit (equation 2.48). The model predicts the correct shape of $\sigma_{\gamma p}(s)$ but overestimates its magnitude by about 10-15%.

In the Badelek-Kwiecinski model the deuteron structure function is calculated assuming the proton and the neutron are free particles. Shadowing in the deuteron is calculated explicitly [101]. The calculated shadowing correction decreases the deuteron structure function by ~0.001-0.006 in absolute magnitude.

We calculate the Badelek-Kwiecinski model F_2 for the proton and the deuteron using Fortran code obtained from [34] and [101]. In this version the high Q^2 asymptotic structure functions F_2^{AS} are obtained from the MRS(A) set of parton distributions.

Finally, we discuss the modified MRS(A) set of parton distributions produced by Martin, Roberts and Sterling [96]. In section 11.2 we discussed the QCD-evolved leading-twist set of parton distributions, which we call the unmodified MRS(A), and denote by MRS(A)u on the figures. The modified set, denoted by MRS(A)m on the figures, involves the multiplication of the QCD-evolved leading-twist parton distributions by a form factor. The parameters in the form factor expression are obtained by fitting the

resulting F_2 to low Q^2 data. This procedure is described in appendix C and the form factor expression is given in equation C.1. The modification is designed to achieve a phenomenological description of higher twist contributions at low Q^2, while leaving the QCD-evolved leading-twist parton distributions unaffected at high Q^2. However, the modified F_2 is not constrained to match the real photoproduction limit (equation 2.48). The code to calculate the MRSA(A)m parton distributions and the corresponding F_2 is obtained from [96].

We compare these low Q^2 models/fits with our F_2 data in figures 11.6, 11.7, 11.10 and 11.11. We find that all three models are able to describe the data at high Q^2 and x since the models are constrained by previous data. At low Q^2 and x the models are qualitatively similar to the data, but the data are sufficiently precise that we may note quantitative differences. As discussed in appendix C, the MRS(A)m fit included the preliminary results of this analysis [103] which were slightly different from the final F_2 data presented here. This can account for the differences. The Badelek-Kwiecinski curves tend to overshoot the data at low Q^2 and x, which may be due to the fact that this model overestimates the real photoproduction cross-section by 10-15% as mentioned above. The Donnachie-Landshoff model is able to describe the average value of F_2 in a bin of x or Q^2. However, the slope of the data with respect to x or Q^2 is steeper than that predicted by either the Donnachie-Landshoff or the Badelek-Kwiecinski models. As one can see from the definition of the variables, the slope of F_2 with respect to x at fixed Q^2, and the slope of F_2 with respect to Q^2 at fixed x, both reflect the slope of F_2 with respect to W^2 at fixed Q^2. The W^2 dependence of F_2 at low Q^2 is derived in both models from the observed W^2 dependence of the real photon-nucleon and hadron-nucleon cross-sections, which are similar (see section 2.3.5). Thus the data suggests that the W dependence of the virtual photon-nucleon cross-section is stronger than the W dependence of the real photon-nucleon cross-section.

In figure 11.12 we show the logarithmic derivative of F_2 with respect to Q^2 ($\partial ln F_2/\partial ln Q^2$) compared with the same quantity from the Donnachie-Landshoff model. While the model qualitatively reproduces the trend that the slope increases as x decreases, the data tend to lie above the model prediction. We have already seen in figure 10.25 that the logarithmic slope of F_2 with x ($\partial ln F_2/\partial ln x$) is more negative in the data than the value expected in the photoproduction limit from the Donnachie-Landshoff model. These comparisons show more clearly the tendency that the W dependence at fixed low Q^2 in our data is stronger than the W dependence expected in the photoproduction limit. The significance of the c_2 term in the fit to our data (see section 10.4) shows this effect. At the same time the W dependence at low Q^2 is weaker than at high Q^2 as seen from HERA data.

The Q^2 dependence at fixed W also shows a transition from high to low Q^2. In figures 11.13 and 11.14, we show the virtual photon-nucleon cross-section computed

from F_2 (see equation 2.11) using the Hand convention for the virtual photon flux ($K = \frac{W^2 - M^2}{2M}$). The same quantity computed from the Donnachie-Landshoff model is over-plotted to guide the eye. The data show a smooth transition in $\sigma_{\gamma^* N}$ as a function of Q^2, showing how the photon varies between a point-like probe at high Q^2 and a hadronic object at low Q^2.

11.4   Conclusions

We have presented measurements of the proton and deuteron structure functions F_2 in the kinematic range $x > 0.0008$ and $Q^2 > 0.2 GeV^2$. These are the first precise measurements of F_2 at such low x and Q^2. The data were obtained using a muon beam of average momentum 470 GeV, and liquid hydrogen and deuterium targets at the experiment 665 during 1991-92 at Fermilab.

The E665 measurements have a significant overlap in x and Q^2 with the measurements from NMC. In the region of overlap the two measurements are in good agreement. The E665 measurements also overlap in x with the HERA data, the E665 data being at lower Q^2 at fixed x. There is a smooth connection in Q^2 over a very large range between the two data sets.

The E665 data clearly show a transition in the nature of the photon-nucleon interaction when $Q^2 \sim \mathcal{O}(0.5 GeV^2)$. While perturbative QCD evolution-based models give a good description of the data at higher Q^2, they fail to describe the data at lower Q^2. Thus the data can be used to quantify the higher-twist effects as a function of x and Q^2, which are negative in the low Q^2 range of the data. Models that incorporate the hadronic nature of the photon at low Q^2 are able to describe qualitatively the W and Q^2 dependence of the data. We find that at low Q^2, the W dependence of our data is stronger than that of real photoproduction and hadroproduction cross-sections, but weaker than the W dependence of the high Q^2 HERA data. Thus the data provides a measurement of the transition between high and low Q^2 in both the W and the Q^2 dependence of the photon-nucleon interaction mechanism.
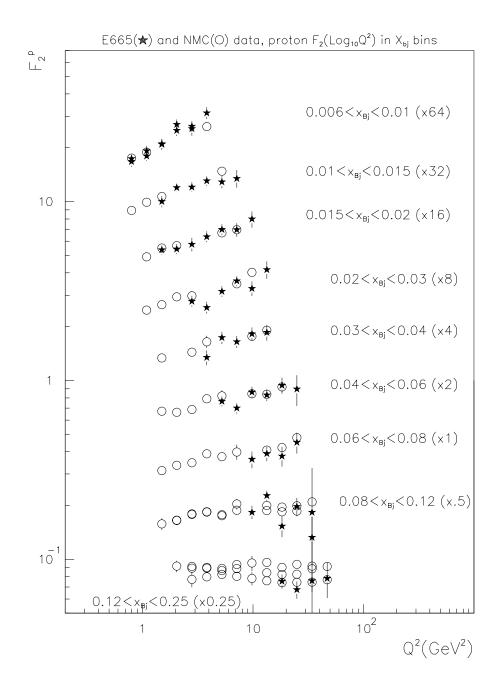

Figure 11.1: proton F_2 from E665 and NMC over-plotted vs Q^2 in x bins. In certain x bins one of the two experiments has multiple data points because the actual binning in x is narrower. In these cases all the data points falling in those bins are shown.

232
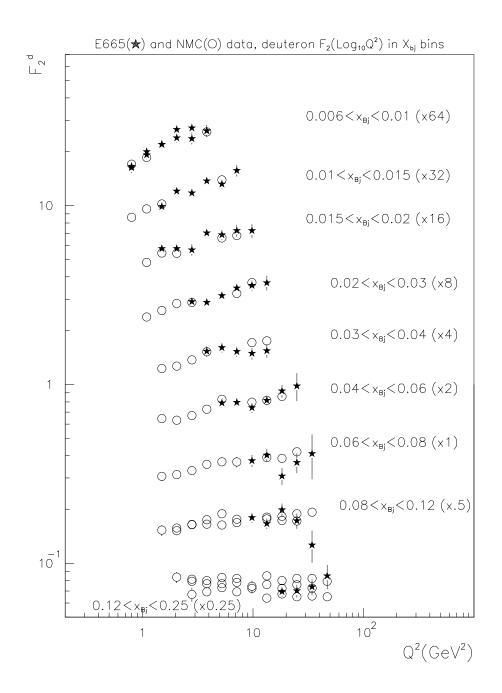

Figure 11.2: deuteron F_2 from E665 and NMC over-plotted vs Q^2 in x bins. In certain x bins one of the two experiments has multiple data points because the actual binning in x is narrower. In these cases all the data points falling in those bins are shown.
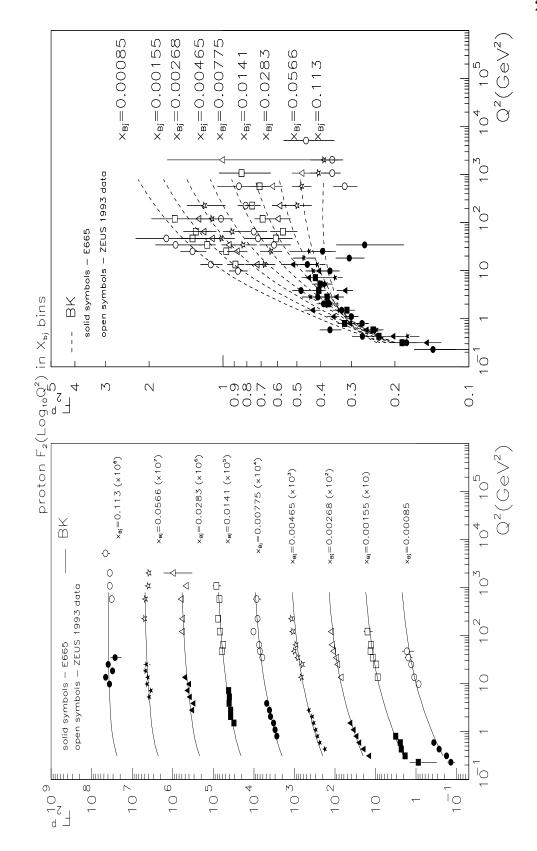

Figure 11.3: proton F_2 vs $Q^2(GeV^2)$ in x_{Bj} bins, from E665 and ZEUS. The Badelek-Kwiecinski (BK) model is also shown.

11.5 Experimental Perspectives and Outlook

The measurement of the absolute rate of any kind is very demanding on an experiment. Many aspects of the hardware and the online and offline software have to work well, and the capability to monitor and understand any limitations must be built in. With every successive experiment, the need for more information pushes the next experiment to newer kinematic regions where a new set of experimental challenges is encountered.

Let us briefly review the earlier charged lepton scattering experiments. The earliest experiments were done with electron beams, because electrons are stable and plentiful. Very high intensities can be achieved with electron beams, hence it was not necessary to collect each and every scatter. A single-arm spectrometer that could be moved in angle was the choice made at SLAC. This means that the unscattered beam does not pass through the spectrometer. This eliminates the problems of high rates and high flux in the detector. The SLAC detector is able to achieve very high triggering and reconstruction efficiencies on the scattered electrons. On the other hand, the geometrical acceptance of the spectrometer is small, hence it must be calculated very carefully. Also, the total beam count is difficult to measure for a high intensity beam, and losses due to experimental dead times etc. must be carefully accounted for. Finally, radiative corrections tend to be large for electrons due to their low mass.

Electrons are difficult to accelerate to high energies in a circular accelerator because they lose more and more energy by synchrotron radiation. The alternative is to make a longer linear accelerator, which is expensive. The energy limitation translates into a minimum x for any given Q^2. Since the spectrometer must stay away a minimum distance from the beam, the minimum scattering angle, and hence the minimum Q^2 achievable is bounded. The maximum Q^2 is also bounded by the beam energy. SLAC data ranges between Q^2 of about $0.5 GeV^2$ and about $15 GeV^2$. The x range achieved is between 0.07 and 1.

In order to achieve higher energies and higher Q^2, muon beams were the first choice. High energy proton machines produced high energy pions, of which a fraction decay into high energy muons given a sufficiently long decay length. At the same time, the muon lifetime is Lorentz-dilated so the muons don't all decay inside the experimental apparatus. Thus a viable high energy muon beam can be produced. While the muon intensity cannot match the electron beam intensity, a sufficient scattering rate can be obtained by using a longer target and a full-acceptance spectrometer. A long target compared to an electron beam target is not a problem because a "radiation length" for a muon is longer by a factor of the square of the muon-to-electron mass ratio. Also, since the muon intensity is low enough that the beam can actually pass through the detector.

There have been many muon scattering experiments [102]. Inelastic structure function measurements at high energy have been reported by E319, CHIO, EMC, BCDMS, NMC and E665. Of these, E319 and BCDMS used a toroidal magnetic spectrometer, while the other four used a dipole magnet. The BCDMS toroid has a central hole through which the beam passes, where the detector has no acceptance. The minimum scattering angle for the muon to enter the toroid, translates into a minimum Q^2. While the cross-section falls rapidly with Q^2, BCDMS was able to use a high beam flux, and also used very long targets to achieve high scattering rates. Thus, BCDMS was suited to measurements of structure functions at high Q^2.

Both SLAC and BCDMS detectors were designed to be sensitive only to the scattered lepton. Hence triggering and reconstruction are probably not the most difficult issues at BCDMS. Compared to the electron beam, the muon beam facilitates the luminosity measurement, and the radiative corrections are smaller. However, the absolute energy scale of the BCDMS experiment is difficult to determine, because the toroidal magnet with an iron yoke is hard to calibrate.

The dipole geometry spectrometer is simpler and easier to build, and this path was chosen by CHIO, EMC, NMC and E665. These spectrometers are similar in many respects. In addition to cross-section measurement capabilities, the open geometry allows measurements of the hadronic final states as well, considerably increasing the physics scope of the experiment. On the other hand, hadron measurement capability necessarily involves the sacrifice of long targets, with the corresponding reduction in muon scattering statistics.

An advantage of the open geometry is that the tracking detector can in principle have acceptance at smaller scattering angles than in the toroidal geometry. In this structure function analysis at E665, the emphasis has been to extend the range of the previous measurements to lower scattering angles, and hence lower Q^2. This, in addition to the increased beam energy compared to previous muon experiments, increases significantly the reach to lower x at E665. In reality, in order to achieve this dynamic range, many new problems need to be tackled.

The first challenge is triggering on the scattered muon at small angles in the presence of the beam. In this analysis, scatters at angles as small as $1 mrad$ are used[1]. At these small angles, the scattered muon deflects by a few centimeters at a distance of $30m$ from the target. Muon trigger elements placed downstream of the hadron absorber would experience a large rate of shower particles, making a positive trigger infeasible. A veto trigger suffers from inefficiencies due to the shower particles. The calorimeter trigger provided the opportunity to measure the rate of shower particles causing trigger losses.

---

[1]To compare, the minimum scattering angle required in the structure function measurement by NMC was 13-15 *mrad* [11]

The upstream veto was required to reduce the rate of triggering on muon scatters in the absorber. The capability of studying the hadron-induced vetoes was provided by other triggers.

In hindsight, the issues to be addressed in understanding the absolute veto trigger efficiency are unavoidable if one desires to trigger at small angles. These issues can be anticipated and the necessary information can be collected.

The second important issue is reconstruction efficiency. As with the trigger efficiency, the higher the efficiency, the better off one is. In E665, the central detector regions have suffered from significant radiation damage, resulting in efficiency loss. Here, one may suggest some precautions that can be taken in this regard. The instantaneous rate effects can be curtailed by using high-speed electronics on the central wires. The long term radiation damage can be reduced by maintaining the gas at high purity inside the chambers. Also, the chamber can be operated at lower voltage, and high efficiency can be maintained by using low-noise, high gain electronics. Certainly, the demands for high-speed, high-gain, low-noise electronics are rather stringent.

Concerning the drift chambers, the efficiency loss due to radiation damage in the central region may be unavoidable. One must protect against this by using sufficiently large MWPCs to overlap the central regions of the drift chambers where the rates are high. In E665, the PSA chamber was meant to serve this purpose, but it was too small and there wasn't sufficient overlap. Also, at least two stations of chambers are desirable downstream of the CCM. The PSA provided only one. A similar situation existed in the muon detector. The overlap between the SMS hodoscopes and the PTM tubes was incomplete.

It is interesting to note that the EMC and NMC experiments, which were in many ways similar to E665, were also plagued by issues related to drift chamber inefficiencies [11]. The need to build drift chambers downstream of the magnet is motivated by the large aperture that is needed at this location. To cover the whole area with MWPCs is prohibitive. It would seem, from the measurements made during this analysis and the experience of EMC and NMC, that drift chambers are perfectly adequate when the multiplicities and the flux are low. It is only when instantaneous or integrated flux is large that alternatives must be sought.

A related source of inefficiency in E665 was the track-finding loss increasing with event multiplicity. Outside the beam region, the detector is capable of reconstructing an isolated muon track with high efficiency. However, with increasing final state multiplicity the efficiency falls substantially. Part of the reason is the focussing effect of the double dipole geometry, increasing the local track density. The kinematics resolution gained by this geometry is valuable, so it is worthwhile to find an alternate solution to this

problem, if one exists. Perhaps it is some combination of chamber arrangement and pattern recognition algorithm. Since the sharing of hits between different tracks is worse in the z (non-bend) view, additional z and/or stereo views may help to ameliorate the tracking loss. Again, one may be faced with a trade-off between muon and hadron tracking capabilities.

The combination of the length of the E665 detector and the high transverse momentum kick of the magnet makes it perhaps the highest-resolution spectrometer ever built. This provides a significant advantage in the structure function measurement. The spectrometer calibration was performed by making various measurements *in situ*. This method has the advantage of avoiding the process of transferring the calibration obtained by other means. However, it would have been useful to have NMR probes installed in the various spectrometer magnets, the most important one being the beam spectrometer magnet. The ability to measure the magnetic field to an accuracy of 10^{-4} would provide another handle on the absolute energy scale of the experiment.

In this structure function analysis, the emphasis has been on maximizing the range of the kinematic space over which the measurement is made. This has been achieved by going to lower scattering angles at this high beam energy. The muon triggers lose acceptance for scattering angles below about $0.5mrad$, or Q^2 below $0.1GeV^2$. However, the calorimeter trigger acceptance is insensitive to muon scattering angle, thereby allowing the apparatus to trigger on events with Q^2 as low as $0.001GeV^2$, as long the event contains hadronic activity with a minimum W. If the calorimeter trigger acceptance is understood to greater accuracy, it might enable the structure function measurement to be extended to lower Q^2 by two decades. This would provide additional data to help understand the properties of the photon at low Q^2.

The ep collider at HERA is now taking data to make structure function measurements at low x and high Q^2. The colliding beam technique provides the large center-of-mass energy necessary to access this kinematic region. The data from E665 and HERA together span a wide range in x at low and high Q^2. Together with the earlier fixed-target electron and muon scattering data, the structure function F_2 is now measured or constrained over a large region of the kinematic phase space. Extending the measurement to lower scattering angles at both E665 and HERA would be a worthwhile effort.

Measurement of the longitudinal-to-transverse photon cross-section ratio R has remained elusive below x of 0.1 or so. Since this involves the difference between cross-sections measured at the same kinematic point with different beam energies, it is a difficult quantity to pin down. The comparison between the E665 and the NMC measurements of F_2 in the region of overlap may provide some information on R at low x. A precise measurement of R at low x may be the next major item on the menu of structure function measurements with charged lepton beams.

Appendix A

Tabulated F_2 Results and Systematics

In this appendix we provide the tabulated results on F_2, and the systematic uncertainties from various sources. The overall detector acceptance in each bin is also tabulated. The systematic uncertainties are discussed in section 10.3. The F_2 results and the bin acceptance are discussed in section 10.6.

Table A.1: Systematic Uncertainty in Trigger Acceptance. Numbers are in %.
(% change in F_2 caused by each of the following changes.)

G = increase minimum distance of muon to SSA veto by 1mm and SMS veto by 2mm.
$M+$ = increase SMS veto probability by 15% (*1.15).
$M-$ = decrease SMS veto probability by 15% (/1.15).
$A+$ = increase SSA veto probability by 10% (*1.1).
$A-$ = decrease SSA veto probability by 10% (/1.1).

Table A.4: Systematic Uncertainty in Reconstruction Efficiency. Numbers are in %.
(% change in F_2 caused by each of the following changes.)

DS = ignore final DC-PSA efficiency correction.
A = neglect dependence of reconstruction efficiency on scattering angle.
N+ = increase reconstruction inefficiency as a function of multiplicity by 10%.
N- = decrease reconstruction inefficiency as a function of multiplicity by 10%.

Table A.13: Kinematics-dependent systematic uncertainty in F_2 due to various sources.
(Numbers are in %.)

TR = Trigger Efficiency.
RE = Reconstruction Efficiency.
EA = Absolute Energy Scale.
ER = Relative Energy Scale between beam and forward spectrometers.
RC = Radiative Correction.
RS = Variation in R_{slac}.
BN = Bin Centering and Bin Edge effects.

Appendix B

Constructing a Trial F_2

The lepton-nucleon scattering cross-section is usually understood in terms of a single virtual photon being absorbed by the nucleon. The cross- section is measured as a function of the momentum 4-vector and the polarization of the virtual photon.

In inclusive lepton-nucleon scattering, only the incoming and outgoing leptons, and the initial target nucleon are measured. In the approximation of single photon exchange, these are sufficient to determine the parameters of the virtual photon. In reality, multiple photon emission and detector resolution imply some loss of information on an event-by-event basis. However, the migration of the measured virtual photon kinematics can be calculated on a statistical basis and the measured cross-section can be corrected appropriately.

The calculation of the radiative correction (due to multiple photon emission) and the smearing correction (due to detector resolution) requires an initial guess for the true single photon exchange cross-section. This guess can then be convoluted with the calculated radiative kernel and the smearing kernel, yielding the prediction for the measured differential cross-section. This is then compared with the measured distribution, and the comparison is used to adjust the initial guess. This iteration is continued until the prediction for the measured quantity agrees with the measured quantity.

The effect of the radiative kernel and the smearing kernel is to equate the measured cross-section at some kinematic point to a linear combination of cross-sections at many kinematic points. In principle, if the phase space accessible to the detector spans the phase space over which the true cross-section can contribute, then no external information is needed. However this is usually not the case. In general, there are regions of phase space that contribute to the observed cross-section only because the kernel is

274

non-diagonal. This can be illustrated by a simple example: suppose the detector cannot trigger on any event where the lepton hits a veto counter. In the absence of multiple scattering in the detector, this would correspond to some lepton parameter cuts at the primary vertex. However, in the presence of multiple scattering[1], some of these events, which would normally not be seen, would show up in the event sample because the muon trajectory changes sufficiently that it manages to escape the veto counter. In order to subtract these events out on a statistical basis, one needs to know how many events are really produced at the small angles. But this we don't know because we can't see all these events.

Therefore we are forced to use the measurements from other experiments in those regions of phase space where we are not fully efficient. This supplies the information that we are missing. In addition, this reduces the sensitivity to errors in the calculation of the radiative and smearing kernels. By holding the cross-section fixed in some region of phase space (where it is known), we increase the the sensitivity of the measurement in the region where it is not known.

Having established the necessity and usefulness of using all available information on the cross-section, let us turn to the task of obtaining this information.

B.1 $\mathbf{F_2}$ Parametrization

In the single photon exchange approximation, there are two components of the 4-momentum of the virtual photon, and we will choose the two combinations Q^2 and W. The Q^2-W plane can be divided into the following regions: elastic, resonance, low W inelastic and high W inelastic regions. We will discuss each of these regions in turn.

B.1.1   Elastic Scattering

This region is identified by the constraint $W^2 = M^2$, where M is the mass of the target. The simplest desciption of the Q^2 dependence of the elastic form factor is given by the dipole form $(1 + \frac{Q^2}{0.71 GeV^2})^{-2}$. More precise parametrizations have been provided by many authors (e.g. [64]). These form factors are built into computer codes such as GAMRAD [67] and FERRAD [61] that calculate the radiative cross-section. Therefore we do not need to include the elastic form factors in the our parametrization of the structure function.

---

[1]This is an example of an effect that worsens the detector resolution.

B.1.2 Resonance Region

The resonance region is usually identified with the range $M < W < 2$ GeV. At low Q^2 the cross-section in the resonance region is about a third of the elastic cross-section. At higher Q^2 it is a larger fraction since the elastic form factor is more strongly suppressed as a function of Q^2. Since the radiative tail from the elastic peak is an important component of the radiative correction, the resonance region also deserves attention. In addition, the smearing corrections tend to be larger at low W since the fractional resolution in W is poorer and the cross-section is larger.

A parametrization of the cross-section in the resonance region can be obtained from [73]. These authors used all existing data available then in their fit. Electroproduction data from SLAC and DESY and photoproduction data from Daresbury are included, spanning the range $0 \leq Q^2 \leq 50 GeV^2$. The quantity parametrized is the virtual photon absorption cross-section $\Sigma = \sigma_t + \epsilon \sigma_l$, where ϵ is the degree of polarization of the virtual photons, and σ_t and σ_l are the absorption cross-sections for transverse and longitudinal polarized virtual photons respectively. The flux of virtual photons is chosen using the Hand convention.

The data is fitted in various ranges of ϵ. At E665 the beam energy is very high so one expects the resonance excitation to occur for $\epsilon \sim 1$. Hence we take the fit for $\epsilon \geq 0.9$ so that the sensitivity to $R \equiv \frac{\sigma_l}{\sigma_t}$ is reduced. We then convert Σ to F_2 using the average value of ϵ for the data and the parametrization of R from SLAC$(1990)^2$ from [78]. As $W \to M$, we force F_2 to 0 as a quadratic function of W^2.

In Figure B.1 we show $F_2{}^p$ computed using this parametrization for various values of Q^2. With increasing Q^2, we see greater suppression of the lower W resonances. At very low Q^2 there is little dependence on Q^2, apart from the fact that $F_2{}^p$ vanishes linearly with Q^2 at fixed W.

In the following, we will refer to this parametrization as F2PRES. F_2 in the resonance region is taken to be the same for the proton and the deuteron.

B.1.3 Low W Inelastic Region

This is identified with the interval $2 < W < 5 GeV$. A parametrization of F_2 in this region is provided in [74]. These authors use a compilation of then available world

---

[2]An average over three fits is used, one of which can be found in [78]. The other two are obtained by private communication with L. W. Whitlow.

data spanning the resonance and deep inelastic region including photoproduction. They show that $\omega_W = \frac{2M\nu + M_W^2}{Q^2 + a^2}$ is a good variable to describe the data (where M_W^2 and a^2 are parameters). We will refer to this parametrization as F2LONU. This parametrization is provided for both proton and neutron.

Both F2PRES and F2LONU have been used by a DESY experiment [75]. Good agreement is observed between the data from this experiment and the predictions based on the parametrizations. There is some ambiguity due to the choice of R, so we use the F2LONU as used by [75].

In Figure B.2, we show $F_2{}^p$ computed using F2PRES and F2LONU as a function of W for various Q^2. F2PRES is used for $W < 1.95 GeV$ and F2LONU is used for $W > 1.95 GeV$. We note that for low Q^2, the two functions connect with each other quite smoothly. For $Q^2 > 1 GeV^2$ there is a small discontinuity between them. For our purposes this is not a serious discrepancy, however such discontinuities are troublesome for computer programs that do numerical integrations. So we use a Fermi-Dirac function in W to connect these two parametrizations smoothly [3], using $W = 1.95 GeV$ for threshold and 30 MeV for width. The resulting function is referred to as F2LOWW.

B.1.4 High W Inelastic Region

We use two parametrizations to describe the high W region. For high Q^2, we use the parametrization provided by the NMC that describes their data ([11]). Since this fit is not constrained by their data for $Q^2 < 0.7$ GeV^2, we do not trust the parametrization (referred to as F2NMC) in this region. Instead, we use a model by Donnachie and Landshoff, described in [35]. We use the form provided in eqn.4 of [35], which is based on the ideas that total cross-sections may be parametrized as a sum of two Regge powers of s, and that the same powers appear as powers of x_{Bj}^{-1} in the small x_{Bj} behaviour of F_2 (see equation 2.52). The authors fit this form to photoproduction data over a wide energy range, and to the NMC data from [11] for $Q^2 < 10$ GeV^2. This fit, which we call F2DOLA, can then be used for low Q^2. We merge these two parametrizations using the same technique mentioned previously, using Q^2 as the variable and setting the threshold at $Q^2 = 3 GeV^2$ with a width of $200 MeV$. We shall call the resulting function F2PHIW for the proton. The NMC parametrization is available for both the proton and the deuteron. We use the Donnachie-Landshoff form as is for the proton, and multiply it by 0.97 to use for the deuteron. This factor is derived from the E665 measurement [59] of the deuteron-to-proton cross-section ratio at low x_{Bj} and Q^2.

---

[3]This means that one uses $f = F2PRES.(f_{FD}) + F2LONU.(1 - f_{FD})$. The Fermi-Dirac function is $f_{FD} = (1 + exp((x - \mu)/\beta))^{-1}$ where μ is the threshold in x and β is the width.

In Figure B.3, we show F2PHIW evaluated for $W > 5GeV$, and F2LOWW evaluated for $W < 5GeV$. We see that at low Q^2 the two functions connect with each other smoothly. This is expected since the photoproduction data is included in both fits. At high Q^2 we note a discrepancy. At $W = 5GeV$, the data used in the low W fits is limited due to beam energy restrictions, especially at high Q^2. The high W NMC data is limited due to detector resolution. So we attempt to simulate the curve that would be obtained if all the data used so far were fitted simultaneously. We do this by merging F2LOWW and F2PHIW with our usual technique, setting the threshold at $W = 5GeV$ and the width at $400MeV$.

The resulting function is capable of giving a reasonable value for F_2 over the entire $Q^2 - W$ space relevant to E665. This is shown in Figure B.4.

B.1.5   Conclusion

Using various parametrizations of data that are available in the literature, we have constructed a reasonable parametrization of F_2 that can be used at E665 as a starting point.

Appendix C

$R = \sigma_L/\sigma_T$

At fixed x and Q^2 which specify the kinematics of the virtual photon, the photoabsorbtion cross-section depends on the polarization of the virtual photon. In lepton scattering, the polarization of the exchanged virtual photon depends on y, hence the Born cross-section for lepton scattering is a y-dependent combination of the longitudinal and transverse structure functions. Therefore, at fixed x and Q^2, the lepton cross-section must be measured as a function of y to extract both the longitudinal and transverse structure functions. This requires variation in the beam energy. At E665, the spread in the beam momentum spectrum is only about 10%, which is not sufficient to extract both structure functions.

As can be seen in equation 4.1, $\sigma_{1\gamma}$ is related only to F_2 as y approaches zero. The F_2 extracted from $\sigma_{1\gamma}$ depends weakly on $R = \sigma_L/\sigma_T$ (the ratio of photoabsorbtion cross-sections for longitudinal and transverse photons) at low y. Hence we choose to extract F_2 by using R from elsewhere.

R is a difficult quantity to measure and data on it is scarce. We use the parametrization of R obtained from the global analysis of SLAC data [78]. The main reason is that R_{slac} has become the standard which is used by most fixed target lepton scattering experiments to quote F_2. The fortran code we have used is shown in figure C.1, and the function is plotted with the error in figures C.2, C.3 C.4, and C.5. The data used to extract R falls in the kinematic range $0.1 < x < 0.9$ and $0.6 < Q^2 < 20.0 GeV^2$. In this range, the data are consistent with the equality of R for the proton and the deuteron. Hence we use the same parametrization for both targets.

The parametrization holds R constant below $Q^2 = 0.35 GeV^2$, with an error equal in magnitude to R itself. The E665 measurements do not extend much lower in Q^2.

However, they extend more than two decades lower in x than the SLAC data used to extract R. In this low x, low Q^2 region, R is unconstrained. Hence, we also try a QCD-motivated parametrization of R, and $R = 0$. The parametrization of R_{QCD} we have tried is given in figure C.6.

We have also tried R computed by Martin, Roberts and Sterling [96] using the "modified" MRS(A) set of parton distributions in the $\overline{MS}$ scheme. The "modification" involves the multiplication of the MRS(A) parton distributions by a form factor,

$$
\begin{aligned}
f_i(x, Q^2) &= \rho(x, Q^2) f_i^{MRSA}(x, Q^2) \\
\rho(x, Q^2) &= \frac{Q^2}{Q^2 + m^2} \\
m^2 &= m_0^2(x) exp(-Q^2/Q_0^2)
\end{aligned} \tag{C.1}
$$

with $Q_0^2 = 4 GeV^2$. The behavior of the parameter $m_0^2(x)$ is determined by MRS as a function of x by fitting to the F_2 data of E665, SLAC and NMC. The E665 data included in this fit were from a preliminary version of the analysis presented in this thesis [103]. The E665 data were multiplied by 1.2 to achieve consistency with NMC, which was permitted by the 10-20% systematic uncertainty quoted on the preliminary result. This procedure provides the modified set of MRS(A) parton distributions which can be used above Q^2 of $0.1 GeV^2$.

In our use of R_{MRSA}, we also force the condition that R must not be less than zero. When the R value returned by the calculation is less than zero, we set it equal to zero.

Calorimeter Response in the Central Region

Various studies of chamber efficiencies in run91 show that the region exposed to the beam suffers from reduced efficiencies. This could be due to the cumulative effects of radiation damage and instantaneous effects. The E665 calorimeter is a lead-proportional chamber sampling calorimeter, so it is susceptible to similar effects that cause reduction in gas gain.

In addition, very large electromagnetic showers can be sensitive to non-linearities in the calorimeter response. This leads to saturation effects at high energies. However, high energy particles tend to hit the calorimeter closer to the center. In order to understand the calorimeter response as a function of particle energy, one needs to take into account the energy dependence and the position dependence of the response simultaneously.

D.1   Calibration Sample

$\mu - e$ elastic scatters provide the best calibration sample for the central region of the calorimeter. The muon energy loss and the reconstructed electron momentum provide redundancy in the knowledge of the calibration energy. Since this sample is obtained during normal running conditions, the calorimeter measurements include the effects of instantaneous beam loading.

This entire analysis is performed with the run91 analysis ntuples that were produced

by the data production jobs. To isolate a good sample of $\mu - e$ events, the following quality cuts are first applied on the muon:

- One and only one beam track is found.

- The event should satisfy the LAT or SAT beam definition simulated using the SBT beam hodoscope hits. This ensures the beam is in-time.

- $\nu > 25 \ GeV$

- The PCV chamber should be on the muon track. This ensures a long upstream lever arm.

- The last keyplane on the muon should be the DC5 keyplane. This ensures the longest possible downstream lever arm.

The last two cuts select muons that are well-reconstructed. The following cuts select $\mu - e$ candidates:

- One and only one calorimeter cluster is found.

- One negative track fitted to the primary vertex, and no other tracks apart from the muon.

The X distribution of the primary vertex after these cuts is shown in figure D.1. Also shown in figure D.1 is the distance between the calorimeter cluster and the impact point of the negative track on the calorimeter.

The following cuts are applied on these distributions:

- $-11.5m > X_{vtx} > -13.5m$

- The distance between track impact point and cluster is required to be less than $5cm$ to associate the cluster with the track.

Following these cuts, the distribution of $log_{10}x_{Bj}$ is shown in figure D.2. The peak near $x_{Bj} = m_e/m_p = 0.000545$ is clear, along with a tail at higher x_{Bj}. This tail is probably due to events in which a negative hadron produces a cluster in the calorimeter.
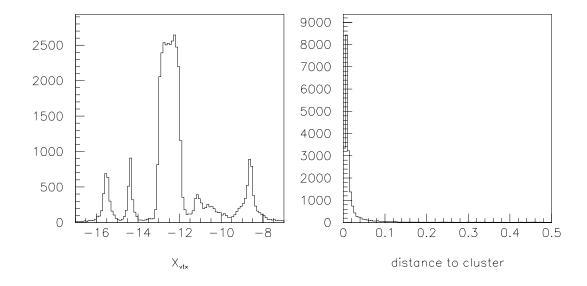

Figure D.1: a) X distribution of primary vertex in meters. b) distance (in meters) between calorimeter cluster and negative track impact point on calorimeter.

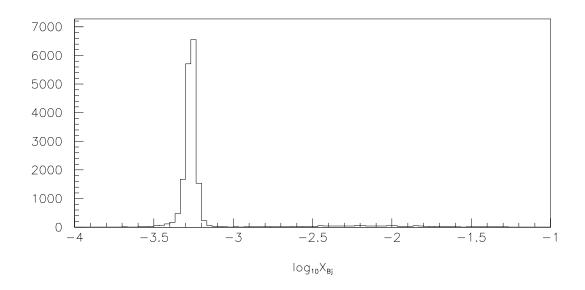

Figure D.2: $log_{10}x_{Bj}$ distribution following calorimeter and track multiplicity cuts.

We first make the cut $-4.0 < log_{10}x_{Bj} < -3.0$ to isolate the $\mu - e$ candidates. Figure D.3a shows the distribution of $Z_{track} \equiv P_{track}/\nu$, the ratio of the momentum of the negative track to the muon energy loss. This distribution peaks near 1 with a radiative tail extending to lower values of Z_{track}. This supports the $\mu - e$ hypothesis. It argues against the photon conversion hypothesis where the positron is lost, as this would produce a Z_{track} spectrum peaking at small values. Further evidence in support of the $\mu - e$ hypothesis is provided by the normalized error on the reconstructed value of x_{Bj}, assuming the true value is $x_{Bj} = m_e/m_p = 0.000545$. This is shown in figure D.3b.

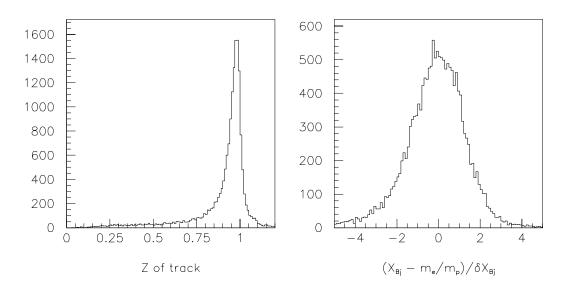

Figure D.3: a) $Z_{track} \equiv P_{track}/\nu$ distribution of $\mu - e$ candidates. b) normalized error on reconstructed x_{Bj}.

There is evidence of radiative tails in both the $log_{10}x_{Bj}$ and the Z_{track} distributions. Events in these tails are difficult to use for calorimeter calibration because it is not clear how much energy actually hit the calorimeter. The two-dimensional distribution of $log_{10}x_{Bj}$ vs Z_{track} plotted in figure D.4a to help remove the radiative tails. Only the peak of the distribution is chosen by making the following cuts:

- $-3.2 > log_{10}x_{Bj} > -3.32$

- $1.02 > Z_{track} > 0.92$

After these cuts, the distribution of normalized error on x_{Bj} is shown in figure D.4b. This distribution is now quite Gaussian. The distribution of Z_{track} peaks at about 0.97,

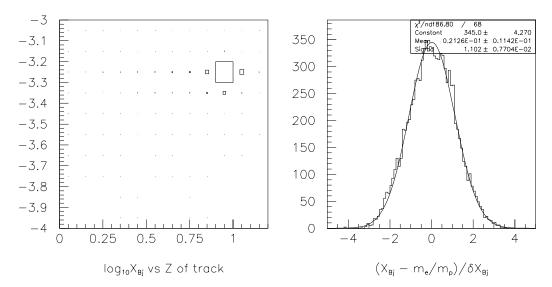

Figure D.4: a) $log_{10}x_{Bj}$ vs Z_{track} distribution of $\mu - e$ candidates. b) normalized error on reconstructed x_{Bj} of final calibration sample.

indicating that there is measurable energy loss through photon radiation. This may or may not be merged with the electron cluster in the calorimeter. As a compromise, the average of the muon energy loss ν and the electron momentum P_{track} is used as the calibration energy.

Figure D.5 shows some other properties of the final calibration sample. We see that a fairly wide range of energy is available for calibration. The μe events are triggered by both the SAT and the SATPS triggers, the former being sensitive to the electron veto from the SSA for high electron energies. The energy distribution shows evidence of a double-peaked structure. The position distributions also show evidence of a pileup around the edges of the SSA. We see that the position is correlated with the energy, so we have to allow for the possibility that the non-linearity in the energy response is due to position-dependent effects.

Figure D.5: Distributions of the final calibration sample. top row) ν and P_{track}. middle row) Y and Z position of the calorimeter cluster in meters. bottom row) mean cluster position in Y and Z (meters) as a function of calibration energy.

D.2   Calibration Procedure

One way to use the calibration information is to correct the data with the function that describes the calorimeter response. The corrected data can then be used as is. This means that the calorimeter response has to be parameterized in terms of the variables available from the uncorrected data. For a calorimeter cluster, we have the position of the cluster, $clusterY$ and $clusterZ$, and the energy of the cluster, $E_{cluster}$. It should be noted that the data being used here has already been processed through the standard calorimeter analysis code of the experiment. However, this code did not include the corrections being discussed here.

The dependent variable is $Z_{cluster} \equiv E_{cluster}/E_{calib}$, where $E_{calib} \equiv (\nu + P_{track})/2$. After correction, $Z_{cluster}$ should be 1 within resolution. After a preliminary analysis, it was found that there was some time dependence to the calorimeter response. This time dependence was parameterized as a function of run number as follows:

$$21600 > NRUN > 21000 : RUNDEP = 1.121 - 0.0002875 * (NRUN - 21000)$$
$$22200 > NRUN > 21600 : RUNDEP = 0.919 + 0.0003160 * (NRUN - 21600)$$
$$22800 > NRUN > 22200 : RUNDEP = 1.098 - 0.0004019 * (NRUN - 22200)$$

$Z_{cluster}$ was divided by $RUNDEP$ to correct for the time dependence before further analysis.

Figure D.6 shows $Z_{cluster}$ obtained from the data at this point, and its dependencies. Its mean value is clearly not 1. The time dependence is rather erratic. There is a clear correlation with the position of cluster and calibration energy.

In order to find a multivariate function that tries to take into account all the correlations, a regression analysis is performed. Using the plots in figure D.6 as a guide, the independent variables are chosen as follows:

$$X(0) = 1.0$$
$$X(1) = E_{cluster}$$
$$X(2) = EXP(-(\tfrac{clusterY}{0.111})^2))$$
$$X(3) = EXP(-(\tfrac{clusterZ}{0.075})^2))$$
$$X(4) = X(2) * X(3)$$
$$X(5) = X(1) * X(4)$$
$$X(6) = clusterY * X(2)$$
$$X(7) = clusterY^2 * X(2)$$

where the unit of energy is GeV and the unit of displacement is $meter$. The regres-

sion analysis calculates a function

$$Z_{cor} = B.\Sigma A_n X(n)$$

such that the χ^2 between Z_{cor} and $Z_{cluster}$ is minimized when all events in the calibration sample are summed over. The statistical error on $Z_{cluster}$ is taken to be :

$$\sigma(Z_{cluster}) = \frac{0.38\sqrt{E_{cluster}}}{E_{calib}}$$

The factor of 0.38 is derived from analysis of low energy electron beam calibration data, outside the central region of the calorimeter [55].

D.3 $E_{cluster}$ Parameterization

The result of the regression is the set of coefficients A_n and the function B, given below:

$A_0 = 0.9626$
$A_1 = 0.239E - 02$
$A_2 = -0.4674$
$A_3 = -0.5756$
$A_4 = 0.2906$
$A_5 = -0.183E - 02$
$A_6 = 0.8945$
$A_7 = -0.101E + 02$
$B = 1.21 - 0.0018 * E_{cluster}$

This is called the $E_{cluster}$ parameterization. It can be checked by examining the corrected $Z_{cluster}$ distributions, where corrected $Z_{cluster} \equiv \frac{Z_{cluster}}{Z_{cor}}$. These distributions are shown in figure D.7. We see that most of the dependencies of $Z_{cluster}$ have been removed by the correction. A Gaussian fit to the corrected $Z_{cluster}$ distribution gives a mean of 0.997 and RMS of 0.108.

D.4 E_{calib} Parameterization

For the purposes of Monte Carlo simulation, one would like to match the data that is obtained from the general E665 production program. This means that one would like the Monte Carlo to reproduce the distributions of the uncorrected $Z_{cluster}$ shown in
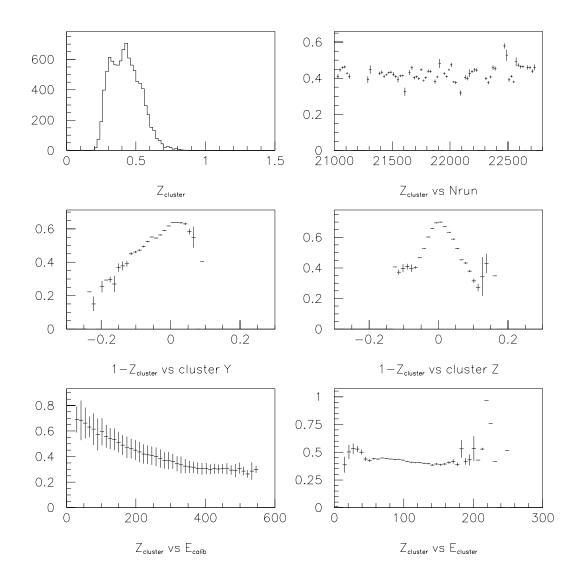

Figure D.6: Distributions of $Z_{cluster}$ uncorrected for non-linearities. The errors on the $Z_{cluster}$ vs E_{calib} plot show the spread on $Z_{cluster}$ and not the error on the mean.
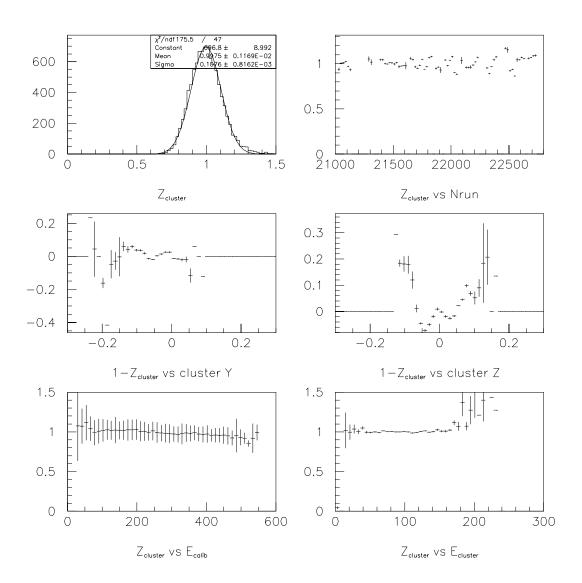

Figure D.7: Distributions of $Z_{cluster}$ corrected for non-linearities using the $E_{cluster}$ parameterization.

figure D.6. The quantities available in the Monte Carlo are the true energy of the cluster and the cluster position.

To obtain a parameterization that can be used for the Monte Carlo simulation, the variable $X(1)$ is defined as:

$$X(1) = EXP(-0.1896E - 02 * E_{calib})$$

The parameterization obtained is called the E_{calib} parameterization. The parameters are:

$A_0 = 0.6577$
$A_1 = 0.1773$
$A_2 = -0.1064$
$A_3 = -0.3996$
$A_4 = 0.405E - 01$
$A_5 = -0.301E - 01$
$A_6 = 0.1353E + 01$
$A_7 = 0.2766E + 02$
$B = 1$

The efficacy of this parameterization is tested by the plots shown in figure D.8, where the corrected $Z_{cluster}$ is plotted. The bulk of the dependencies are removed, but a small systematic variation with $E_{cluster}$ remains. The corrected $Z_{cluster}$ distribution can be fitted with a Gaussian with a mean of 1.016 and RMS of 0.107 .

D.5 Consistency of $E_{cluster}$ and E_{calib} Parameterizations

The $E_{cluster}$ and E_{calib} parameterizations are meant to describe the same quantity in the data. Hence they should agree with each other on an event-by-event basis. Suppose we use the E_{calib} parameterization to simulate a calorimeter cluster, instead of using the cluster from the real data. Then this cluster is corrected back using the $E_{cluster}$ parameterization. The corrected $Z_{cluster}$ of the simulated cluster should be 1 if both parameterizations were completely consistent. The results of this consistency check are shown in figure D.9. These parameterizations agree to within 5%. The disagreement is worst when the independent variables are at the edges of their respective distributions.
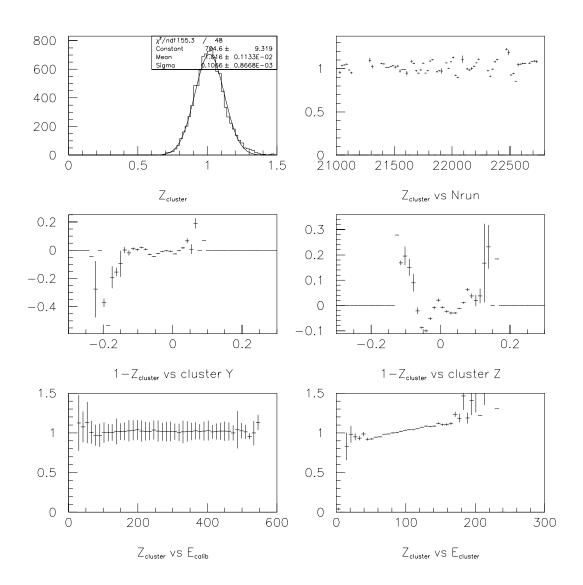

302

Figure D.8: Distributions of $Z_{cluster}$ corrected for non-linearities using the E_{calib} parameterization.
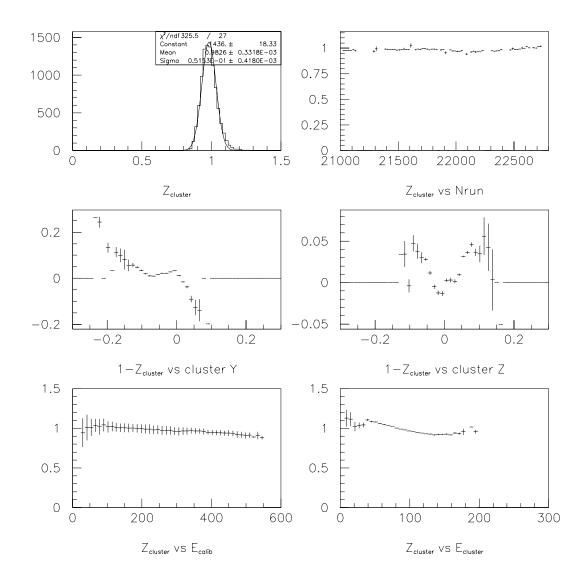

Figure D.9: Distributions of $Z_{cluster}$ for clusters simulated using the E_{calib} parameterization and corrected using the $E_{cluster}$ parameterization.

D.6   Conclusion

A sample of μe events is identified for the purpose of calibration of the central region of the calorimeter. There is evidence that the calorimeter response in this region depends on the position and the energy of the cluster. The position dependence is consistent with reduction of gain in the regions exposed to the beam. This response is parameterized as a function of time, the Y and Z position of the cluster, and the energy of the cluster or the energy measured by the spectrometer. When these parameterizations are used to correct the data, the cluster energy agrees with the spectrometer measurement with an RMS of 11%. The energy dependence of the spread suggests that the error has a large systematic component in addition to any stochastic component. The two parameterizations are quite consistent with each other except at extreme values of the independent variables. Overall they agree at the 5% level though the differences are systematic. This should be adequate for a simulation of the uncorrected data in the Monte Carlo, followed by a correction applied to data and Monte Carlo in identical fashion.

This description of the calorimeter response applies only for the region of the calorimeter illuminated by the electrons in the calibration sample. It should not be used outside of this central region. It is also not likely to be appropriate for run90, since the cumulative beam flux was less and any radiation damage would not be as severe as run91.
