A SEARCH FOR DIRECT PHOTON PRODUCTION AT FERMILAB ENERGIES
AND COMPARISON WITH DIRECT PHOTON MEASUREMENTS AT ISR ENERGIES

B. Cox

Abstract

A search for direct photon production has been performed at Fermilab in 200 and 300 GeV/c Proton-Be interactions over a wide range of $P_L$ and $X_F$. An excess of photons has been detected which when interpreted as single photon production yields a $\gamma/\pi^0$ ratio which averages $0.070 \pm 0.025$ in the region $1.5 < P_L < 4.0$ GeV/c and $-0.7 < X_F < 0.0$. This measurement is discussed and a comparison of this result with the ISR measurements of the $\gamma/\pi^0$ ratio has been made in an attempt to infer the energy dependence of direct photon production.

1. Introduction

Prior to the 1977 Lepton-Photon Conference in Hamburg, considerable interest had been aroused by the possibility that photons could be produced directly in hadron-hadron collisions by the interactions of the constituents of the nucleons. At the 1977 conference, the two pieces of data which existed at the time were presented. This data is shown in Fig. 1. Since that time, efforts to detect a direct photon signal have intensified. The ISR measurements have been superceded by new ISR experiments and the early result of Ref. 4 is now considered to be an upper limit determination. The Fermilab-JHU experimenters have performed a new and improved search with 200 and 300 GeV/c proton beams. We will discuss this new experiment and compare the results with the new ISR experiments. Finally, several new theoretical calculations of the level of direct photon production arising from QCD Compton scattering of gluons, QCD quark-antiquark annihilation, and the CIM virtual meson process (shown in Fig. 2a, b, and c respectively) have been performed. Some comparisons of the observed $\gamma/\pi^0$ ratios with the predictions of these models will be made.

2. Direct Photon Production in 200 and 300 GeV/c pBe Interactions

The measurement which is described in this section was performed in the P-West branch of the Proton area of Fermilab by a Fermilab-JHU collaboration using the lead glass spectrometer shown in Fig. 3. This experiment, which was conducted over a wide range of $P_L$ and $X_F$ (300 GeV region of measurement shown in Fig. 3) by varying the spectrometer arm angles over a large range of $\phi$, consisted of the four distinct measurements listed below:

1) Measurement of the total "single photon" flux. By "single" we mean all signals including coalescing $\pi^0$, and neutral hadrons which simulate a single photon shower.

2) Measurement of $\pi^0$ production in the same kinematic region by detecting both of the decay photons and reconstructing their energy and position.

3) Measurement of the $\eta^0/\pi^0$ ratio (This could only be performed near $X_F = 0$ because of the limited acceptance for $\eta$'s at larger center of mass angles).

4) Measurement of the ratio of neutral hadron to "single photon" flux.

In the case of all of these measurements, each spectrometer arm was triggered independently. The trigger consisted of the requirement of a neutral particle which was imposed by demanding no signal in the lucite hodoscopes L1, L2, and L3 in front of the Pb glass arrays and the requirement of total energy in the Pb glass above trigger threshold. The measurements of
'single photons', π₀'s, and the π₀/π⁰ ratio were performed simultaneously. A typical π⁰ spectrum is shown in Fig. 4 and the π⁰ production data which was accumulated is shown in Fig. 5. As noted in Fig. 5 the π⁰/π⁰ ratio obtained from this data is .47±.10 in good agreement with other measurements⁴ at 200 GeV/c and slightly smaller than the ISR measurements⁵-⁷ performed at higher energies.

The measurement of the neutral hadron component of the neutral flux required a separate run at each spectrometer angle and energy. In order to eliminate the photons, 11.3 radiation length of lead were inserted in the apertures of both arms during these runs. The flux of non-interacting neutral hadrons which penetrated the lead and triggered the spectrometer were then corrected for a 31% attenuation due to interactions in the lead. This attenuation was calculated from the measured total cross sections⁸ for hadrons in lead. Typical ratios of neutral hadrons to total neutral flux as a function of P_L are shown in Fig. 6 for two laboratory angle settings of the spectrometer arms. This ratio was determined as a function of X_F and P_L and subtracted in each X_F and P_L bin from the observed 'single photon' flux.

The results of the measurement of the π⁰ flux over the range .1< X_F< .5 and -.8< X_F< .0 are shown in Figs. 8, 9, and 10 and are described in Ref. 19. At both 200 and 300 GeV/c the data fit the form

\[ E_{\text{π⁰}}^{-\frac{d\sigma}{dp}} = A \left(1 - X_F\right)^N \]

with N = 8.9±1 and M = 4.9±2. As shown by the product spectra P_L N E_{\text{π⁰}} dp and (1-X_F) M E_{\text{π⁰}} dp in Figs. 8 and 9, the cross sections exhibit scaling with energy and show no flattening of the P_L spectrum in the X_F range in which ISR experiments²⁰ have observed a change in the P_L exponent. The flatness of the product P_L N E_{\text{π⁰}} dp vs. X_F shown in Fig. 10 gives further confirmation of the correctness of equation (1). This data supplies the basis for the denominator of the γ/π⁰ ratio.

$p+\pi^0 - \pi^+\pi^-$

Fig. 7 Measured ratio of neutral hadron production to total "single photon" candidates.

$p+\pi^0 - \pi^+\pi^-$

Fig. 8 $(1-X_n)^{-5} \times E_d^{10}$ vs. $p_x$ displays the explicit $p_x^3$ dependence of the data.

$p+\pi^0 - \pi^+\pi^-$

Fig. 9 $p^9 \times E_d^{10}$ vs. $X_n$ displays the explicit $(1-X_n)^3$ dependence of the data.

$p+\pi^0 - \pi^+\pi^-$

Fig. 10 $p^9 \times E_d^{10}$ vs. $\theta_{cm}$ demonstrates the $\theta_{cm}$ independence of the data.
The explicit method for calculating the $\gamma/\pi$ ratio in any $X_F$ and $P_L$ bin is given by

$$\frac{\gamma}{\pi^0} = \frac{\varepsilon(\pi^0) \cdot N_{\gamma}^{\text{MC}}}{\varepsilon(\gamma) \cdot N_{\pi^0}^{\text{MC}}}$$

where $N_{\gamma}$ = Number of observed photons (neutral hadrons subtracted).

$N_{\pi^0}$ = Number of observed $\pi^0$ (background two photon combinations subtracted).

$N_{\gamma}^{\text{MC}}$ = Number of predicted single photon-like events.

$\varepsilon(\pi^0)$ = Acceptance of the spectrometer arms as a function of $X_F$ and $P_L$ for $\pi^0$ events.

$\varepsilon(\gamma)$ = Acceptance of the spectrometer arms as a function of $X_F$ and $P_L$ for direct $\gamma$.

with $N_{\gamma}^{\text{MC}} = \varepsilon(\gamma) \cdot N_{\pi^0}^{\text{MC}}$ normalized region.

$W_{\gamma}^{\text{MC}}$ = Monte Carlo weight of accepted single photon-like events predicted from the three sources.

$N_{\pi^0}$ = Ratio of the number of observed pizero's in a given normalization region to the Monte Carlo calculated weight of the accepted $\pi^0$ events predicted in the normalization region.

In order to assign errors to the final $\gamma/\pi^0$ ratio calculated in the manner described above, many possible sources of systematic error were investigated. These sources are listed in Table I along with their contributions to the uncertainty in the ratio.

### Table I

</tbody>
</table>

The total systematic error dominates the error in the average value of $\gamma/\pi^0 = 0.702\pm0.025$ found for the entire region of acceptance averaging over both the 200 and 300 GeV/c data. The systematic error is approximately the same as the statistical errors on individual bins in the plots of $\gamma/\pi^0$ vs. $X_F$, $X_B$, $X_B$ and $\theta$ which are displayed in Figs. 11a, 11b, 12a and 12b respectively. The systematic uncertainty is shown as a band within which the data can be raised or lowered. The error bars on the data include both the statistical error and the error in the determination of the neutral hadron background. The spectrometer arms in this experiment are different lengths and because of this the systematic effects as well as the contributions of the various components of the "single photon" spectrum to the total spectrum differ for the arms. The data from each arm has been analyzed separately and the $\gamma/\pi^0$ ratio agrees within the assigned errors. A more detailed discussion of these systematic effects is given in Ref. 8.

The excess of single photons which was observed in this experiment when interpreted as direct photon production give the $\gamma/\pi^0$ ratio shown in Figs. 12a, 12b, 13a, and 13b.

These results indicate that $\gamma/\pi^0$ is increasing as a function of $X_B$ and $X_F$. However, it should be emphasized that the values of $\gamma/\pi^0$ given in these plots are average over the region of observation (see Fig. 3) and therefore cannot be directly compared with the theoretical predictions which are typically for $90^0$ in cms. In particular, since some increase of $\gamma/\pi^0$ with $X_F$ is observed experimentally, the level of $\gamma/\pi^0$ vs. $X_F$ might be expected to be raised and flattened by the averaging over a finite angle region. The statistical level of the data sample did not allow the detailed study of $\gamma/\pi^0$ vs. $X_F$ in bands of $X_B$, which would be needed in order to cleanly separate the $X_F$ and $X_B$ behavior. Ignoring these two problems in making the comparison of data and theory, we show in Fig. 12a four
theoretical predictions for the level of $\gamma/\pi^0$ at these low energies. Curve a is the prediction of Ruckel, Brodsky, and Gunion for $\gamma/\pi^0$ ratio at 200 and 300 GeV/c. This prediction includes both QCD and CIM effects, uses a calculated $\pi^0$ cross section for the denominator, and is valid, strictly speaking, only for $90^\circ$. Curve b is the QCD calculation of Halzen and Scott which includes both diagrams 2a and 2b but fixes the absolute level of the direct photon production not by using the normal value of $\alpha_s$, the running QCD coupling constant, but rather by normalizing to the level of high mass dimuon production (which proceeds via virtual photons by the same diagrams). If the usual $\alpha_s$ is used, curve b would be lowered by a factor of 2.5. Curve c is the sum of a CIM calculation performed by Halzen and Scott and curve b. The denominator of the $\gamma/\pi^0$ ratio of both curve b and curve c is experimental data and the prediction is a $90^\circ$ calculation. Finally curve d is the QCD calculation of Contogouris et al. Once again, the calculation is for $90^\circ$ and the denominator is derived from experimental data. Notice that in this region the calculation is similar to that of Halzen and Scott except for normalization.

3. Comparison With Other Data

The theoretical predictions of the $\gamma/\pi^0$ ratio suffer from many difficulties not only in the calculation of the direct photon production cross section but in an ambivalence of attitude about whether experimental data or a theoretical prediction should be used for the $\gamma^0$ production. In addition, most of the experiments inte-
\[ \gamma/\pi^0 = \frac{\frac{d\sigma}{dp_\perp}}{\frac{d\sigma}{dp_\perp}} \gamma \propto P_\perp N(X_L) \frac{g(X_L)}{f(X_L)} \]

and \( \gamma/\pi^0 \) itself is a factorizable function of \( X_L \) and \( P_\perp \).

In order to organize the thinking about this formula, we will investigate three possible forms that this formula can take.

1. \( N=N' \rightarrow \gamma/\pi^0 \propto P_\perp N'-N \) pure \( P_\perp \) dependence ratio independent of \( X_L \)
   
   \[ g(X_L)=f(X_L) \]

2. \( N=N' \rightarrow \gamma/\pi^0 \propto Q(X_L) \) pure \( X_L \) dependence ratio independent of \( P_\perp \)
   
   \[ g(X_L)=f(X_L) \]

3. \( N=N \rightarrow \gamma/\pi^0 \propto P_\perp N'-N \) \( X_L \) dependence
   
   \[ g(X_L)=f(X_L) \]

The first two cases are extreme cases and case 3 encompasses all the possibilities in between. By ignoring the differences of angular range encompassed by the various experiments and ignoring possible A dependence effects in comparing the fixed target experiment and the ISR data we can check these possibilities.

In order to check possibility 1, we plot \( \gamma/\pi^0 \) at a fixed \( P_\perp \) as a function of \( \sqrt{s} \) of the interaction.
If the ratio is a function only of \( P_L \), then the \( \gamma/\pi^0 \) ratio should be independent of energy. The data is shown in Fig. 14. With the underlined caveats the ratio seems to decrease with \( \sqrt{s} \) at fixed \( P_L \).

We have compared the energy dependence of the QCD calculation of Contogouris et al. to the data in the \( 4 \leq P_L \leq 4.5 \). The prediction is below the data at low \( \sqrt{s} \) (remember that the angular range of the data for the low energy points in \( 90^\circ < \theta < 160^\circ \) as compared to \( 90^\circ < \theta < 100^\circ \) for Kourkoumelis et al.) but in general a fall off of \( \gamma/\pi^0 \) with \( \sqrt{s} \) at fixed \( P_L \) seems to be predicted. The theory of Ruckel et al. would predict no \( \sqrt{s} \) dependence.

In order to check possibility 2 we have plotted the various data as a function of \( X_L \). This is shown in Fig. 15. From this data one can see that there is no universal function of \( X_L \). At a fixed \( X_L \) the data indicates quite clearly that the \( \gamma/\pi^0 \) ratio increases.

Finally, since neither of the two simple possibilities seem to be indicated, an attempt can be made to investigate more complicated cases. The data indicates that the \( \gamma/\pi^0 \) ratio is rising slowly at a given energy with \( P_L \). Therefore \( \gamma/\pi^0 > 0 \) but not large. If we assume \( \gamma/\pi^0 \propto 1 \), by plotting \( \gamma/\pi^0 \) vs. \( X_L \) we can check to determine if the data lies on some universal function of \( X_L \). This is shown in Fig. 16. Once again we are disappointed. While the higher \( X_L \) data tends to line up, the lower \( X_L \) data seems to disperse a bit. No simple answer is evident at this time with the existing data.

---

**Fig. 15** \( \gamma/\pi^0 \) vs. \( X_L \).

**Fig. 16** \( \gamma/\pi^0 \cdot P_L^{-1} \) vs. \( X_L \).

### Conclusions

What inferences can we draw from these data? First and foremost, there is an excess of single photons above that which we can expect from \( \eta \) and \( \pi^0 \) decay. In addition, direct photon production is expected to be present (at least in some calculations) copious enough to supply this excess. The \( \frac{\gamma}{\pi^0} \) ratio which is calculated from this excess is

\[
\frac{\gamma}{\pi^0} = \frac{0.65 \pm 0.025}{0.076 \pm 0.025} \Rightarrow \frac{\sqrt{s}}{\pi^0} = 19.4
\]

\[
1.5 < P_L < 4.0 \text{ GeV/c} \\
90^\circ < \theta < 160^\circ
\]

This \( \frac{\gamma}{\pi^0} \) signal seems to increase slowly with \( P_L \) and \( X_L \) although a clean separation of \( X_L \) and \( P_L \) dependence is not possible with existing data. If we compare the Fermilab data with the CERN ISR results, \( \frac{\gamma}{\pi^0} \) seems to decrease at fixed \( P_L \) (for the moderate \( P_L \) range\( < 5.0 \text{ GeV/c} \)). However, a flat \( P_L \) dependence is not ruled out because comparison of different experiments complicated by different kinematic ranges of measurements, possible A effects, and differences in data sample which could arise because of different charge particle vetos for different experiments. In general, \( \frac{\gamma}{\pi^0} \) seems to increase with energy at a fixed \( X_L \) beyond \( X_L = 2 \). No signal has been observed by any experiment below \( X_L = 1 \).
Finally, in closing, it should be obvious that progress has been made since the Hamburg Conference. It should be equally obvious that more and better experiments are needed. It is to be hoped that by the next Lepton-Photon Conference outstanding questions about this exciting new process may be resolved.

Acknowledgements
