AN OPTICAL AND TERAHERTZ INSTRUMENTATION SYSTEM AT THE FAST LINAC AT FERMILAB*

R. Thurman-Keup†, A. H. Lumpkin, J. Thangaraj, FNAL, Batavia, IL, 60510, USA

Abstract

FAST is a facility at Fermilab that consists of a photoinjector, two superconducting capture cavities, one superconducting ILC-style cryomodule, and a small ring for studying non-linear, integrable beam optics called IOTA. This paper discusses the layout for the optical transport system that provides optical radiation to an externally located streak camera for bunch length measurements, and THz radiation to a Martin-Puplett interferometer, also for bunch length measurements. It accepts radiation from two synchrotron radiation ports in a chicane bunch compressor and a diffraction/transition radiation screen downstream of the compressor. It also has the potential to access signal from a transition radiation screen or YAG screen after the spectrometer magnet for measurements of energy-time correlations. Initial results from both the streak camera and Martin-Puplett will be presented.

INTRODUCTION

The Fermilab Accelerator Science and Technology (FAST) facility has been constructed for advanced accelerator research [1-3]. It will eventually consist of 3 entities: a photoinjector-based linac followed by an ILC-type cryomodule, an RFQ-based proton injector, and a small ring called IOTA (Integrable Optics Test Accelerator) for studying non-linear optics among other things. Presently, the facility has the linac, cryomodule, and beamline to a high-energy dump. The IOTA ring is under construction and should be completed next year. The proton source is also under construction and will be completed in the next couple of years. When the full beamline to IOTA has been completed, the electron linac will provide beam to IOTA to map out the optics of the ring in preparation for injecting protons once the source is completed. In addition to the experiments in the IOTA ring, there are various experiments in the linac; both before the cryomodule and after. In support of these experiments, there is an optical / THz instrumentation system containing a Hamamatsu streak camera and a Martin-Puplett interferometer. This paper will describe the system and present some initial measurements from it.

FAST FACILITY

The FAST injector starts with a 1.3 GHz normal-conducting rf photocathode gun with a Cs2Te coated cathode. The photoelectrons are generated by irradiation with a YLF laser at 263 nm that can provide several µJ per pulse [4]. Following the gun are two superconducting 1.3 GHz capture cavities that accelerate the beam to its design energy of around 50 MeV. After acceleration, there is a section for doing round-to-flat beam transforms, followed by a magnetic bunch compressor and a short section that can accommodate small beam experiments. At the end of the experimental section is a spectrometer dipole which can direct the beam to the low energy dump. If the beam is not sent to the dump, it enters the ILC-type cryomodule where it receives up to 250 MeV of additional energy and is sent to either a high-energy dump or the IOTA ring. Table 1 lists the typical beam parameters.

OPTICAL AND TERAHERTZ INSTRUMENTATION SYSTEM

The optical / THz instrumentation system (OTIS) [5] is located near the low energy dump. The transport system is constructed of stainless steel pipes and flanges connected between boxes containing mirrors for steering the light (Fig. 1).

There are currently three source points for the radiation. One each from the third and fourth dipoles in the bunch compressor, D3 and D4, and one from a cross downstream of the bunch compressor, X121. There is also the possibility of implementing one from the cross (X124) in the low energy dump beamline that normally measures the energy spread.

The source points D3 and D4 in the bunch compressor provide coherent synchrotron edge radiation (CSR) from the entrance of the corresponding dipole magnets. The CSR is generally in the high GHz / low THz region [6].

The source point X121 consists of an aluminized, silicon wafer on a translatable actuator (Fig. 2). The wafer can be inserted all the way into the beam to generate both coherent transition radiation (CTR) and optical transition radiation (OTR). The screen can also be extracted partly, with its edge a few mm above the beam, to generate coherent diffraction radiation (CDR).

† keup@fnal.gov
All the sources converge to the OTIS box containing translatable mirrors to switch between the various inputs (Fig. 3). There are effectively three outputs from the box: a Hamamatsu streak camera, a Martin-Puplett interferometer, which is housed inside the OTIS box, and a ‘user’ location in the box which is currently unpopulated. Any input can be switched to any output. In addition, the mirror to switch light to the streak camera is a dielectric bandpass mirror with a reflection bandwidth of 400 – 700 nm. This transmits GHz/THz radiation to the Martin-Puplett interferometer.

The transport lines consist of stainless steel, 4 inch diameter pipes with quick disconnect flanges (Tri-clamp). In the bunch compressor, light is extracted through a single crystal quartz viewport. Since space is limited at these ports, a small box with one or two flat mirrors is attached to the port to redirect the radiation to a more readily accessible location. The radiation is then collimated by a pair of 3 inch diameter, 90° off-axis, parabolic, aluminium coated, UV-enhanced mirrors mounted in an adjustable mount. To enable the system to be disassembled when access to the beamline is needed, the longer pipes are cut in two and have a rubber bellows between them.

The streak camera is located outside the accelerator enclosure. The pipe running to the streak camera goes through one of the penetrations to the outside where the streak camera is housed in a small enclosure.
ALIGNMENT

The OTIS setup has many mirrors which forces one to consider how to align everything such that light gets from one end to the other. For the D3 and D4 ports, a laser is directed down the beamline with its waist at the location of the radiation source point. The mirrors are adjusted first for directionality and then for focus with the process iterated as necessary. At X121, a permanent alignment laser upstream is used to set the OTR screen angle, while a local laser is used to set the transport alignment and focusing. Figure 4 shows the local alignment laser.

INSTRUMENTATION

The end points of the optical and THz radiation include a Hamamatsu streak camera and a Martin-Puplett interferometer, both of which are used for bunch length measurements.

Streak Camera

The streak camera [7] is a Hamamatsu C5680 mainframe with S20 PC streak tube that can accommodate a vertical sweep plugin unit and a horizontal sweep unit or blanking unit. The device is fitted with all-mirror input optics enabling the assessment of the UV OTR component as well as the visible light OTR. The mirror optics also mitigate the streak image blurring due to the inherent chromatic temporal dispersive effects of the lens-based input optics for broadband sources such as OTR. The unit is equipped with the M5675 synchroscan unit with its resonant circuit tuned at 81.25 MHz such that the streak image has jitter of less than 1 ps from the system itself.

Interferometer

The Martin-Puplett interferometer is a polarizing-type interferometer with wire grids as the polarizer and beam splitters (Fig. 5). The wire grids are 10 µm diameter Tungsten wires with a 45-µm wire spacing. The device uses pyroelectric detectors to measure GHz/THz frequencies needed to determine the bunch length. The pyroelectric detectors are mounted on remote-controlled 2-D linear stages to allow optimization of the detected signal.

TRANSPORT SIMULATION

The transport of GHz and THz frequencies over long distances is problematic due to the combined effect of diffraction and apertures. Simulations have been done for CTR/CDR at a frequency of 250 GHz. The simulation is written in MATLAB. It calculates the near-zone transition radiation from the X121 source using the prescription of [8]. The electric fields are evaluated at the first mirror location in the transport line and propagated from there using the vector diffraction formulation in [9]. The propagation presently takes into account the aperture of the mirrors, but not the change in direction. The intensity distributions at various points along the transport are shown in Fig. 6.
more light to be lost to the apertures. Figure 7 quantifies the loss down the transport line for various CTR screen positions.

Figure 7: Integrated intensity along the transport line for a variety of CTR screen scenarios. The vertical steps in the intensity are due to either mirror apertures or polarizers. The offset of 1.75 cm corresponds to the screen acting as a CDR source.

**INITIAL DATA**

The system has been used to measure the bunch length as a function of rf chirp induced by the second accelerating cavity (CC2). Figure 8 shows the rms bunch length as measured by the streak camera as a function of degrees off crest (DOC) of the rf accelerating gradient in CC2. The minimum bunch length is a bit under 1 ps. Other streak camera measurements can be found in [10].

Figure 8: Streak camera measurements of rms bunch length using OTR from the X121 source point [11].

Initial setup of the Martin-Puplett involved scanning the pyroelectric detectors to find the peak signal. Figure 9 shows the measured and simulated signals. The interferometer has been used to make several autocorrelation measurements at varying bunch charges (Fig. 10). The bunch lengths were too long to distinguish subtle differences in length for different bunch charges, however the presence of an autocorrelation trace with a reasonable spectrum is promising for future measurements.

**SUMMARY**

A general purpose optical and terahertz instrumentation system has been installed and partially commissioned at the FAST facility at Fermilab. Measurements have been taken utilizing the streak camera, and some initial measurements have been done using the Martin-Puplett interferometer. Further commissioning and use is expected in experiments planned for the next several months.

**ACKNOWLEDGEMENTS**

The authors would like to thank the FAST department staff for their efforts in constructing and installing this system.
