Abstract

The Deep Underground Neutrino Experiment is a next-generation neutrino oscillation experiment that aims to measure CP-violation in the neutrino sector as part of a wider physics program. A deep learning approach based on a convolutional neural network has been developed to provide highly efficient and pure selections of electron neutrino and muon neutrino charged-current interactions. The electron neutrino (antineutrino) selection efficiency peaks at 90% (94%) and exceeds 85% (90%) for reconstructed neutrino energies between 2-5 GeV. The muon neutrino (antineutrino) event selection is found to have a maximum efficiency of 96% (97%) and exceeds 90% (95%) efficiency for reconstructed neutrino energies above 2 GeV. When considering all electron neutrino and antineutrino interactions as signal, a selection purity of 90% is achieved. These event selections are critical to maximize the sensitivity of the experiment to CP-violating effects.

I. INTRODUCTION TO DUNE

Over the last twenty years neutrino oscillations [1, 2] have become well-established [3–10] and the field is moving into the precision measurement era. The PMNS [1, 2] neutrino oscillation formalism describes observed data with six fundamental parameters. These are three angles describing the rotation between the neutrino mass and flavor eigenstates, two mass splittings (differences between the squared masses of the neutrino mass states), and CP-violating phase, δ_{CP}. If $\sin(\delta_{CP})$ is non-zero then the vacuum oscillation probabilities of neutrinos and antineutrinos will be different. DUNE [11] is a next-generation neutrino oscillation experiment with a primary scientific goal of making precise measurements of the parameters governing long-baseline neutrino oscillation. A particular priority is the observation of CP-violation in the neutrino sector. In DUNE, a muon neutrino (ν_μ)- or muon antineutrino ($\bar{\nu}_\mu$)-dominated beam will be produced by the Long-Baseline Neutrino Facility (LBNF) beamline and characterized by a near detector (ND) at Fermilab before the neutrinos travel 1285 km to the Sanford Underground Research Facility (SURF). The far detector (FD) will consist of four 10 kt (fiducial) liquid argon time projection chamber (LArTPC) detectors. Oscillation probabilities are inferred from comparison of the observed

---

neutrino spectra at the near and far detectors which are used to constrain values of the neutrino oscillation parameters.

A. CP-violation measurement

Symmetries under charge conjugation and parity inversion are both maximally violated by the weak interaction. Their combined operation has been shown to be violated, to a small degree, by quark mixing processes [12, 13]. The neutrino oscillation formalism allows for an analogous process in lepton flavor mixing which can be measured with neutrino oscillations. DUNE is sensitive to four neutrino oscillation parameters, namely Δm_{31}^2, θ_{23}, θ_{13} and δ_{CP}, which can be measured using four data samples: two for neutrinos and two for antineutrinos. Two beam configurations with opposite polarities of the magnetic focusing horns are used to produce these samples: "forward horn current" (FHC) mode produces a predominantly ν_μ beam while a primarily $\bar{\nu}_\mu$ beam is produced in "reverse horn current" (RHC) mode. The FD data used in the oscillation analysis measure the "disappearance" channels (i.e. $\nu_\mu \rightarrow \nu_\mu$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$), which are primarily sensitive to $|\Delta m_{31}^2|$ and $\sin^2 2\theta_{23}$, and the "appearance" channels (i.e. $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$), which are sensitive to all four parameters, including the sign of Δm_{31}^2. In all of these samples, interactions where the neutrinos scatter via charged-current (CC) exchange off the nuclei in the far detector are selected. In a CC interaction, the final state includes a charged lepton with the same flavor as the incoming neutrino and one or more hadrons, depending on the details of the interaction. Therefore, a critical aspect of event selection is the ability to identify the flavor of the final-state lepton. Thus it is key to be able to efficiently identify the signal (i.e. CC ν_μ, CC $\bar{\nu}_\mu$, CC ν_e and CC $\bar{\nu}_e$) interactions and have a powerful rejection of background events. At the energies relevant to the DUNE oscillation analysis, a final-state muon produces a long, straight track in the detector, while a final-state electron produces an electromagnetic (EM) shower. Examples of signal CC ν_e and CC ν_μ interactions are shown in Figs. 2 and 3a, respectively.

The main background to the CC ν_μ and CC $\bar{\nu}_\mu$ event selections are neutral current (NC) interactions with charged pions ($\pi^\pm$) in the final state that can mimic the $\mu^\pm$, an example of which is shown in Fig. 3b. Neutral current interactions with a final-state π^0 meson, such as the one shown in Fig. 3c, where the photons from π^0 decay may mimic the EM shower from an electron, form the primary reducible background to the CC ν_e and CC $\bar{\nu}_e$ event

15

selections. A small fraction of electron neutrinos are intrinsic to the beam (and thus are not the result of neutrino oscillations). These events form a background for the oscillation analysis as they are indistinguishable from CC ν_e appearance events. Once the four samples have been selected and the neutrino energy has been reconstructed, a fit is performed to the reconstructed neutrino energy distributions in the four samples to extract the neutrino oscillation parameters θ_{13}, θ_{23}, Δm^2_{31}, and δ_{CP}. This fit accounts for the effects of systematic uncertainties, including the constraints on those uncertainties from fits to ND data. Figure 1 shows the appearance samples and how they are expected to vary with the true value of δ_{CP}, for a data collection period of 3.5 years staged running in both FHC and RHC beam modes. Details of the DUNE staging plan, assumed oscillation parameters and the oscillation analysis are provided in [14].

(a) Neutrino mode.   (b) Antineutrino mode.
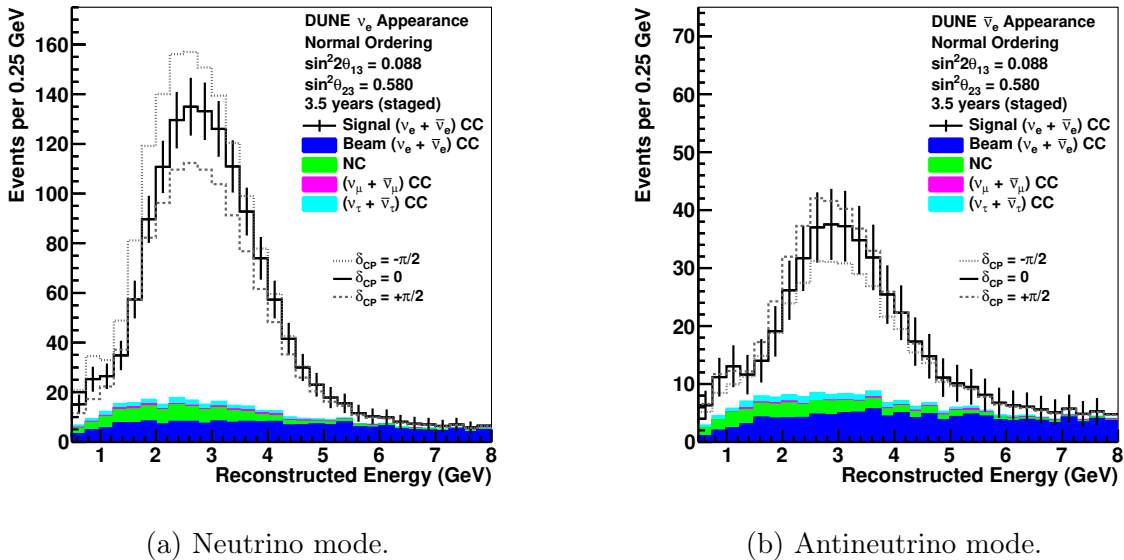

FIG. 1: Reconstructed energy distribution of ν_e and $\bar{\nu}_e$ CC-like events selected by the convolutional neural network algorithm (CVN) assuming 3.5 years (staged) running in the neutrino-beam mode (a) and antineutrino-beam mode (b), for a total of seven years (staged) exposure. The plots assume normal mass ordering and include curves for $\delta_{CP} = -\pi/2$, 0, and $\pi/2$. Background from ν_μ-CC, ν_τ-CC, intrinsic ν_e-CC, and NC interactions are shown as stacked, filled histograms. Figure reproduced from Ref. [14].

16

B. DUNE Far Detector

Neutrinos are detected via their interaction products i.e. observation of the leptons and hadrons that are produced when the neutrinos interact in the detector. In the single-phase LArTPC design that will be used for the first DUNE FD module, three wire readout planes collect the ionization charge that is generated when charged particles traverse the liquid argon volume. The ionization charge drifts in a constant electric field to the readout planes and the drift time provides a third dimension of position information, giving rise to the name "time projection chamber." The position of the charge observed in each of the three planes is combined with the drift time to create three views of each neutrino interaction. The wires that form the planes are separated by approximately 5 mm giving the FD a fine-grained sampling of the neutrino interaction products. The electronic signals from the wires are sampled at a rate of 2 MHz, giving a similar effective spatial resolution in the time direction. Two of the wire planes are induction planes, biased to be transparent to the drifting electrons, such that they induce net-zero fluctuation in the wire current as they pass the wire plane. The third view is called the collection plane as it actually collects the drifting electrons. The four DUNE FD modules may not all have identical designs, but they will all produce similar images of the neutrino interactions, so the performance of the single-phase design is used throughout this article. Other potential designs must have at least the same sampling capabilities as the single-phase design, if not better, to be considered.

C. DUNE Simulation and Reconstruction

Neutrino interactions in the far detector are simulated within the LArSoft [15] framework, using the neutrino flux from a GEANT4-based [16] simulation of the LBNF beamline, the GENIE [17] neutrino interaction generator (version 2.12.10), and a GEANT4-based (version 10.3.01) detector simulation. Detector response to, and readout of, the ionization charge is also simulated in LArSoft. Raw detector waveforms are processed to remove the impact of the electric field and electronics response; this process is referred to as "deconvolution" and the resulting deconvolved waveforms contain calibrated charge information. Current fluctuations in the wires above threshold, or "hits", are parameterized by Gaussian functions fit to deconvolved waveforms around local maxima. A reconstruction algorithm is used

to cluster hits linked in space and time into groups associated with a particular physical object, such as a track or shower. More details of the DUNE simulation and reconstruction are available in Ref. [11].

The energy of the incoming neutrino in CC events is estimated by a dedicated algorithm that adds the reconstructed lepton and hadronic energies, using particles reconstructed by Pandora [18, 19]. Pandora uses a multi-algorithm approach to reconstruct all the visible particles produced in neutrino interactions. It provides a hierarchy of reconstructed particles, representing particles produced at the interaction vertex and their decays or subsequent interactions. If the event is selected as CC ν_μ, the neutrino energy is estimated as the sum of the energy of the longest reconstructed track and the hadronic energy, where the energy of the longest reconstructed track is estimated from its range if the track is contained in the detector and from multiple Coulomb scattering if the track exits the detector. The hadronic energy is estimated from the energy associated with reconstructed hits that are not in the longest track. If the event is selected as CC ν_e, the energy of the neutrino is estimated as the sum of the energy of the reconstructed shower with the highest energy and the hadronic energy. In all cases, simulation-based corrections for missing energy (due to undetected particles, reconstruction errors, etc) are applied.

II.   CVN NEUTRINO INTERACTION CLASSIFIER

The DUNE Convolutional Visual Network (CVN) classifies neutrino interactions in the DUNE FD through image recognition techniques. In general terms it is a convolutional neural network (CNN) [20]. The main feature of CNNs is that they apply a series of filters (using convolutions, hence the name of the CNN) to the images to extract features that allow the CNN to classify the images [21]. Each of the filters - also known as kernels - consists of a set of values that are learnt by the CNN through the training process. CNNs are typically deep neural networks that consist of many convolutional layers, with the output from one convolutional layer forming the input to the next. Similar techniques have been demonstrated to outperform traditional event reconstruction-based methods to classify neutrino interactions [22, 23].

Convolutional neural networks make use of learned kernel operations, usually followed by spatial pooling, applied in sequence to extract increasingly powerful and abstract features.

In domains such as natural image analysis where important features of the data are locally spatially correlated they now greatly outperform previous state-of-the-art techniques that relied on manual feature extraction and simpler Machine Learning methods [24–27]. Recently they have proven to also be appropriate for the analysis of signals in particle physics detectors [28–30]. They have found particular success in neutrino experiments where signals can arrive at any location in large uniform detector volumes [22, 23, 31], and the characteristic translational invariance of CNN methods represents an advantage rather than a challenge.

A. Inputs to the CVN

Figure 4 shows that there are three inputs to the CVN. The three inputs are $500{\times}500$ pixel images of simulated neutrino interactions with one image produced for each of the three readout views of the LArTPC. The images are produced at the hit-level stage of the reconstruction algorithms and are hence independent of any potential errors in high-level reconstruction such as clustering, track-finding and shower reconstruction. The images are produced in (wire number, time) coordinates, where the wire number is simply the wire on which the reconstructed hit was detected, and the time is the interval from when the interaction happened to when the hit was detected on that wire (given by the peak time of the hit). The color of the pixel gives the hit charge where white shows that no hit was recorded for that pixel. Each pixel represents approximately 5 mm in the wire coordinate due to the spatial separation of the wires in the readout plane, and the time coordinate is down-sampled to approximately correspond to the same 5 mm size after consideration of the electron drift velocity within the LArTPC.

Convolutional neural networks operate on fixed-size images, hence the neutrino interaction images must all be of a fixed size. To facilitate this, interactions that span more than 500 wires in a given view are cropped to fit in 500×500 pixel images. The steps below are used to find the 500 pixels in the wire coordinate:

1. Integrate the charge on each wire.

2. Scan from low wire number, where low wire number corresponds to the upstream end of the detector, to high wire number and check the following 20 wires for recorded

19

signals. If fewer than five of the 20 subsequent wires have no signals then this wire is chosen as the first column of the image.

3. If no wire satisfies 2., choose the continuous 500 wire range that contains the most deposited charge.

For the time axis, a window of $3200\,\mu$s centred on the mean time of the hits is formed and divided into 500 bins that fill the 500 pixels. As such, no analogous region-of-interest search is performed.

In order to ensure high quality images of the interactions, images were only produced for events that have their true neutrino interaction vertex within the detector fiducial volume described in Ref. [14]. Once the images have been produced, any events that contain any view with fewer than 10 non-zero pixels are removed in order to discount empty and almost empty images from the training and testing datasets. Figure 2 shows a signal CC ν_e event as seen in the three detector readout views. Figure 3a shows a signal CC ν_μ interaction, and example NC background images containing a long $\pi^\pm$ track and a π^0 are given in Figs. 3b and 3c, respectively.

The number of pixels in the images was chosen to maximize the size of the image whilst ensuring that the memory usage during training and inference of the network was manageable. The spatial dimension of the images covers $2.5\,$m, meaning any tracks with projected lengths in the readout planes above $2.5\,$m will not be fully contained within the image, as is the case for the majority of muon tracks, including the one shown in Fig. 3a. However, the key details for the neutrino interaction classification come from the region surrounding the vertex, so this choice of image size does not significantly impact the classification performance.

B. Network architecture

A simple overview of the architecture is shown in Fig. 4. The detailed architecture of the CVN is based on the 34-layer version of the SE-ResNet architecture, which consists of a standard ResNet (Residual neural network) architecture [32, 33] along with Squeeze-and-Excitation blocks [34]. Residual neural networks allow the nth layer access to the output of both the $(n-1)^{\text{th}}$ layer and the $(n-k)^{\text{th}}$ layer via a residual connection, where k is a

positive integer ≥ 2. This is an important feature for the DUNE CVN as it allows the fine-grained detail of a LArTPC encoded in the input images to be propagated further into the CVN than would be possible using a traditional CNN such as the GoogLeNet (also called Inception v1) [35] inspired network used by NOvA [22].

The DUNE CVN differs from the architectures of other residual networks discussed in

the literature [32, 33] in the following ways:

- The input and the shallower layers of the CVN are forked into three branches - one for each view - to let the model learn parameters from each individual view (see section II A for more details). The outputs of the three branches are merged together by using a concatenation layer that works as input for the deeper layers of the model, as shown in Fig. 4.

- The CVN returns scores for each event through seven individual outputs (see section II C and Fig. 4 for more details). Since the deeper layers of the CVN contain the model parameters[1] that are simultaneously in charge of the classification for the different outputs of the network, some outputs might take advantage of the learning process of other outputs to improve their performance. Also, a multi-output network lets us weight the outputs in order to make the network pay more attention to some specific outputs (see section II D for more details).

- Each of the three branches (blocks 1-2, the shallower layers of the architecture shown in Fig. 4) consists of 7 convolutional layers, while the deeper layers (blocks 3-N in Fig. 4) consist of 29 convolutional layers, making a total of 50 convolutional layers for the entire network.

C.   Outputs from the CVN

There are seven outputs from the CVN, each consisting of a number of neurons with values v_i for $i = 1 \rightarrow n$ where n is the number of neurons. The sum of neuron values for each output (except for the last output since it consists of a single neuron) is given by $\sum_{i=1}^{n} v_i = 1$ such that each value of a neuron within a single output gives a fractional score that can be used to classify images.

The first output below, which classifies the flavor of the neutrino interaction, is the primary output and it is the only one used in the analysis presented in the DUNE TDR [11, 14]. The other outputs are included in the architecture for potential use in future analyses.

[1] Model parameters: coefficients of the model learnt during the training stage, also known as weights.

FIG. 4: Simplified diagram of the DUNE CVN architecture.

1. The 1st output (4 neurons) returns scores for each event to be one of the following flavors: CC ν_μ, CC ν_e, CC ν_τ and NC. This is the primary output of the network used for the main goal of neutrino interaction flavor classification.

2. The 2nd output[2] (4 neurons) returns scores for each event to be one of the following interaction types: CC quasi-elastic (CC QE), CC resonant (CC Res), CC deep inelastic (CC DIS) and CC other.

3. The 3rd output (4 neurons), returns scores for each event to contain the following number of protons: 0, 1, 2, >2.

4. The 4th output (4 neurons), returns scores for each event to contain the following number of charged pions: 0, 1, 2, >2.

---

[2] Outputs to 'sub-classify' CC events. NC events are not considered for the training of this output.

23

5. The 5$^{\text{th}}$ output (4 neurons), returns scores for each event to contain the following number of neutral pions: 0, 1, 2, >2.

6. The 6$^{\text{th}}$ output (4 neurons), returns scores for each event to contain the following number of neutrons: 0, 1, 2, >2.

7. The 7$^{\text{th}}$ output[2] (1 neuron) returns the score for each event to be a neutrino as opposed to an antineutrino.

Outputs 2, 6 and 7 are not considered in the analyses presented here and are hence not further discussed, but they are included in the training and the overall loss calculations. The prediction of an event as a given underlying (anti)neutrino interaction is highly model-dependent and not as important as the number of final-state particles that can be observed in the detector, hence output 2 is not used. The neutron counting is very difficult since it is hard to define whether a neutron interaction would be visible and identifiable in the detector, so this output will not be used until it has been shown to work reliably. Finally, the antineutrino vs neutrino output is not likely to provide highly efficient or pure event selections since there is only a weak dependence on the event observables to try to differentiate neutrinos and antineutrinos.

D. Training the CVN

The CVN[3] was trained using Python 3.5.2 and Keras 2.2.4 [36] on top of Tensorflow 1.12.0 [37], on eight NVIDIA Tesla V100 GPUs. Stochastic Gradient Descent (SGD) is used as the optimizer, with a mini-batch size of 64 events (192 views), a learning rate of 0.1 (divided by 10 when the error plateaus, as suggested in [32]), a weight decay of 0.0001, and a momentum of 0.9. The network was trained/validated/tested on 3,212,351 events (9,637,053 images/views), consisting of 27% CC ν_μ, 27% CC ν_e, 6% CC ν_τ and 40% NC, from a single Monte Carlo sample as follows: training ($\sim 98\%$), validation ($\sim 1\%$) and test ($\sim 1\%$). The sample of events is an MC prediction for the DUNE unoscillated FD neutrino event rate (flux times cross section) distribution in FHC beam mode as described in Ref. [11]. Samples where the input fluxes to the MC are "fully oscillated" (i.e. all ν_μ are replaced with ν_e, or

---

[3] A small data release of the code is available at `https://github.com/DUNE/dune-cvn`.

all ν_μ are replaced with ν_τ) are also used (these samples are usually weighted by oscillation probabilities and combined to produce oscillated FD event rate predictions). Analogous versions of each input sample are used for the RHC beam mode. For training purposes all CC ν_e events were considered signal since the intrinsic beam ν_e are indistinguishable from signal (appearance) ν_e at any given energy. The results presented in the following sections use a statistically independent Monte Carlo sample.

The individual loss functions for the different outputs that were used for training the model, as well as the overall loss function, are given below[4]:

- Neutrino flavor ID, interaction type[5], proton count, charged pion count, neutral pion count, neutron count loss functions (J_1, J_2, J_3, J_4, J_5, and J_6, respectively): categorical cross-entropy, the loss function needed for multi-class classification.

$$J_1 = J_2 = J_3 = J_4 = J_5 = J_6 = -\frac{1}{m} \sum_{i=1}^{m} \sum_{j=1}^{c} y_j^{(i)} \log \hat{y}_j^{(i)} \tag{1}$$

- Neutrino/antineutrino ID loss function[5] (J_7): binary cross-entropy, the loss function needed for binary classification.

$$J_7 = -\frac{1}{m} \sum_{i=1}^{m} \boldsymbol{y}^{(i)} \log(\hat{\boldsymbol{y}}^{(i)}) + (1 - \boldsymbol{y}^{(i)}) \log(1 - \hat{\boldsymbol{y}}^{(i)}) \tag{2}$$

- Overall loss function:

$$J = \sum_{i=1}^{o} w_i J_i = w_1 J_1 + w_2 J_2 + w_3 J_3 + w_4 J_4 + w_5 J_5 + w_6 J_6 + w_7 J_7 \tag{3}$$

- Where:

    - $\boldsymbol{y}^{(k)}$: true values of a specific output corresponding to the *k-th* training example.
    - $\hat{\boldsymbol{y}}^{(k)}$: predicted values of a specific output corresponding to the *k-th* training example.
    - m: number of training examples $\{\mathbf{X}^{(1)}, \boldsymbol{y}^{(1)}\}$, $\{\mathbf{X}^{(2)}, \boldsymbol{y}^{(2)}\}$, ..., $\{\mathbf{X}^{(m)}, \boldsymbol{y}^{(m)}\}$, where $\mathbf{X}^{(k)}$ means the input readout views corresponding to the kth training example.

---

[4] Generally, a_k represents the kth element of some vector $\boldsymbol{a}$.

[5] A mask is applied to only consider CC events during the loss computation.

– c: number of classes/neurons corresponding to a specific output $\boldsymbol{y}_1$, $\boldsymbol{y}_2$, ... , $\boldsymbol{y}_c$.

– o: number of outputs of the network; the CVN has seven different outputs.

– $\boldsymbol{w}$: output weights; vector of length o.

The CVN was trained for 15 epochs[6] for ~4.5 days (7 hours per epoch), and similar classification performance was obtained for the training and test samples. Figure 5 shows the loss and accuracy training and validation results for the four main CVN outputs, where accuracy is defined as the fraction of events correctly classified for a given output. The red vertical lines show the epoch at which the CVN weights were taken for the model used in the presented analysis. After that epoch, the validation accuracy remains constant and small signs of overtraining begin to emerge (a small divergence of the training and validation accuracy curves). However, at epoch 10 the difference between training and validation is still negligible.

E. Feature maps

To study how the CVN is classifying the interactions it is advisable to look at feature maps at different points in the network architecture. An example is shown in Fig. 6 for a CC $\bar{\nu}_e$ interaction, demonstrating the position from which two sets of feature maps are viewed within the network. The set of images in the top right shows the response of the filters in the first convolutional layer to the input electromagnetic shower image, where red shows a high response to a given filter, and yellow shows a low response. Across the different particle types and event topologies, the filters respond to different components in the images. The 512 feature maps from the final convolutional layer, shown at the bottom of Fig. 6 for the aforementioned CC $\bar{\nu}_e$ interaction, are much more abstract in appearance since the input images have passed through many convolutions and have hence effectively been down-sampled to a size of 16×16 pixels from their original 500×500 pixel size.

---

[6] Epoch: one forward pass and one backward pass of all the training examples. In other words, an epoch is one pass over the entire dataset.

III.   NEUTRINO FLAVOR IDENTIFICATION PERFORMANCE

The primary goal of the CVN is to accurately identify CC ν_e, CC $\bar{\nu}_e$, CC ν_μ and CC $\bar{\nu}_\mu$ interactions for the selection of the samples required for the neutrino oscillation analysis. The values of the neurons in the flavor output give the score for each neutrino interaction to be one of the neutrino flavors. The CVN CC ν_e score distribution, $P(\nu_e)$, is shown for the FHC beam mode (left) and RHC (right) in Fig. 7 for all interactions with a reconstructed event vertex within the FD fiducial volume, as described in Ref. [14]. The contributions from neutrino and antineutrino components for each flavor are combined since the detector can not easily distinguish between them. Very clear separation is seen between the signal (CC ν_e and CC $\bar{\nu}_e$) interactions and the background interactions including those from NC ν and NC $\bar{\nu}$ events. The beam CC ν_e background is seen to peak in the same way as the

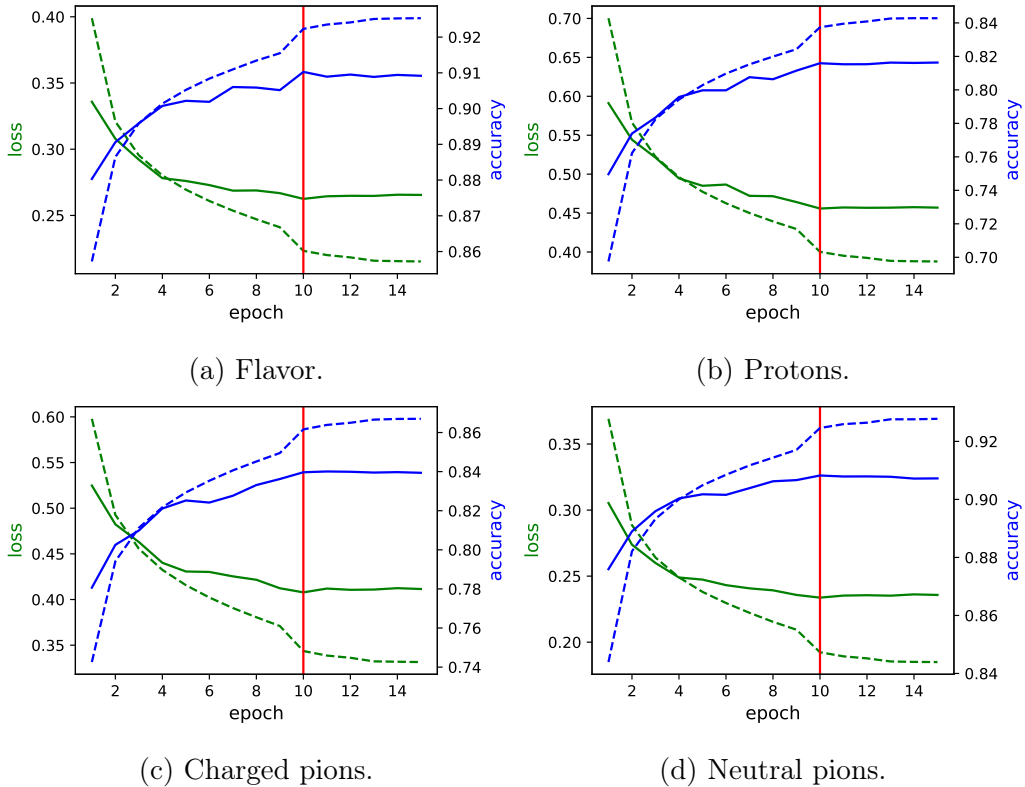

FIG. 5: Loss and accuracy results for training (dashed lines) and validation (solid lines), given for the four main CVN outputs. The red vertical lines guide the eye to the network results at epoch 10, after which flavor classification performance of the validation sample does not improve.
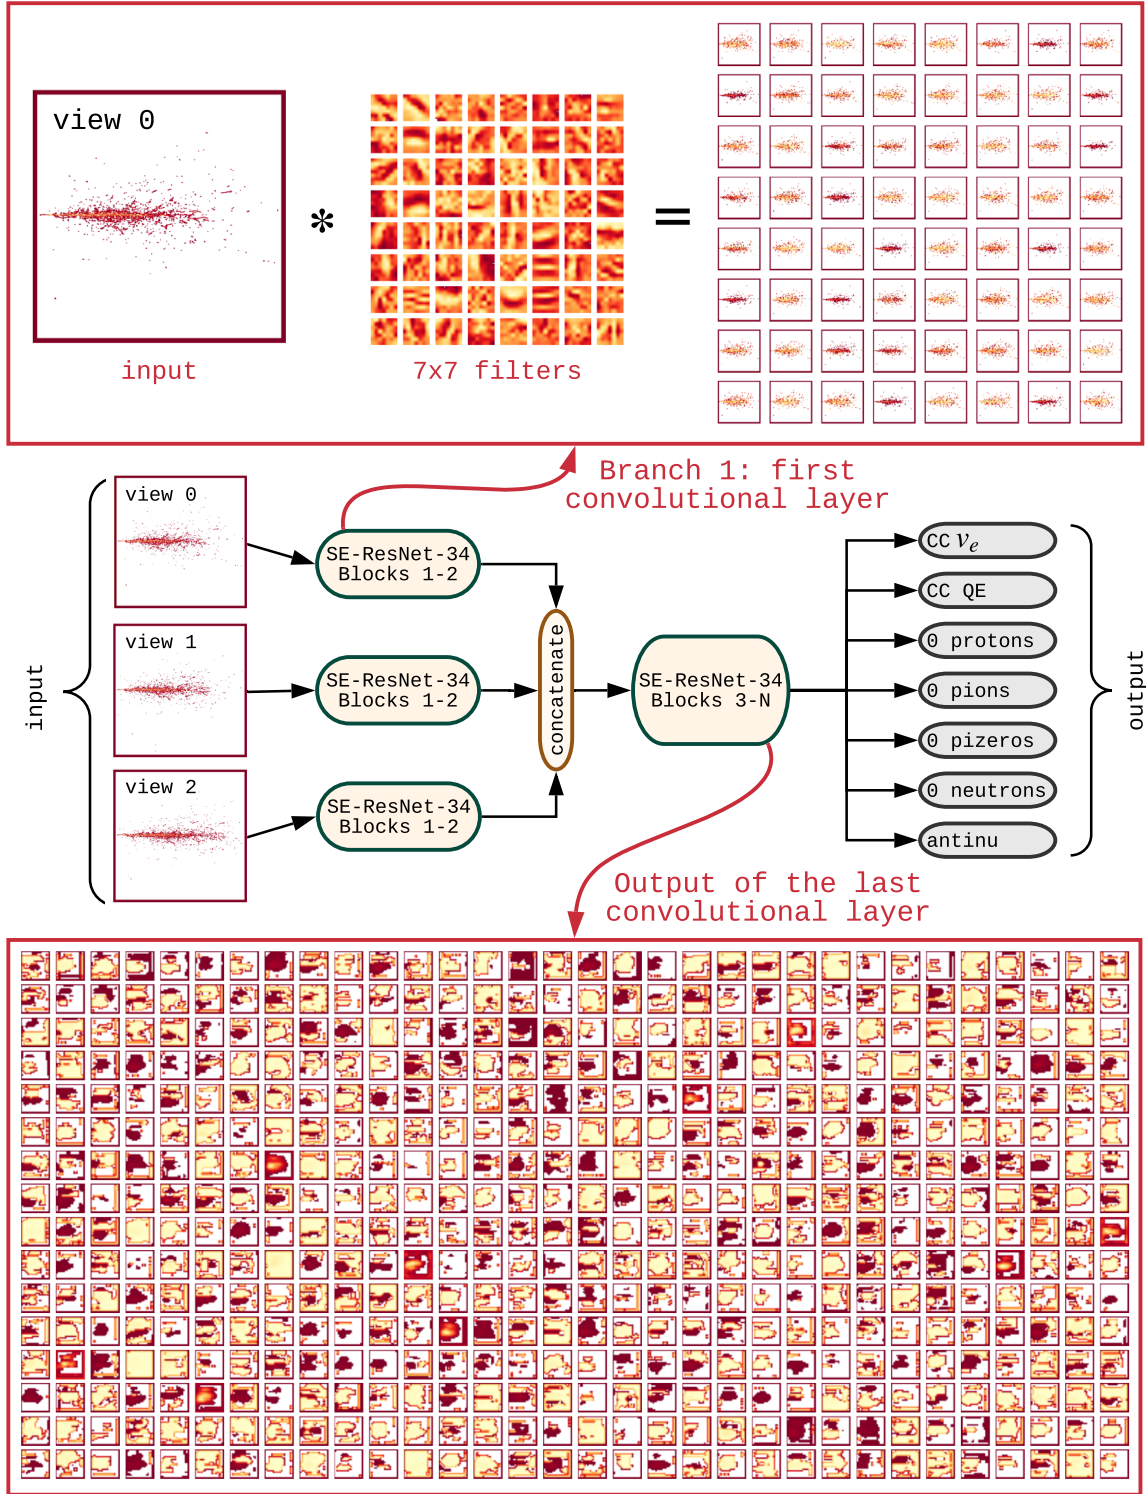

FIG. 6: Visualisations of the feature extraction in the CVN for a 12.2 GeV CC $\bar{\nu}_e$ interaction. The top box shows the output from the first convolutional layer of the first branch of the network: 64 convolution kernels of size 7x7 each are applied to the image, resulting in 64 different feature maps. The bottom box shows the 512 feature maps produced by the final convolutional layer.
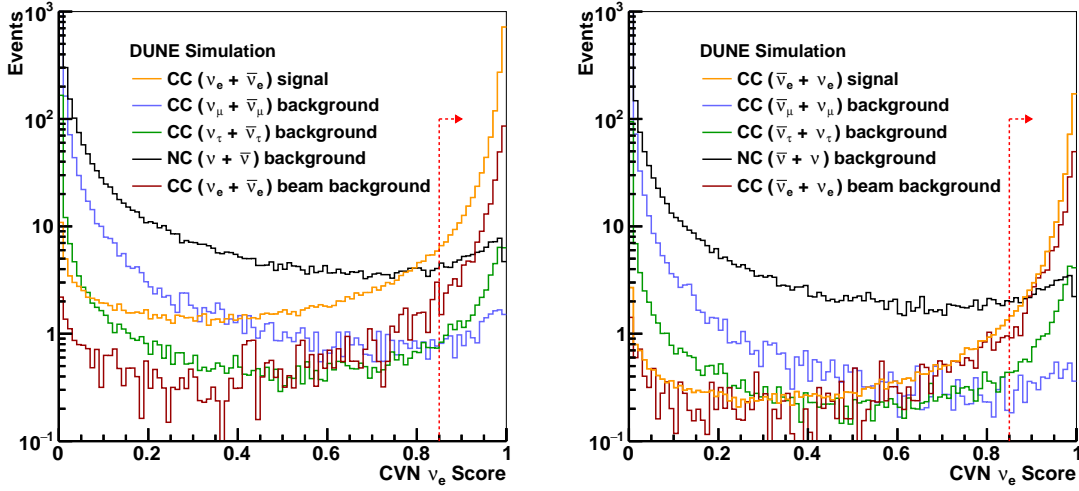

FIG. 7: The number of events as a function of the CVN CC ν_e classification score shown for FHC (left) and RHC (right) beam modes. For simplicity, neutrino and antineutrino interactions have been combined within each histogram category. A log scale is used on the y-axis, normalized to 3.5 years of staged running, and the arrows denote the cut values applied for the DUNE TDR analyses [11].

CC ν_e signal, which is expected since both arise from the same type of neutrino interaction. Figure 8 shows the corresponding plots for $P(\nu_\mu)$ for FHC and RHC beam modes for the same set of interactions. In all four histograms the signal interactions are peaked closely near score values of unity and the backgrounds lie close to zero score, as expected.

The CC ν_e event selection criteria are chosen to maximize the oscillation analysis sensitivity to CP-violation; i.e.: significance of the determination that $\sin(\delta_{CP}) \neq 0$ [14]. The optimization was performed using a simple scan of cuts on $P(\nu_e)$ for a single true value of δ_{CP}. CP-violation sensitivity does not strongly depend on the selection criterion for $P(\nu_\mu)$ so this cut was chosen by inspection of Fig. 8. The resulting requirements are $P(\nu_e) > 0.85$ for an interaction to be selected as a CC ν_e candidate and $P(\nu_\mu) > 0.5$ for an interaction to be selected as a CC ν_μ candidate. These cut values are represented by the red arrows in Figs. 7 and 8. Since all of the flavor classification scores must sum to one, these two samples are mutually exclusive. The same CVN and selection criteria are used for both FHC and RHC event selections.

Figure 9 shows the efficiency as a function of reconstructed energy (under the electron
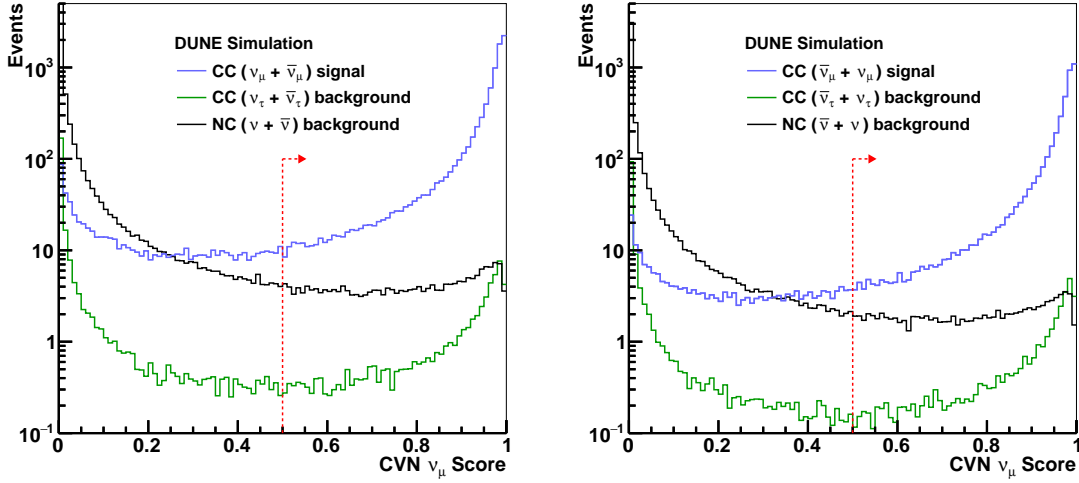

FIG. 8: The number of events as a function of the CVN CC ν_μ classification score shown for FHC (left) and RHC (right) beam modes. For simplicity, neutrino and antineutrino interactions have been combined within each histogram category. Backgrounds from CC ν_e interactions are negligible and not shown. A log scale is used on the y-axis, normalized to 3.5 years of staged running, and the arrows denote the cut values applied for the DUNE TDR analyses [11].

neutrino hypothesis, as discussed in Section I C) for the CC ν_e and CC $\bar{\nu}_e$ event selections. The efficiency for the CVN is shown compared to the predicted efficiency used in the DUNE Conceptual Design Report (CDR) [38], demonstrating that, across the most important part of the flux distribution (less than 5 GeV), the performance can exceed the CDR assumption. The efficiency in FHC (RHC) mode peaks at 90% (94%) and exceeds 85% (90%) for reconstructed neutrino energies between 2-5 GeV. The CDR analysis was based on a fast simulation that employed a parameterized detector response based on GEANT4 single particle simulations, and a classification scheme that classified events based on the longest muon/charged pion track, or the largest EM shower if no qualifying track was present. The efficiencies at low energy were tuned to hand scan results as a function of lepton energy and event inelasticity. Figure 10 shows the corresponding selection efficiency for the CC ν_μ event selection. The efficiency has a maximum efficiency of 96% (97%) and exceeds 90% (95%) efficiency for reconstructed neutrino energies above 2 GeV for the FHC (RHC) beam mode. The optimized cut values permit a larger background component than the CDR analysis
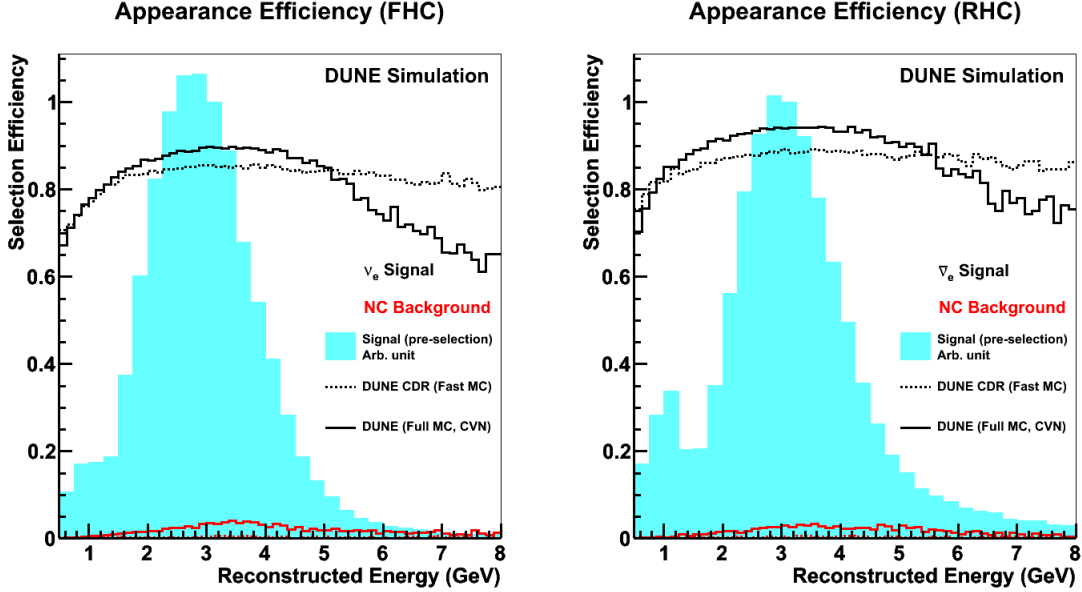

30

FIG. 9: The CC ν_e selection efficiency for FHC-mode (left) and RHC-mode (right) simulation with the criterion $P(\nu_e) > 0.85$. The solid (dashed) lines show results from the CVN (CDR) for signal CC ν_e and CC $\bar{\nu}_e$ events in black and NC background interactions in red. The cyan shaded region shows the oscillated flux to illustrate the most important regions of the energy distribution.

but the overall performance of the selection is increased due to the significantly improved signal efficiency. Considering all electron neutrino interactions (both appeared and beam background CC ν_e and CC $\bar{\nu}_e$ events) as signal interactions, the CVN has a selection purity of 91% (89%) for the FHC (RHC) beam mode, assuming the normal neutrino mass ordering and $\delta_{CP} = 0$ [14].

IV.   EXCLUSIVE FINAL STATE RESULTS

The CVN has three outputs that count the number of final-state particles for the following species: protons, charged pions, and neutral pions. Neutrino interactions with different final-state particles can have different energy resolutions and systematic uncertainties depending on the complexity and particle multiplicity of the interaction. It may be possible to improve the oscillation sensitivity of the analysis by identifying subsamples of events with specific interaction topologies and very good energy resolution.
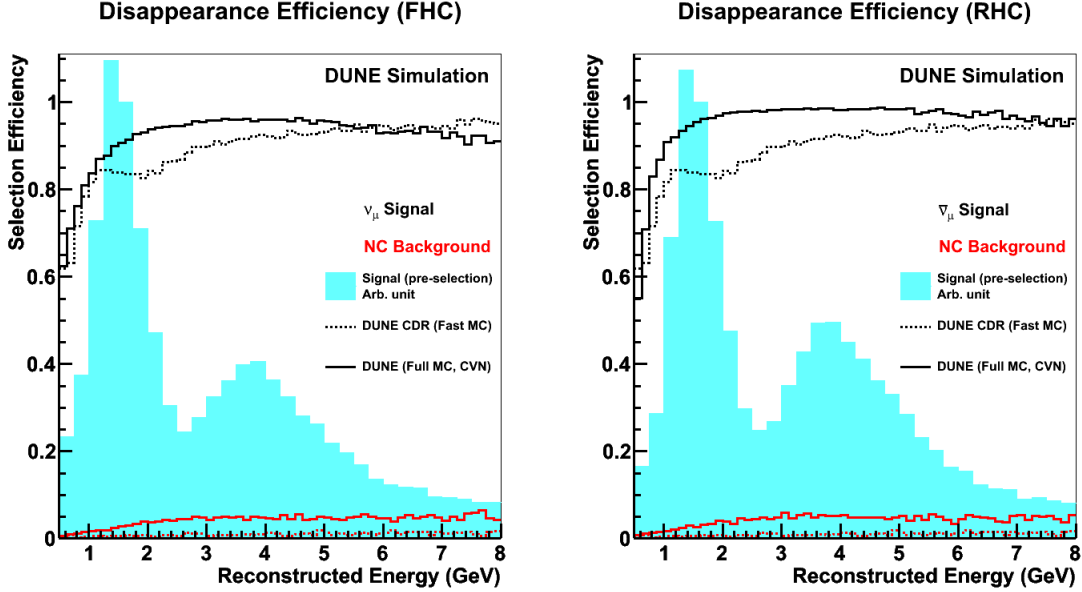

31

FIG. 10: The CC ν_μ selection efficiency for FHC-mode (left) and RHC-mode (right) simulation with the criterion $P(\nu_\mu) > 0.5$. The solid (dashed) lines show results from the CVN (CDR) for signal CC ν_μ and CC $\bar{\nu}_\mu$ events in black and NC background interactions in red. The cyan shaded region shows the oscillated flux to illustrate the most important regions of the energy distribution.

The individual output scores from the CVN can be multiplied together to give compound scores for exclusive selections. For example, the left plot in Fig. 11 shows the combined score for an event to be CC ν_μ with only a single proton in the final-state hadronic system, formed by the product

$$P\left(\mathrm{CC}\nu_\mu\,1\mathrm{p}\right) = P\left(\nu_\mu\right)P\left(1\,\mathrm{p}\right)P\left(0\pi^\pm\right)P\left(0\pi^0\right). \tag{4}$$

Similarly, the right plot of Fig. 11 shows NC1π^0 score, which contains only a single visible π^0 meson in the final state, defined as:

$$P\left(\mathrm{NC}\,1\pi^0\right) = P\left(\mathrm{NC}\right)P\left(0\mathrm{p}\right)P\left(0\pi^\pm\right)P\left(1\pi^0\right). \tag{5}$$

The background and signal distributions, closely peaked toward 0 and 1 respectively, demonstrate that the efficient selection of exclusive final states will be possible with the DUNE CVN technique. However, it is possible that the CVN is keying in on features of the model that are not well-supported by data (e.g. kinematic distributions of particles in the hadronic shower) rather than well-supported features, like the individual particle energy deposition
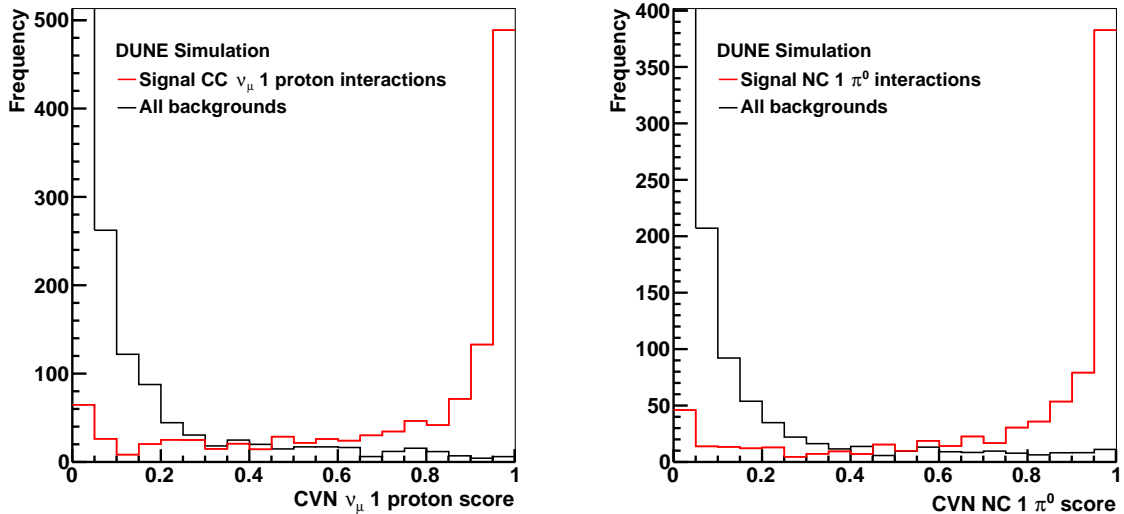

32

FIG. 11: The CC ν_μ 1 proton (left) and NC $1\pi^0$ (right) combined score distributions from the CVN. In both cases the number of other particles is required to be zero. All events that do not fit the signal description comprise the all backgrounds histograms. The histograms are shown in the expected relative fractions but the overall scale is arbitrary.

patterns. Studies of potential bias from selections based on these classifiers are required before they can be used to generate analysis samples. Provided that the particle counting outputs can be shown to work in a robust manner for simulations and experimental data, these detailed selections have the potential to significantly improve the scientific output of DUNE FD data.

V.   ROBUSTNESS

A common concern about the applications of deep learning in high energy physics is the difference in performance between data and simulation. A straightforward check of the CVN robustness is to inspect plots of the CVN efficiency as a function of various kinematic quantities. More advanced studies could be imagined where the underlying input physics model is changed to produce alternate input samples for training and testing purposes. Studies of this nature are beyond the scope of this paper, but should be part of the validation scheme for any deep learning discriminant used in eventual analyses of DUNE data.

To be considered well-behaved, the CVN flavor identification should be sensitive to the

presence of a visible charged lepton and not highly dependent on the details of the hadronic system, which could be poorly modeled. A visible charged lepton requires that the track or shower that it produces has clearly distinguishable features that are not masked by the presence of many overlapping energy depositions from particles from the hadronic shower. Furthermore, background interactions selected by the CVN should be those containing charged pions (for CC ν_μ) or neutral pions (for CC ν_e) that mimic the charged leptons in the signal interactions. Plots of selection efficiency for signal and background interactions were generated as a function of a variety of true and reconstructed quantities, several of which are highlighted here.

Figure 12 shows the variation of the signal selection efficiency as a function of the charged lepton energy for three ranges of hadronic energy for the CC ν_e (left) and CC ν_μ (right) selections. There is a threshold around $0.1\,\mathrm{GeV}$ below which no events are correctly identified, and a region at higher lepton energy where the efficiency reaches a maximum and remains relatively flat. As the hadronic energy increases the maximum efficiency decreases, and this effect is more pronounced for the CC ν_e selection since EM showers are more easily masked by hadronic shower energy depositions, as compared with long, straight muon tracks. The CC ν_μ efficiency as a function of the true muon energy also demonstrates that the performance is not affected by the lack of confinement of higher energy muons ($\gtrsim 1\,\mathrm{GeV}$) within the 500×500 pixel images, as was discussed in Section II A.

The plot on the left of Fig. 13 shows the efficiency in the CC ν_e selection for background interactions containing a π^0 meson as a function of the reconstructed ν_e energy distribution for three ranges of π^0 energy, E_{π^0}. As expected, the selection efficiency is larger for the background interactions with higher energy π^0 mesons. Similarly, the selection efficiency for background interactions containing a π^+ meson in the CC ν_μ selection is shown on the right of Fig. 13 to be larger for higher energy mesons.

Figure 14 shows the selection efficiency for CC ν_μ and CC ν_e interactions as a function of the charged lepton angle, defined with respect to the neutrino direction. This angle is defined in 3D, hence when the angle is $90°$ it corresponds to two cases where the efficiency is expected to be lower: the lepton is travelling almost perpendicular to the readout planes, or the lepton is travelling parallel to the collection plane (view 2) wires. In these two cases the CVN does not have clear images of the charged lepton in one or more readout views. This angle is also strongly correlated with the charged lepton energy, explaining the lower
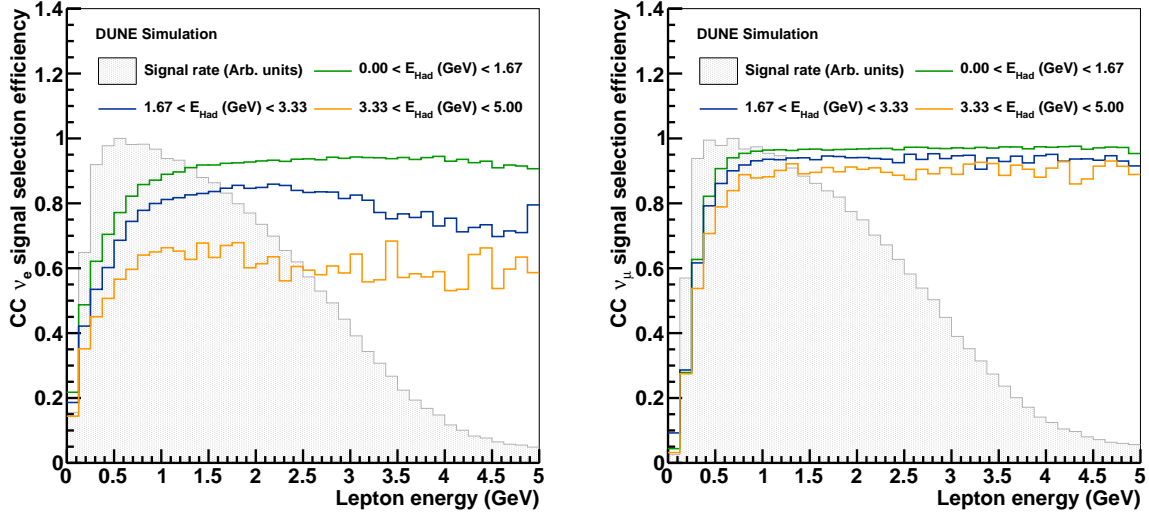

FIG. 12: The variation of the signal selection efficiency as a function of the charged lepton energy shown for three ranges of hadronic energy, E_{Had}, for the CC ν_e (left) and CC ν_μ (right) selections. In both cases the distribution of the unoscillated signal events before selection is shown by the filled grey histogram.

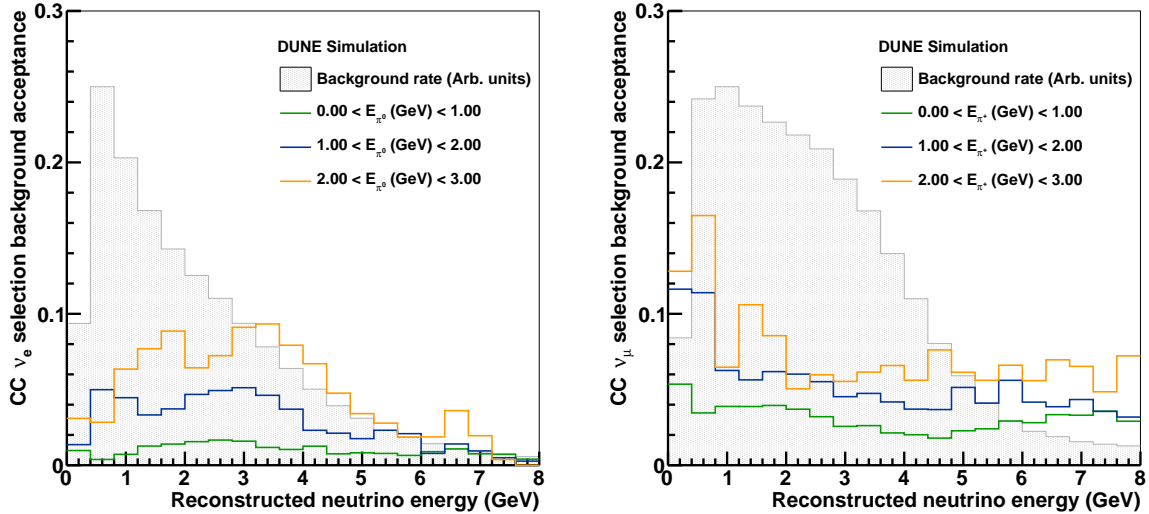

FIG. 13: Left: the background acceptance in the CC ν_e selection for background interactions containing a final-state π^0 meson. Right: the background acceptance in the CC ν_μ selection for background interactions containing a final-state π^+ meson. In both cases the energy distribution of the unoscillated backgrounds before selection is shown by the filled grey histogram.
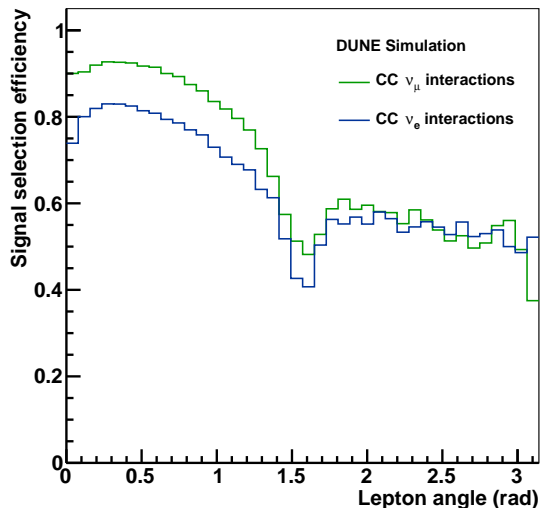

FIG. 14: The signal selection efficiency for CC ν_μ (green) and CC ν_e (blue) interactions as a function of the angle between the outgoing charged lepton and the parent neutrino.

efficiency for events containing backward going, and hence lower energy, charged leptons.

Additional studies, not shown here, help to elucidate other features of these distributions. For example, a small fraction of events with very low energy leptons are still correctly identified. For these events it can be shown that they contain high energy pions which are likely responsible for their strong CVN flavor identification scores. Also of note are studies of the efficiency for other kinematic variables that showed no dependence other than those induced by their correlations with the leptonic and hadronic system energies. Finally, studies of CC ν_τ events showed that efficiencies were consistent with the tau decay rates to muons and electrons. Roughly 17% of CC ν_τ events were classified as CC ν_μ, and about 17% as CC ν_e. The primary $\tau^\pm$ decays before leaving a track in the detectors, and though CC ν_τ event kinematics are different from CC ν_e and CC ν_μ events, these events are classified based on the visible charged lepton in the event.

The outcome of these studies provides confidence that the CVN classification is strongly tied to the charged lepton features: EM showers and muon tracks. The lowest performance is seen for indistinguishable intrinsic backgrounds, such as beam-induced electron neutrinos, and events with a misidentified hadron and no visible, lepton-induced track or shower.

VI. CONCLUSION

The DUNE CVN algorithm provides excellent neutrino flavor classification, reaching efficiencies of 90% for electron neutrinos and 95% for muon neutrinos. These efficiencies have basic features that are consistent with those presented in the DUNE CDR [38]. The CVN outperforms the CDR estimates, exceeding the signal selection efficiency over most of the energy ranges shown, albeit with slightly decreased background rejection capability. The results presented here form a key part of the neutrino oscillation analysis sensitivities presented in the DUNE TDR [11]. A proof-of-principle demonstration of final-state particle counting showed a potential mechanism by which to subdivide the event selections to further improve the analysis sensitivity. Future studies of possible systematic biases arising from physics models are planned to ensure the robustness of the particle counting outputs.
