This work presents a lattice quantum chromodynamics (QCD) calculation of the nonperturbative Collins-Soper kernel, which describes the rapidity evolution of quark transverse-momentum-dependent parton distribution functions. The kernel is extracted at transverse momentum scales in the range $400 \text{ MeV} < q_T < 1.7 \text{ GeV}$ in a calculation with dynamical fermions and quark masses corresponding to a larger-than-physical pion mass, $m_\pi = 538(1) \text{ MeV}$. It is found that different approaches to extract the Collins-Soper kernel from the same underlying lattice QCD matrix elements yield significantly different results and uncertainty estimates, revealing that power corrections, such as those associated with higher-twist effects, and perturbative matching between quasi and light-cone beam functions, cannot be neglected.

I. INTRODUCTION

Transverse-momentum-dependent parton distribution functions (TMDPDFs) describe the intrinsic transverse momentum q_T of the partonic constituents of hadrons [1–3]. These non-perturbative functions can be accessed directly in high-energy scattering processes such as Drell-Yan production and semi-inclusive deep-inelastic scattering with small transverse hadron momentum q_T [4, 5], and indirectly through other processes such as studies of hadrons in jets [6, 7]. Significant efforts are underway to improve constraints on TMDPDFs both from current and planned experiments [8–12] and through theory calculations in the framework of lattice quantum chromodynamics (QCD) [13–22] using approaches such as large-momentum effective theory (LaMET) [23–25] or the Lorentz-invariant method based on ratios of TMDPDFs [13].

TMDPDFs $f_i^{\text{TMD}}(x, b_T, \mu, \zeta)$, defined for a parton of flavor i in a given hadron state, are functions of the longitudinal momentum fraction x of the parton, the Fourier conjugate b_T of q_T , the virtuality scale μ , and the rapidity scale ζ which is related to the hadron momentum. While the μ -evolution of TMDPDFs is perturbative for perturbative scales μ and ζ , the ζ -evolution is governed by the Collins-Soper evolution kernel (or anomalous dimension) $\gamma_\zeta^i(\mu, b_T)$, which is nonperturbative for scales $b_T \sim q_T^{-1} \sim \Lambda_{\text{QCD}}^{-1}$, even if both μ and ζ are perturbative. Constraints on the kernel $\gamma_\zeta^i(\mu, b_T)$ in the nonperturbative region are necessary in order to relate TMDPDFs determined from experiment or lattice QCD at different scales.

Recently, it was shown in Refs. [26–28] that the Collins-Soper kernel can be calculated from ratios of quasi TMDPDFs at different hadron momenta, quantities which are

both calculable in lattice QCD and which can be related to TMDPDFs [27, 29–32]. This provides a pathway to first-principles QCD calculations of the kernel in the non-perturbative region, which will provide valuable complementary information to constraints from global analyses of experimental data. This prospect has motivated a series of proof-of-principle lattice QCD investigations of the Collins-Soper kernel both directly [18–22] through the approach of Refs. [26–28] and via related prescriptions [33].

In this work, a direct calculation of the Collins-Soper kernel is presented, based on a lattice QCD study with dynamical fermions and quark masses corresponding to a larger-than-physical pion mass $m_\pi = 538(1) \text{ MeV}$, and a single value of the lattice spacing and volume. The kernel is extracted at transverse momentum scales in the range $400 \text{ MeV} < q_T < 1.7 \text{ GeV}$ and compared with phenomenological parametrizations and existing lattice QCD calculations. This analysis includes several advances over previous lattice QCD studies of the Collins-Soper kernel via the same approach. In particular, matching of quasi TMDPDFs and TMDPDFs is performed to one-loop order, the mixing of different TMDPDFs under renormalization is fully accounted for, and the analysis includes improved treatments of power corrections and systematic effects arising from the finite lattice volume and various statistical limitations of the calculation. It is found that different approaches to extract the Collins-Soper kernel from the same underlying lattice QCD matrix elements yield significantly different results and uncertainty estimates, revealing that power corrections, such as those associated with higher-twist effects, and perturbative matching between quasi and light-cone beam functions, cannot be neglected.

The method by which the Collins-Soper kernel can be computed following Refs. [26, 27] is detailed in Section II. The lattice QCD calculation is reported in Section III, while a summary and outlook is provided in Section IV.

II. QUASI TMDPDFS AND THE COLLINS-SOPER KERNEL

The quark Collins-Soper kernel $\gamma_\zeta^q(\mu, b_T)$ can be computed in lattice QCD from a ratio of nonsinglet quasi TMDPDFs $\tilde{f}_{\text{ns}}^{\text{TMD}}$ at different hadron momenta (taken in the z -direction) $P_i^z \gg \Lambda_{\text{QCD}}$ [26, 27, 32]:

$$\begin{aligned} \gamma_\zeta^q(\mu, b_T) &= \frac{1}{\ln(P_1^z/P_2^z)} \\ &\times \ln \frac{C_{\text{ns}}^{\text{TMD}}(\mu, xP_2^z) \tilde{f}_{\text{ns}}^{\text{TMD}}(x, \vec{b}_T, \mu, P_1^z)}{C_{\text{ns}}^{\text{TMD}}(\mu, xP_1^z) \tilde{f}_{\text{ns}}^{\text{TMD}}(x, \vec{b}_T, \mu, P_2^z)} \\ &+ \mathcal{O}\left(\frac{1}{(xP^z b_T)^2}, \frac{\Lambda_{\text{QCD}}^2}{(xP^z)^2}\right). \end{aligned} \quad (1)$$

The perturbative matching coefficient $C_{\text{ns}}^{\text{TMD}}$ relates the quasi TMDPDFs, which are defined in terms of Euclidean-space matrix elements as detailed below, to the corresponding light-cone TMDPDFs through a factorization theorem based on an expansion in powers of the nucleon momentum [26, 27, 31, 32]. Additional non-perturbative factors related to the soft sector [27, 30] cancel in the ratio; recently exploratory lattice QCD studies of these factors have been performed [20, 22] following the approach proposed in Refs. [31, 32]. The flavor nonsinglet unpolarized quark quasi TMDPDF is defined as $\tilde{f}_{\text{ns}}^{\text{TMD}} = \tilde{f}_u^{\text{TMD}} - \tilde{f}_d^{\text{TMD}}$, where

$$\begin{aligned} \tilde{f}_i^{\text{TMD}}(x, \vec{b}_T, \mu, P^z) &\equiv \lim_{a \rightarrow 0} \int \frac{db^z}{2\pi} e^{-ib^z(xP^z)} \mathcal{Z}_{\gamma^4 \Gamma}^{\overline{\text{MS}}}(\mu, b^z, a) \\ &\times \frac{P^z}{E_{\vec{P}}} \tilde{B}_i^\Gamma(b^z, \vec{b}_T, a, \eta, P^z) \tilde{\Delta}_S(b_T, a, \eta). \end{aligned} \quad (2)$$

Here a denotes the lattice spacing, and $E_{\vec{P}} = \sqrt{\vec{P}^2 + m_h^2}$ where $\vec{P} = P^z \vec{e}_z$ is the hadron three-momentum and m_h is the hadron mass. The factor $\mathcal{Z}_{\gamma^4 \Gamma}^{\overline{\text{MS}}}(\mu, b^z, a)$, where Γ is a Dirac matrix label, renormalizes the quasi TMDPDF and matches it to the $\overline{\text{MS}}$ scheme at scale μ [18, 28, 34], and the quasi soft factor $\tilde{\Delta}_S$ [26, 27, 29, 30] and quasi beam function $\tilde{B}_i^\Gamma$ are both calculable in lattice QCD. Summation over Γ is implied, accounting for operator mixing between quasi TMDPDFs with different Dirac structures resulting from the breaking of rotational and chiral symmetries in lattice QCD calculations [18, 34–36]. Mixing with gluon operators is neglected in Eq. (2), but cancels in the nonsinglet combination of quasi TMDPDFs. It should be noted that the choice of the Dirac structure γ^4 in Eq. (2) is not unique; the quasi TMDPDF with Dirac structure γ^3 can also be boosted onto γ^+ and thus be matched to the spin-independent TMDPDF in the infinite-momentum limit (in that case, the factor of $P^z/E_{\vec{P}}$ in Eq. (2) is replaced by 1). While the notation is specialized to γ^4 for clarity throughout this exposition, numerical results are presented for both choices of Dirac structure in Sec. III.

FIG. 1. Diagrammatic representation of the Wilson line included in the operators $\mathcal{O}_i^i(b^\mu, z^\mu, \eta)$, see Eq. (4).

The quasi beam function $\tilde{B}_i^\Gamma$ is defined as the matrix element of a nonlocal quark bilinear operator with a staple-shaped Wilson line in a boosted hadron state:

$$\tilde{B}_i^\Gamma(b^z, \vec{b}_T, a, \eta, P^z) = \langle h(P^z) | \mathcal{O}_i^i(b^\mu, 0, \eta) | h(P^z) \rangle, \quad (3)$$

where $h(P^z)$ denotes the state of hadron h with four-momentum $P^\mu = (0, 0, P^z, E_{\vec{P}})$. The operator $\mathcal{O}_i^i(b^\mu, 0, \eta)$, depicted in Fig. 1, is defined as

$$\begin{aligned} \mathcal{O}_i^i(b^\mu, z^\mu, \eta) &\equiv \bar{q}_i(z^\mu + b^\mu) \frac{\Gamma}{2} W_{\hat{z}}(z^\mu + b^\mu; \eta - b^z) \\ &\times W_T^\dagger(z^\mu + \eta \hat{z}; b_T) W_{\hat{z}}^\dagger(z^\mu; \eta) q_i(z^\mu) \\ &\equiv \bar{q}_i(z^\mu + b^\mu) \frac{\Gamma}{2} \widetilde{W}(\eta; b^\mu; z^\mu) q_i(z^\mu), \end{aligned} \quad (4)$$

where $b^\mu = (\vec{b}_T, b^z, 0)$, and $W_{\hat{\alpha}}(x^\mu; \eta)$ denotes a Wilson line beginning at x^μ with length η in the direction of $\hat{\alpha}$. The subscript T denotes that the associated Wilson line is in a direction transverse to $\hat{z}^\mu = (0, 0, 1, 0)$.

In practice, it is useful to define a dimensionless ‘bare’ nonsinglet quasi beam function:

$$\begin{aligned} B_\Gamma^{\text{bare}}(b^z, \vec{b}_T, a, \eta, P^z) &\equiv \frac{1}{2E_{\vec{P}}} \left(\tilde{B}_u^\Gamma(b^z, \vec{b}_T, a, \eta, P^z) \right. \\ &\quad \left. - \tilde{B}_d^\Gamma(b^z, \vec{b}_T, a, \eta, P^z) \right), \end{aligned} \quad (5)$$

as well as a modified $\overline{\text{MS}}$ -renormalized quasi beam function $B_\Gamma^{\overline{\text{MS}}}$ [19]:

$$\begin{aligned} B_{\gamma^4}^{\overline{\text{MS}}}(\mu, b^z, \vec{b}_T, a, \eta, P^z) &\equiv Z_{\mathcal{O}_{\gamma^4 \Gamma}}^{\overline{\text{MS}}}(\mu, b^z, b_T^R, a, \eta) \\ &\times \tilde{R}(b_T, b_T^R, a, \eta) B_\Gamma^{\text{bare}}(b^z, \vec{b}_T, a, \eta, P^z). \end{aligned} \quad (6)$$

Compared with the standard $\overline{\text{MS}}$ -renormalized quasi beam function, this definition includes the additional factor $\tilde{R}$, described further below. The renormalization factor $Z_{\mathcal{O}_{\gamma^4 \Gamma}}^{\overline{\text{MS}}}$ is defined as the product of a regularization-independent momentum subtraction scheme (RI'/MOM) factor $Z_{\mathcal{O}_{\gamma^4 \Gamma}}^{\text{RI'/MOM}}$ and a perturbative matching factor to the $\overline{\text{MS}}$ scheme, $\mathcal{R}_{\mathcal{O}_{\gamma^4 \Gamma}}^{\overline{\text{MS}}}$, which has been calculated at next-to-leading order in continuum perturbation theory

with dimensional regularization ($D = 4 - 2\epsilon$) [28, 34]:

$$\begin{aligned} Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}(\mu, b^z, b_T, a, \eta) &= \mathcal{R}_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}(\mu, p_R, b^z, \vec{b}_T, \eta) \\ &\times Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\text{RI}'/\text{MOM}}(p_R, b^z, \vec{b}_T, a, \eta). \end{aligned} \quad (7)$$

In this expression, the dependence on the RI'/MOM scale p_R and on the direction of $\vec{b}_T$ cancels between $Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\text{RI}'/\text{MOM}}$ and $\mathcal{R}_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}$ at all orders in perturbation theory (up to discretization artifacts). The quasi beam function renormalization factor is related to the TMDPDF renormalization factor $\mathcal{Z}_{\gamma^4\Gamma}^{\overline{\text{MS}}}$ in Eq. (2) as

$$\mathcal{Z}_{\gamma^4\Gamma}^{\overline{\text{MS}}}(\mu, b^z, a) = Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}(\mu, b^z, b_T, a, \eta) Z_S^{\overline{\text{MS}}}(\mu, b_T, a, \eta), \quad (8)$$

where $Z_S^{\overline{\text{MS}}}$ renormalizes the quasi soft factor $\tilde{\Delta}_S$. The η and b_T -dependence on the right-hand side of Eq. (8) describes linear power divergences proportional to η/a and b_T/a which cancel between the two terms.

To ensure that the matching factor $\mathcal{R}_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}$ is in the perturbative region, both $Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\text{RI}'/\text{MOM}}$ and $\mathcal{R}_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}$ should be computed at a scale $b_T^R \ll \Lambda_{\text{QCD}}^{-1}$. In Eq. (6), this scale is taken to be distinct from $\vec{b}_T$ which is associated with the staple geometry of the operator defining the bare quasi beam function. As a result, $Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}$ cannot completely cancel the ultraviolet (UV) divergence in the bare quasi beam function, and remnant linear divergences $\sim |b_T - b_T^R|/a$ appear in Eq. (6). The factor $\tilde{R}$ is included to cancel such divergences. One possible choice of $\tilde{R}$ is [18]

$$\tilde{R}(b_T, b_T^R, a, \eta) = \frac{Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\text{RI}'/\text{MOM}}(p_R = \tilde{p}_R, b^z = 0, \vec{b}_T, a, \eta)}{Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\text{RI}'/\text{MOM}}(p_R = \tilde{p}_R, b^z = 0, \vec{b}_T^R, a, \eta)}, \quad (9)$$

defined for a fixed choice of $\tilde{p}_R$, and of the directions of $\vec{b}_T$ and $\vec{b}_T^R$. An alternative choice of $\tilde{R}$ is defined and used in Ref. [28].

In terms of the modified $\overline{\text{MS}}$ -renormalized quasi beam functions, the Collins-Soper kernel may be computed as

$$\begin{aligned} \gamma_\zeta^q(\mu, b_T) &= \frac{1}{\ln(P_1^z/P_2^z)} \ln \left[\frac{C_{\text{ns}}^{\text{TMD}}(\mu, xP_2^z)}{C_{\text{ns}}^{\text{TMD}}(\mu, xP_1^z)} \right. \\ &\times \left. \frac{\int db^z e^{-ib^z x P_1^z} P_1^z \lim_{\eta \rightarrow \infty} B_{\gamma^4}^{\overline{\text{MS}}}(\mu, b^z, \vec{b}_T, a, \eta, P_1^z)}{\int db^z e^{-ib^z x P_2^z} P_2^z \lim_{\eta \rightarrow \infty} B_{\gamma^4}^{\overline{\text{MS}}}(\mu, b^z, \vec{b}_T, a, \eta, P_2^z)} \right] \\ &+ \mathcal{O}\left(\frac{1}{(xP^z b_T)^2}, \frac{\Lambda_{\text{QCD}}^2}{(xP^z)^2}\right). \end{aligned} \quad (10)$$

Since $\tilde{\Delta}_S$ and its renormalization factor $Z_S^{\overline{\text{MS}}}$, as well as the factor $\tilde{R}$ included in the definition of $B_{\gamma^4}^{\overline{\text{MS}}}$, are

independent of b^z , this expression is equivalent to that in Eq. (1). The specific choice of $\tilde{R}$ (including the choices of $\tilde{p}_R$ and $\vec{b}_T$ and $\vec{b}_T^R$ orientations) does not affect the value of γ_ζ^q .

III. NUMERICAL STUDY

The Collins-Soper kernel is computed via Eq. (10) in a lattice QCD calculation with four dynamical quark flavors, using an ensemble of gauge field configurations generated by the MILC collaboration with the one-loop Symanzik improved gauge action and the highly improved staggered quark action. A single ensemble is studied, with a lattice volume of $L^3 \times T = 48^3 \times 64$, a lattice spacing corresponding to $a = 0.12$ fm, and sea quark masses tuned to approximately match the physical quark masses in nature; see Ref. [37] for further details of the ensemble generation. Calculations are performed in a partially-quenched mixed-action setup, with the tree-level $\mathcal{O}(a)$ -improved Wilson clover fermion action used for the valence quarks, with $\kappa = 0.1241$ tuned such that the pion mass is $m_\pi = 538(1)$ MeV. The gauge fields used in the calculation have been subjected to Wilson flow to flow-time $t = 1.0$ [38], to enhance the signal-to-noise ratio in the numerical results¹. The following sections detail the computation of each element of γ_ζ^q .

A. Bare quasi beam functions

Quasi beam functions in a pion external state are computed from ratios of three-point and two-point correlation functions:

$$\begin{aligned} \mathcal{R}_\Gamma(t, \tau, b^\mu, a, \eta, P^z) &= \frac{C_{3\text{pt}}^{\Gamma, u}(t, \tau, b^\mu, a, \eta, P^z \vec{e}_z) - C_{3\text{pt}}^{\Gamma, d}(t, \tau, b^\mu, a, \eta, P^z \vec{e}_z)}{C_{2\text{pt}}(t, P^z \vec{e}_z)} \\ &\xrightarrow{t \gg \tau \gg 0} B_\Gamma^{\text{bare}}(b^z, \vec{b}_T, a, \eta, P^z) + \dots, \end{aligned} \quad (11)$$

where

$$\begin{aligned} C_{3\text{pt}}^{\Gamma, i}(t, \tau, b^\mu, a, \eta, \vec{P} = P^z \vec{e}_z) &= \sum_{\vec{x}, \vec{z}} e^{i\vec{P} \cdot \vec{x}} \langle 0 | \pi_{\vec{P}, S}(\vec{x}, t) \mathcal{O}_\Gamma^i(b^\mu, (\vec{z}, \tau), \eta) \pi_{\vec{P}, S}^\dagger(0) | 0 \rangle \\ &\xrightarrow{t \gg \tau \gg 0} \frac{Z_{\vec{P}}}{4aE_{\vec{P}}^2} e^{-E_{\vec{P}} t} \tilde{B}_i^\Gamma(b^z, \vec{b}_T, a, \eta, P^z) + \dots \end{aligned} \quad (12)$$

¹ Note that the flowed gauge fields were also used for constructing $\not{D}$.

n_z	P^z [GeV]	η/a	n_{src}	n_{cfg}
3	0.65	{12,14}	4	96
3	0.65	23	16	100
5	1.1	{12,14}	4	449
7	1.5	{12,14}	16	596

TABLE I. Quasi beam functions are computed for n_{src} source locations on each of n_{cfg} configurations for each pion boost P^z . Matrix elements of operators with staple widths $\vec{b}_T$ in the positive $\hat{x}$ direction with $0 \leq |b_T| \leq \eta$ and asymmetries $-\eta \leq b^z \leq \eta$ are computed.

and

$$C_{2\text{pt}}(t, \vec{P}) = \sum_{\vec{x}} e^{i\vec{P} \cdot \vec{x}} \langle 0 | \pi_{\vec{P},S}(\vec{x}, t) \pi_{\vec{P},S}^\dagger(0) | 0 \rangle$$

$$\xrightarrow{t \gg 0} \frac{Z_{\vec{P}}}{2aE_{\vec{P}}} e^{-E_{\vec{P}}t} + \dots \quad (13)$$

In the construction of the correlation functions, momentum-smeared interpolating operators $\pi_{\vec{P},S}(\vec{x}, t) = \bar{u}_{S(\vec{P}/2)}(\vec{x}, t) \gamma_5 d_{S(\vec{P}/2)}(\vec{x}, t)$ are built from quasi local smeared quark fields $q_{S(\vec{P})}(\vec{x}, t)$ constructed with 50 steps of iterative Gaussian momentum-smearing [39] with smearing radius $\varepsilon = 0.2$. $Z_{\vec{P}}$ denotes the combination of overlap factors for the source and sink interpolating operators.

Two and three-point functions are constructed for three choices of pion boost $\vec{P} = P^z \vec{e}_z$, with $P^z = n^z 2\pi/L$ for $n_z \in \{3, 5, 7\}$. An effective energy function that asymptotes to $E_{\vec{P}}$ can be defined as

$$E_{\vec{P}}^{\text{eff}}(t) = \frac{1}{a} \text{arccosh} \left(\frac{C_{2\text{pt}}(t+a, \vec{P}) + C_{2\text{pt}}(t-a, \vec{P})}{2C_{2\text{pt}}(t, \vec{P})} \right)$$

$$\xrightarrow{t \gg 0} E_{\vec{P}} + \dots, \quad (14)$$

where the ellipses denote exponentially-suppressed corrections from excited states. This function is shown for the ensemble investigated here in Fig. 2, including the results of fits to the two-point correlation functions. The fits are performed as described in Appendix A of Ref. [19], with the number of states in each fit chosen by maximizing an information criterion, and different choices of fit range sampled and combined in a weighted average. The relative deviations in the extracted energies from the continuum dispersion relation $E_{\vec{P}} = \sqrt{m_\pi^2 + |\vec{P}|^2}$ are at most 5% for all momenta studied, increasing with increasing $|\vec{P}|$, but consistent with the expected size of lattice artifacts.

The ratio $\mathcal{R}_\Gamma$ defined in Eq. (11) is constructed for all Dirac structures Γ and a range of operators with different staple widths and asymmetries, detailed in Table I. As indicated, the number of measurements is varied for the different boost momenta, to partially compensate for the differences in statistical noise. All ratios are computed

FIG. 2. Effective energy function defined in Eq. (14) for pion states boosted in the $\hat{z}$ -direction with $P^z = n^z 2\pi/L$. Shaded bands display the result of single-exponential fits to the two-point correlation functions with the largest two momenta, and two-exponential fits to those with the smallest two momenta, obtained as described in the text.

for sink times $t \in \{7, 9, 11, 13\}$ and with all operator insertion times τ such that $0 < \tau < t$. The fitting procedure used to determine B_Γ^{bare} at each set of parameters is precisely the same procedure as detailed in Appendix A of Ref. [19]. Several examples of the fits in t and τ used to extract the quasi beam functions are shown in Appendix A. An example of the resulting bare quasi beam functions, for particular choices of b_T and η , is shown in Fig. 3. Additional examples are provided in Appendix B.

B. Non-perturbative renormalization

Computing the modified $\overline{\text{MS}}$ -renormalized quasi beam function $B_\Gamma^{\overline{\text{MS}}}$ by Eq. (6) requires, in addition to the bare quasi beam functions, the RI'/MOM renormalization factor $Z_{\mathcal{O}_{\gamma^4\Gamma}}^{\text{RI}'/\text{MOM}}$. This factor enters the calculation of the renormalized quasi beam function both through the renormalization itself (Eq. (7)) and in the computation of the factor $\hat{R}$ (Eq. (9)). The calculation of the nonperturbative renormalization undertaken here follows closely the presentation of Ref. [18].

The matrix $Z_{\mathcal{O}_{\Gamma\Gamma'}}^{\text{RI}'/\text{MOM}}$ is defined by the renormalization condition

$$Z_q^{-1}(p_R) Z_{\mathcal{O}_{\Gamma\Gamma'}}^{\text{RI}'/\text{MOM}}(p_R) \Lambda_{\alpha\beta}^{\mathcal{O}_{\Gamma'}}(p) \big|_{p^\mu = p_R^\mu} = \Lambda_{\alpha\beta}^{\mathcal{O}_\Gamma; \text{tree}}(p), \quad (15)$$

where dependence on the lattice spacing is left implicit and $\Lambda_{\mathcal{O}_\Gamma; \text{tree}}$ denotes the bare (tree-level) amputated Green's function of the operator $\mathcal{O}_\Gamma$ defined in Eq. (4) in an off-shell quark state in the Landau gauge:

$$\Lambda_{\mathcal{O}_\Gamma}(p) = S^{-1}(p) G^{\mathcal{O}_\Gamma}(p) S^{-1}(p). \quad (16)$$

Here $S(p)$ is the quark propagator projected to momen-

FIG. 3. An example of a bare quasi beam function, computed as described in the text, for $b_T/a = 1$ and $\eta/a = 14$. Further examples are included in Appendix B.

tum p :

$$S_{\alpha\beta}(p, x) = \sum_y e^{-ip \cdot y} \langle q_\alpha(x) \bar{q}_\beta(y) \rangle, \quad (17)$$

$$S_{\alpha\beta}(p) = \frac{1}{V} \sum_x e^{ip \cdot x} S_{\alpha\beta}(p, x), \quad (18)$$

and $G^{\mathcal{O}_\Gamma}$ denotes the non-amputated quark-quark Green's function with one insertion of $\mathcal{O}_\Gamma$, which implicitly depends on the geometry of the staple-shaped Wilson line defining the operator:

$$\begin{aligned} G_{\alpha\beta}^{\mathcal{O}_\Gamma}(p) &= \frac{1}{V} \sum_{x,y,z} e^{ip \cdot (x-y)} \langle q_\alpha(x) \mathcal{O}_\Gamma(z+b, z) \bar{q}_\beta(y) \rangle, \\ &= \frac{1}{V} \sum_z \langle \gamma_5 S^\dagger(p, b+z) \gamma_5 \widetilde{W}(\eta; b+z, z) \frac{\Gamma}{2} S(p, z) \rangle_{\alpha\beta}, \end{aligned} \quad (19)$$

where $V = L^3 \times T$ is the lattice volume. The quark wavefunction renormalization Z_q is defined as

$$\begin{aligned} Z_q(p_R) S(p) \Big|_{p^2=p_R^2} &= S^{\text{tree}}(p) \\ \Rightarrow Z_q(p_R) &= \frac{1}{12} \text{Tr} [S^{-1}(p) S^{\text{tree}}(p)] \Big|_{p^2=p_R^2} \\ &= \frac{\text{Tr} [i \sum_\lambda \gamma_\lambda \sin(ap_\lambda) S^{-1}(p)]}{12 \sum_\lambda \sin^2(ap_\lambda)} \Big|_{p^2=p_R^2}. \end{aligned} \quad (20)$$

From Eq. (15), the matrix of RI'/MOM renormalization factors may be computed as

$$\left(Z_{\mathcal{O}_{\Gamma\Gamma'}}^{\text{RI'/MOM}}(p_R) \right)^{-1} = \frac{\mathcal{V}_{\mathcal{O}_{\Gamma\Gamma'}}(p)}{6e^{ip_R \cdot b} Z_q(p_R)} \Big|_{p^\mu=p_R^\mu}, \quad (21)$$

where b^μ denotes the separation of the endpoints of the nonlocal operator $\mathcal{O}_\Gamma$, the projected vertex function is defined as

$$\mathcal{V}_{\mathcal{O}_{\Gamma\Gamma'}}(p) \equiv \text{Tr} [\Lambda^{\mathcal{O}_\Gamma}(p) \Gamma'], \quad (22)$$

and the replacement

$$\text{Tr} [\Lambda^{\mathcal{O}_{\Gamma}; \text{tree}}(p_R) \Gamma'] = 6e^{ip_R \cdot b} \delta^{\Gamma\Gamma'} \quad (23)$$

has been made. It should be noted that since the operator $\mathcal{O}_\Gamma$ is nonlocal and frame dependent, different directions in p_R^μ constitute different renormalization schemes, related by finite renormalization factors. As such, $Z_{\mathcal{O}_{\Gamma\Gamma'}}^{\text{RI'/MOM}}$ depends on p_R^μ itself rather than only on its magnitude, which acts as the renormalization scale.

The complete 16×16 matrix of RI'/MOM renormalization factors $Z_{\mathcal{O}_{\Gamma\Gamma'}}^{\text{RI'/MOM}}$ is computed for the same set of operator geometries defined in Table I, on $n_{\text{cfg}} = 50$ gauge field configurations. For all operator geometries with $\eta/a \in \{12, 14\}$, the renormalization factors are computed for a range of four-momenta tabulated in Tab. II, to enable an investigation of residual dependence on the renormalization scale (which would be canceled by an all-orders matching to the $\overline{\text{MS}}$ scheme) and discretization artifacts. For operator geometries with $\eta/a = 23$, only the four-momentum with $n^\mu = (12, 12, 12, 12)$ is used. An example of the resulting RI'/MOM renormalization matrices is shown in Fig. 4, which displays a subset of the off-diagonal renormalization factors normalized relative to the diagonal components:

$$\mathcal{M}_{\mathcal{O}_{\Gamma\mathcal{P}}}^{\text{RI'/MOM}} \equiv \frac{\text{Abs}[Z_{\mathcal{O}_{\Gamma\mathcal{P}}}^{\text{RI'/MOM}}]}{\frac{1}{16} \sum_i \text{Abs}[Z_{\mathcal{O}_{\Gamma_i\Gamma_i}}^{\text{RI'/MOM}}]}, \quad (24)$$

computed for quark bilinear operators with straight Wilson lines and a particular choice of momentum.

The $\overline{\text{MS}}$ renormalization factors are computed via Eq. (7) from the RI'/MOM renormalization matrices and the perturbative matching factor $\mathcal{R}_{\mathcal{O}_{\gamma^4\Gamma}}^{\overline{\text{MS}}}$, calculated at next-to-leading order in continuum perturbation theory with dimensional regularization ($D = 4 - 2\epsilon$) [28, 34]. In this work, the scale $\tilde{p}_R$ is set to 4.9 GeV. Examples of the resulting $\overline{\text{MS}}$ renormalization factors are presented in Figs. 5 and 6. This renormalization is independent of

TABLE II. Four-momenta used in the calculation of nonperturbative renormalization factors as described in the text, where p^μ is the four-momentum in physical units corresponding to n^μ in lattice units. The H(4) invariant $p^{[4]}$ is defined as $p^{[4]} = \sum_{\mu=1}^4 p_\mu^4$.

FIG. 4. Submatrix of the RI'/MOM mixing matrix $\mathcal{M}_{O, \Gamma p}^{RI'/MOM}$, defined in Eq. (24), computed for quark bilinear operators with straight Wilson lines ($b_T = 0$) with various extents b^z , for momentum $n^\nu = (12, 12, 12, 12)$ in lattice units. Points representing Dirac structures in the upper triangle of the mixing matrix are slightly offset on the horizontal axis for clarity.

p_R up to discretization artifacts, two-loop perturbative matching corrections which are neglected here, and non-perturbative effects that vanish at asymptotically large p_R^2 . While in principle one might fit to results generated at different p_R values to constrain discretization effects, this is not feasible with the data generated here, and the covariance matrices for the nonlocal operators cannot be reliably estimated. The renormalization constants computed with $n^\mu = (12, 12, 12, 12)$ are thus taken as best-estimates and used in the further analysis of the Collins-Soper kernel. For those operator structures where the RI'/MOM renormalization factors have been computed at other choices of p_R , this yields indistinguishable results for the Collins-Soper kernel compared with results obtained using the weighted averaging procedure over momenta which is employed in Ref. [18]. The compo-

FIG. 5. Example of numerical results for $Z_{O_{\gamma^4 \gamma^4}}^{RI'/MOM}$ (orange circles) and $Z_{O_{\gamma^4 \gamma^4}}^{\overline{MS}}$ (blue squares), computed using the different values of p_R given in Table II, for operator geometry $\eta/a = 14$, $b^z/a = 3$, $b_T/a = 3$, at renormalization scale $\mu = 2$ GeV. The blue shaded band shows the value used in further analysis, obtained as described in the text.

nents of $\mathcal{M}_{O, \Gamma p}^{RI'/MOM}$ are of similar magnitude for both $\Gamma \in \{\gamma^3, \gamma^4\}$, which is consistent with the conclusion of Ref. [36] but is in contrast with the results of Refs. [34, 35] which predict no mixing effects for $\Gamma = \gamma^3$ at $\mathcal{O}(a^0)$. The quasi beam functions with both Dirac structures are thus treated on equal footing in this work.

C. Renormalized quasi beam functions

Modified $\overline{MS}$ -renormalized quasi beam functions are computed via Eq. (6) from the bare quasi beam functions and $\overline{MS}$ renormalization factors calculated as described in Secs. III A and III B; the uncertainties of the two components are combined in quadrature. While for clarity all equations in this section are expressed for renormalized quasi beam functions defined with the Dirac structure γ^4 , both $B_{\gamma^4}^{\overline{MS}}$ and $B_{\gamma^3}^{\overline{MS}}$ are computed and analyzed independently.

The real and imaginary parts of the renormalized quasi beam functions should be symmetric and antisymmetric functions of b^z respectively in the $\eta \rightarrow \infty$ limit. The numerical results obtained in this work, however, show significant departures from these expectations at finite η as was also observed in the quenched calculation of Ref. [18]. The b^z -dependence of the asymmetry in the absolute value of the renormalized quasi beam functions is illustrated in Fig. 7a. This asymmetry can be understood as an incomplete cancellation of the Wilson-line self-energy correction proportional to $e^{-V(b_T) b^z}$ between the $\overline{MS}$ renormalization factor and the bare quasi beam function, where $V(b_T)$ is the static quark-antiquark potential at distance b_T . Such an effect yields a b^z -dependent asymmetry proportional to $e^{-\Delta b^z}$, depending on an asymmetry parameter $\Delta = -V(b_T) + V(b_T^R)$. This is in fact a good model of the asymmetry ob-

(a)

(b)

FIG. 6. Diagonal $\overline{\text{MS}}$ renormalization factors $Z_{O_{\gamma^4}}^{\overline{\text{MS}}}$, computed for operator geometry $\eta/a = 14$ and various values of b_T and b^z , at renormalization scale $\mu = 2$ GeV.

served in the numerical calculations of this work; fits to $|B_{\gamma^4}^{\overline{\text{MS}}}(\mu, -b^z, \vec{b}_T, a, \eta, P^z)| / |B_{\gamma^4}^{\overline{\text{MS}}}(\mu, b^z, \vec{b}_T, a, \eta, P^z)|$ (and the analogous expression constructed from $B_{\gamma^3}^{\overline{\text{MS}}}$) to this functional form, fit separately for fixed values of b_T , η , and P^z , achieve acceptable goodness-of-fit with an average $\chi^2/\text{d.o.f.} = 0.56$. These fits, and the resulting values of the asymmetry parameter Δ , are illustrated in Fig. 7 and in Appendix B. Asymmetry-corrected modified $\overline{\text{MS}}$ -renormalized quasi beam functions are thus defined as

$$B_{\gamma^4}^{\overline{\text{MS}};\text{corr}}(\mu, b^z, \vec{b}_T, a, \eta, P^z) = e^{\Delta(\vec{b}_T, a, \eta, P^z)|b^z|} \times \left(\text{Re} \left[B_{\gamma^4}^{\overline{\text{MS}}}(\mu, |b^z|, \vec{b}_T, a, \eta, P^z) \right] + \text{sign}(b^z) \text{Im} \left[B_{\gamma^4}^{\overline{\text{MS}}}(\mu, |b^z|, \vec{b}_T, a, \eta, P^z) \right] \right). \quad (25)$$

Here, the uncertainties in the factor $e^{\Delta|b^z|}$ and the quasi beam functions are added in quadrature and, after asymmetry correction, the more precise results for beam functions with $b^z > 0$ (which involve shorter Wilson lines) are mirrored to $b^z < 0$. An example of the modified $\overline{\text{MS}}$ -renormalized quasi beam functions before and after

(a) Example of the b^z -dependence of the asymmetry in the renormalized quasi beam functions for a fixed choice of operator geometry with $\eta/a = 14$, $b_T/a = 1$.

(b) Example of the b_T -dependence of the asymmetry parameter $\Delta = -V(b_T) + V(b_T^R)$ for operators with $\eta/a = 14$, fit to renormalized quasi beam functions $B_{\gamma^4}^{\overline{\text{MS}}}$ as described in the text. The approximate linear dependence of Δ on b_T can be explained by a linear term in $V(b_T)$; the approximate independence on n^z is expected, as $V(b_T)$ should be independent of the external state.

FIG. 7. Illustration of the asymmetry in the renormalized quasi beam functions computed in this work; additional examples are provided in Appendix B.

asymmetry correction is given in Fig. 8.

It is expected that the renormalized beam functions should be independent of the matching scale b_T^R . This expectation is satisfied within uncertainties for the numerical investigations of this work as illustrated in Fig. 9; for use in the calculation of the Collins-Soper kernel, a weighted average [40] over possible choices of b_T^R in the window $a \ll b_T^R \ll \Lambda_{\text{QCD}}^{-1}$ is thus implemented, performed precisely as detailed in Appendix C of Ref. [19]. Similarly, the asymmetry-corrected renormalized quasi beam functions do not depend on η within uncertainties, and the formal extrapolation to $\eta \rightarrow \infty$ is implemented with an analogous weighted average. The resulting averaged values of the asymmetry-corrected modified $\overline{\text{MS}}$ -renormalized quasi beam function are denoted by $\overline{B}_{\gamma^4}^{\overline{\text{MS}}}(\mu, b^z, b_T, P^z)$, and have no dependence on η or

(a)

(b)

FIG. 8. Comparison of an example of the modified $\overline{\text{MS}}$ -renormalized quasi beam functions before (gray) and after (color) asymmetry correction via Eq. (25), for beam functions computed with operator geometry $\eta/a = 14$, $b_T/a = 1$.

b_T^R ; the dependence on a is also dropped in this notation, as a single lattice spacing is used in this numerical study. Figures showing $\overline{B}_{\gamma^4}^{\overline{\text{MS}}}$ and $\overline{B}_{\gamma^3}^{\overline{\text{MS}}}$ are provided in Appendix B. The contributions to these quantities from mixing between operators with different Dirac structures is generally found to be less than 10%; see Fig. 10 for an illustration. Additional examples are provided in Appendix B.

D. Collins-Soper kernel

To determine the Collins-Soper kernel via Eq. (10) from the averaged asymmetry-corrected modified $\overline{\text{MS}}$ -renormalized quasi beam functions $\overline{B}_{\gamma^4}^{\overline{\text{MS}}}$ and $\overline{B}_{\gamma^3}^{\overline{\text{MS}}}$, defined in the previous section, requires a Fourier transform of the quasi beam functions in b^z . As is clear from Fig. 23, however, the b^z -range of the data is not sufficient for the tails of the quasi beam functions at large $|b^z|$ to decay to plateaus consistent with zero, particularly at the largest b_T and smallest P^z values used in this numerical study.

(a)

(b)

FIG. 9. Example of the asymmetry-corrected modified $\overline{\text{MS}}$ -renormalized quasi beam function $\overline{B}_{\gamma^4}^{\overline{\text{MS}},\text{corr}}$ defined in Eq. (6). The horizontal shaded bands show the results of weighted averages of this quantity over choices of b_T^R and η (as a function of b^z , b_T , and P^z), as described in the text.

As such, it is to be expected that a discrete Fourier transform (DFT) will have significant systematic uncertainties from the truncation of the data in $P^z b^z$; details of a DFT analysis of the quasi beam functions are presented in Appendix C. Instead, Fourier transforms are taken after fitting the quasi beam functions to functional forms that allow extrapolation in b^z . This approach trades the systematic uncertainties of a DFT for model-dependence in the fit form used to extrapolate the quasi beam functions. While this model-dependence is difficult to quantify rigorously, this approach allows the physical expectation that the quasi beam functions should decay smoothly at large $|b^z|$ to be incorporated (a DFT effectively models the beam functions as zero outside the b^z -range in which lattice QCD results are computed).

In particular, the quasi beam functions are modeled as a sum of polynomials in b^z times Gaussian functions, which provide an appropriate basis, since it is expected that the quasi beam functions should be analytic functions of b^z (the $b^z \rightarrow 0$ limit at fixed b_T does not introduce additional divergences), and yield high-quality fits with

(a)

(b)

FIG. 10. Percentage contribution to the renormalized quasi beam functions from mixing of operators with different Dirac structures. Note that the ratios shown are outside of the plot range near the nodes of the beam functions; in this example the maximum mixing that is resolved from zero at greater than 2σ is 0.32(5), and occurs in the real component of the beam function for $n_z = 5$, $b_z/a = 5$.

few free parameters. Specifically, for each choice of b_T and P^z , the real and imaginary parts of the quasi beam function $\overline{B}_{\gamma^4}^{\overline{MS}}$ (and independently $\overline{B}_{\gamma^3}^{\overline{MS}}$) are fit with even and odd functions of b^z respectively, defined as

$$f_{\text{Re}}(\sigma, \{r_n\}; b^z) = \exp[-(b^z)^2/(2\sigma^2)] \sum_{n=0}^{n_{\text{max}}} r_n (b^z)^{2n} \quad (26)$$

$$f_{\text{Im}}(\sigma, \{r_n\}; b^z) = \exp[-(b^z)^2/(2\sigma^2)] \sum_{n=0}^{n_{\text{max}}} i_n (b^z)^{2n+1}. \quad (27)$$

The value of n_{max} is chosen to minimize the Akaike information criterion (AIC) [41] and corresponds to $n_{\text{max}} \in \{2, 3, 4\}$ for all cases. The fits with these optimal values of n_{max} are of high quality in all cases, with an average $\chi^2/\text{d.o.f.} = 0.41$. The resulting models of the quasi beam functions are denoted $\hat{B}_{\gamma^4}^{\overline{MS}}$ (and, correspondingly $\hat{B}_{\gamma^3}^{\overline{MS}}$), and are illustrated in Fig. 11 (with further examples provided in Appendix B).

(a)

(b)

FIG. 11. Example of fits by Eqs. (26) and (27) (shaded bands) to the real and imaginary parts of the quasi beam functions, for $b_T/a = 1$.

Finally, in terms of the models $\hat{B}_{\gamma^4}^{\overline{MS}}$, the relation defining the Collins-Soper kernel in Eq. (10) is realized as

$$\hat{\gamma}_\zeta^q(\mu, b_T; P_1^z, P_2^z, x) \equiv \frac{1}{\ln(P_1^z/P_2^z)} \ln \left[\frac{C_{\text{ns}}^{\text{TMD}}(\mu, x P_2^z)}{C_{\text{ns}}^{\text{TMD}}(\mu, x P_1^z)} \times \frac{\int db^z e^{-ib^z x P_1^z} P_1^z \hat{B}_{\gamma^4}^{\overline{MS}}(\mu, b^z, b_T, P_1^z)}{\int db^z e^{-ib^z x P_2^z} P_2^z \hat{B}_{\gamma^4}^{\overline{MS}}(\mu, b^z, b_T, P_2^z)} \right], \quad (28)$$

which coincides with $\gamma_\zeta^q(\mu, b_T)$ up to power corrections such as higher-twist corrections in the factorization formula for the quasi TMDPDF, and discretization artifacts, which introduce the dependence on P_1^z , P_2^z , and x . One approach to determine $\gamma_\zeta^q(\mu, b_T)$ from $\hat{\gamma}_\zeta^q(\mu, b_T; P_1^z, P_2^z, x)$ is to model, fit, and subtract, these various artifacts. However, the most straightforward models of these effects do not provide good fits to the numerical data of this study, as detailed in Appendix D. Instead, since the contamination in $\hat{\gamma}_\zeta^q$ will be different at each choice of P_1^z , P_2^z , and x , and the effects can be ex-

b_T [fm]	0.12	0.24	0.36	0.48
$\gamma_{\zeta}^{q,\overline{\text{MS}}}(\mu = 2 \text{ GeV})$	-0.419(53)(50)	-0.49(5)(12)	-0.76(9)(8)	-0.82(15)

TABLE III. Collins-Soper kernel with $\mu = 2 \text{ GeV}$ as a function of b_T . The first uncertainty is the average of that determined from calculations using $\hat{B}_{\gamma^4}^{\overline{\text{MS}}}$ and $\hat{B}_{\gamma^3}^{\overline{\text{MS}}}$ as described in the text, while the second is a systematic uncertainty computed as half the difference of the central values of the results obtained using quasi beam functions defined with the two Dirac structures.

pected to be larger² at large and small values of x and at small values of P^z , the variation of $\hat{\gamma}_{\zeta}^q$ over these choices is used to define an estimate of the systematic uncertainty.

Precisely, a best value for the Collins-Soper kernel is determined from $\hat{\gamma}_{\zeta}^q$ via a multi-step procedure. First, the largest window of x is determined for which the data for all choices of the pair $\{P_1^z, P_2^z\}$ are consistent with a common constant value. In practice this region is defined as the largest window in which a constant fit to the data at a set of discrete x points has a $\chi^2/\text{d.o.f.} \leq 1$. The central value and uncertainty are defined as the median and the 68% confidence interval of the union of the bootstrap data in that x window, including all $\{P_1^z, P_2^z\}$ pairs. The result of this procedure is robust to changes in the discretization of x , for sufficiently fine discretization scales (100 points spanning $0 < x < 1$ uniformly are used in the analysis presented). This procedure is performed separately for $\hat{\gamma}_{\zeta}^q$ determined from beam functions calculated with Dirac structures γ^4 and γ^3 ; examples of the resulting values are shown with $\hat{\gamma}_{\zeta}^q$ in Fig. 12, with the remainder presented in Appendix B. The central values of the independent calculations with Dirac structures γ^4 and γ^3 are averaged, and the average uncertainty is added in quadrature with half the difference between the central values obtained using each Dirac structure, to yield the final results of this work which are shown as a function of b_T in Fig. 13, and are tabulated in Table. III.

In addition to the approach followed here, there are a number of alternative methods of extracting the Collins-Soper kernel that have been proposed or employed in other studies, for example:

- “LO”: The perturbative matching coefficient $C_{\text{ns}}^{\text{TMD}}$ computed to leading-order (LO), instead of NLO, can be used in an analysis otherwise mirroring that presented here;
- “Hermite/Bernstein”: As proposed in Ref. [19], the $P^z b^z$ -dependence of the quasi beam functions

FIG. 12. $\hat{\gamma}_{\zeta}^q$, computed as defined in Eq. (28) for all momentum pairs $\{P_1^z, P_2^z\}$, denoted by P_1^z/P_2^z in the legend. The horizontal shaded band shows the fit window in x , as well as the total uncertainty of the best result, determined as described in the text.

FIG. 13. Collins-Soper kernel as a function of b_T , determined from $\hat{B}_{\gamma^4}^{\overline{\text{MS}}}$ (purple circles) $\hat{B}_{\gamma^3}^{\overline{\text{MS}}}$ (red triangles), and the final combined results of this work (green squares), computed as described in the text. For the latter points, the inner (outer) error bars show the first (quadrature-combined) uncertainties given in Table. III.

² The matching coefficient includes large logarithms of xP_i^z at small x , while the quasi beam functions at $x \rightarrow 0$ and $x \rightarrow 1$ are sensitive to the long-range correlations in b^z and are thus affected by the truncation of the data in $P^z b^z$. In addition, the power corrections are expected to be enhanced at small x .

FIG. 14. b_T -dependence of the Collins-Soper kernel computed from the same quasi beam functions via the different approaches defined in Sec. III D. All points other than the primary results of this work (“NLO”) are offset on the horizontal axis for clarity. For the “NLO” and “LO” approaches, results computed based on quasi beam functions with Dirac structures γ^4 and γ^3 are combined as described in the text; the outer error bars include half the difference between the results with γ^4 and γ^3 combined in quadrature with the average uncertainty, shown by the inner error bars. For the other approaches the empty (filled) points show results obtained with Dirac structure γ^4 (γ^3). “Hermite/Bernstein” points with Dirac structure γ_3 are not shown at $b_T/a = 4$ because the corresponding fits of the $P^z b^z$ -dependence of the relevant quasi beam functions were of poor quality, as described in the text.

can be fit to models based on Hermite and Bernstein polynomial bases constructed to yield x -independent Collins-Soper kernels via Eq. (28), taking the LO value of the perturbative matching coefficient $C_{\text{ns}}^{\text{TMD}}$;

- “ $b^z = 0$ ”: An approximation of the Collins-Soper kernel can be computed with LO matching using only the quasi beam functions evaluated at $b^z = 0$ (this approach does not require a Fourier transform in b^z):

$$[\gamma_\zeta^q(\mu, b_T)]^{b^z=0} \equiv \frac{1}{\ln(P_1^z/P_2^z)} \ln \left[\frac{\overline{B}_{\gamma^4}^{\overline{MS}}(\mu, 0, b_T, P_1^z)}{\overline{B}_{\gamma^4}^{\overline{MS}}(\mu, 0, b_T, P_2^z)} \right]; \quad (29)$$

- “ $b^z = 0, \text{bare}$ ”: As proposed in Ref. [20], the same approach described for “ $b^z = 0$ ” can be followed, using bare quasi beam functions $B_{\gamma^4}^{\text{bare}}$ rather than renormalized quasi beam functions (i.e., neglecting operator mixing between different Dirac structures);
- “ $b^z = 0/b_T = 0, \text{bare}$ ”: As proposed in Ref. [22], a variation of the “ $b^z = 0$ ” approach can be used,

approximating the Collins Soper kernel as

$$[\gamma_\zeta^q(\mu, b_T)]^{b^z=0/b_T=0} \equiv \frac{1}{\ln(P_1^z/P_2^z)} \times \ln \left[\frac{B_{\gamma^4}^{\text{bare}}(0, b_T, a, \eta, P_1^z) B_{\gamma^4}^{\text{bare}}(0, 0, a, \eta, P_2^z)}{B_{\gamma^4}^{\text{bare}}(0, b_T, a, \eta, P_2^z) B_{\gamma^4}^{\text{bare}}(0, 0, a, \eta, P_1^z)} \right]. \quad (30)$$

Each of these methods can be followed using the quasi beam functions computed in this work; a comparison of the results is provided in Fig. 14. For the “LO” approach, the same procedure is followed to combine the results obtained using quasi beam functions with Dirac structures γ^3 and γ^4 as for the “NLO” method which yields the main results of this work. For the other approaches the results obtained with the two Dirac structures are not always consistent at one standard deviation, and are shown separately; for $b_T/a = 4$ no results for the “Hermite/Bernstein” approach are shown with Dirac structure γ^3 as the model fits were of poor quality with $\chi^2/\text{d.o.f.} > 2$. In the case of the “ $b^z = 0/b_T = 0, \text{bare}$ ” approach, bare quasi beam functions with $\eta/a = 14$, which is the largest extent studied in this work for all P^z , are used in the analysis.

Clearly, although the same quasi beam functions are used, the Collins-Soper kernel determined via each of these approaches is very different, and many of the results are inconsistent with the best results of this study at several standard deviations, with uncertainties as much as an order of magnitude smaller. This is to be expected if

FIG. 15. b_T -dependence of the Collins-Soper kernel as determined in this work (green squares in both panels) compared with (a) phenomenological results, and (b) the results of other lattice QCD calculations of this quantity.

the effects of higher-order matching, renormalization and mixing, and power corrections, are significant, as each of the approaches listed above treats one or more of these systematic effects differently than in the primary analysis presented here.

IV. OUTLOOK

This work presents a determination of the Collins-Soper kernel from a dynamical lattice QCD calculation following the approach of Refs. [26, 27]. Several systematic uncertainties remain to be addressed; in particular, the quark masses used correspond to an unphysically-large pion mass of $m_\pi = 538(1)$ MeV, and the results are obtained using a single ensemble of gauge field configurations such that effects from the discretization and finite lattice volume cannot be fully quantified. A fully model-independent calculation will require these systematics to be addressed, lattice QCD calculations to be performed over a larger range of $P^z b^z$ to eliminate the need to extrapolate the quasi beam functions to large $|b^z|$ and enable the DFT approach to be used, and larger values of P^z to be included to reduce the contributions from power corrections and higher-twist effects which dominate the uncertainties of this calculation. With these caveats in mind, the results of this work may be compared with phenomenological extractions of the Collins-Soper kernel, as shown in Fig. 15a. The lattice QCD and phenomenological determinations are broadly consistent at large b_T , with clear deviations at the smallest b_T values studied; discretization effects are expected to be largest at small b_T and might be relevant for understanding this effect. It is clear that, while challenging to achieve computationally, future fully-controlled calculations by this

approach with uncertainties comparable to those of the present study will be sufficient to differentiate different models of the Collins-Soper kernel and will provide important input for the analysis of low-energy SIDIS data and the determinations of the TMDPDFs.

In considering the prospects for such future controlled determinations of the Collins-Soper kernel from lattice QCD, it is informative to contrast the results of this study with those of other lattice QCD investigations; a comparison of existing calculations [19–22] is provided in Fig. 15b. All dynamical calculations use quark masses resulting in similar values of the pion mass to that of the calculation presented here (ranging from the lightest ensemble with $m_\pi = 350$ MeV in Ref. [22] to $m_\pi = 547$ MeV in Ref. [20]), while the quenched calculation of Ref. [19], in which the kernel should not depend on the valence quark masses since it is independent of the external state, is performed at $m_\pi = 1.207$ GeV. Each calculation uses a slightly different approach to constrain the Collins-Soper kernel from quasi beam functions. In particular, the “Hermite/Bernstein” approach is followed in Ref. [19] (“SWZ”), the calculation of Ref. [20] (“LPC”) uses the “ $b^z = 0$, bare” approach, that of Ref. [21] (“Regensburg/NMSU”) uses an approach similar to the “ $b^z = 0$, bare” approach but with NLO matching, and Ref. [22] (“ETMC/PKU”) applies the “ $b^z = 0/b_T = 0$, bare” approach. While the various calculations exhibit similar dependence on b_T , there are some significant discrepancies between the numerical results, and a wide range of uncertainty estimates. Given the analysis of Sec. IIID, this is to be expected; even when the same quasi beam function data is used, following the various “ $b^z = 0$ ” approaches and the approach presented here result in significant systematic differences, and significantly different uncertainty estimates. Since Refs. [20–22] all

use somewhat larger maximum P^z values than that of the present study, the effects of power corrections and higher-twist contamination can be expected to be smaller than those found in Sec. III D, but these effects, together with the difference between NLO and LO matching, could nevertheless be responsible for the discrepancies visible in Fig. 15b. Clearly, a fully-controlled determination of the Collins-Soper kernel from lattice QCD will require NLO matching and a treatment of power corrections that is more robust than that achieved in any of the studies performed to date. The analysis presented here constitutes an important step towards that goal, revealing clearly that these important sources of systematic uncertainty cannot be neglected.

Appendix A: Fits to ratios of three and two point functions

As detailed in Sec. III A, ratios $\mathcal{R}_\Gamma(t, \tau, b^\mu, a, \eta, P^z)$ (Eq. (11)) of three-point and two-point correlation functions asymptote to the bare quasi beam functions in the limit $\{\tau, t - \tau\} \rightarrow \infty$, with contamination from matrix elements in excited states present at finite t and τ . The t and τ -dependence of the ratios is fit precisely as defined in Appendix A of Ref. [19] to extract the bare quasi beam functions: fits are performed for all different possible cuts on source/operator/sink separations, with the AIC [41] used to select the number of states included in the spectral representation for each fit. The results are combined via a weighted averaging procedure. Some examples of the results of this fitting procedure are given in Fig. 16.

Appendix B: Additional beam function results

This section collates additional examples of results at intermediate states of the numerical calculation and analysis presented in Sec. III D:

- Bare quasi beam functions $B_\Gamma^{\text{bare}}(b^z, \vec{b}_T, a, \eta, P^z)$: supplementing Fig. 3 of the main text, additional examples of the bare quasi beam functions are provided in Fig. 17 for $B_{\gamma_4}^{\text{bare}}$ and Fig. 18 for $B_{\gamma_3}^{\text{bare}}$.
- Renormalized quasi beam functions $B_\Gamma^{\overline{\text{MS}}}(\mu, b^z, \vec{b}_T, a, \eta, P^z)$: examples of the modified $\overline{\text{MS}}$ -renormalized quasi beam functions $B_{\gamma_4}^{\overline{\text{MS}}}$ and $B_{\gamma_3}^{\overline{\text{MS}}}$, defined in Sec. III C, are given in Figs. 19 and 20 respectively.
- Renormalized quasi beam function asymmetry fits: supplementing Fig. 7 of the main text, fits to the b^z -dependence of the asymmetry in the renormalized quasi beam functions, performed as detailed in Sec. III C, are illustrated in Fig. 21.
- Asymmetry-corrected modified $\overline{\text{MS}}$ -renormalized quasi beam functions $B_\Gamma^{\overline{\text{MS}}; \text{corr}}(\mu, b^z, \vec{b}_T, a, \eta, P^z)$: an example of the dependence of $B_{\gamma_3}^{\overline{\text{MS}}; \text{corr}}$ on b_T^R and η is provided in Fig. 22, supplementing the analogous figure for $B_{\gamma_4}^{\overline{\text{MS}}; \text{corr}}$ which is presented in Fig. 9 in the main text.
- Averaged asymmetry-corrected modified $\overline{\text{MS}}$ -renormalized quasi beam functions $\overline{B}_\Gamma^{\overline{\text{MS}}}(\mu, b^z, b_T, P^z)$: in addition to the example provided in Fig. 11 of the main text, Figs. 23 and 24 give examples of $\overline{B}_{\gamma_4}^{\overline{\text{MS}}}$ and $\overline{B}_{\gamma_3}^{\overline{\text{MS}}}$, including fits to the $P^z b^z$ -dependence of these functions and extrapolations to larger $P^z b^z$, performed as described in Sec. III D.

- Estimator $\hat{\gamma}_\zeta^q(\mu, b_T; P_1^z, P_2^z, x)$ for the Collins-Soper kernel (Eq. (28)): supplementing Fig. 12 of the main text, the remaining numerical results for $\hat{\gamma}_\zeta^q$ as a function of x at different values of b_T are displayed in Fig. 25.

Appendix C: Discrete fourier transform analysis

As discussed in Sec. III D, a model-independent lattice QCD extraction of the Collins-Soper kernel by the approach followed here would require that Eq. (28) is evaluated with a DFT of $\overline{B}_\Gamma^{\overline{\text{MS}}}$ replacing the Fourier transform of analytic fits $\hat{B}_\Gamma^{\overline{\text{MS}}}$ to the $P^z b^z$ -dependence of the quasi beam functions, and that the results are stable under truncation of the data in $P^z b^z$. The $P^z b^z$ -range of the data presented here is, however, not sufficient for the tails of the quasi beam functions at large $|P^z b^z|$ to decay to plateaus consistent with zero, particularly at the largest b_T and smallest P^z values used in this study. It is thus to be expected that a DFT-based analysis has qualitative and quantitative differences from the analytic model approach. These differences can be seen by comparison of Fig. 26, which displays the results of a DFT-based analysis, with Figs. 12 and 25, which show the results of the analysis of Sec. III D. As anticipated, the DFT approach yields numerical values which are significantly different from those achieved by modeling rather than truncating the tails of the quasi beam functions in $P^z b^z$, particularly for evaluations including quasi beam functions computed with the smallest boost corresponding to $n^z = 3$. As a result, the values obtained with different choices of P^z are not consistent within uncertainties at intermediate values of x . The differences are, naturally, less significant for results computed with the largest choices of P^z , supporting the expectation that future studies constraining larger values of $P^z b^z$ will achieve model-independent results via the DFT approach.

Appendix D: Power corrections and higher-twist effects

The estimator $\hat{\gamma}_\zeta^q(\mu, b_T; P_1^z, P_2^z, x)$ (Eq. (28)) coincides with the Collins-Soper kernel up to power corrections, such as higher-twist corrections in the factorization formula for the quasi TMDPDF, and discretization artifacts; in the absence of contamination from these effects, $\hat{\gamma}_\zeta^q$ should be independent of x , P_1^z and P_2^z . Clearly, the results shown in Figs. 12 and 25 indicate that this contamination is not negligible relative to the uncertainties of this calculation. As discussed in Sec. III D, it is natural to attempt to model, fit, and subtract this contamination in order to determine a best value for the Collins-Soper kernel.

One possible approach is to consider a simple model of corrections to the factorization formula [27, 32] for the

quasi TMDPDF, for example through the inclusion of free parameters λ_1 and λ_2 parameterizing power corrections as:

$$\begin{aligned} \tilde{f}_{\text{ns}}^{\text{TMD}}(x, \vec{b}_T, \mu, P^z) &= \left[C_{\text{ns}}^{\text{TMD}}(\mu, x P^z) + \frac{\lambda_1 \Lambda_{\text{QCD}}^2}{(x P^z)^2} \right] \\ &\times \exp \left[\frac{1}{2} \gamma_\zeta^q(\mu, b_T) \ln \frac{(2x P^z)^2}{\zeta_0} \right] g_S^q(b_T, \mu) \\ &\times f_{\text{ns}}^{\text{TMD}}(x, \vec{b}_T, \mu, \zeta_0) \left[1 + \frac{\lambda_2}{(x P^z b_T)^2} \right] \end{aligned} \quad (\text{D1})$$

(here $g_S^q(b_T, \mu)$ is defined as in Ref. [26] as the mismatch between the lightlike and quasi soft factors). This form is chosen since in the $\overline{\text{MS}}$ scheme the higher-twist corrections must appear in even powers, with a suppression through k_T^2/k_z^2 , which in Fourier space becomes $1/(x P^z b_T)^2$. At tree-level, the factor λ_2 is a constant. The $1/(x P^z)^2$ power correction comes from the renormalon ambiguity in the perturbative series for the matching coefficient.

The relationship between the quasi TMDPDF and the quasi beam functions (Eq. (2)) then suggests a model of the Fourier transform of the quasi beam functions, defined as

$$\tilde{B}_{\gamma^4}^{\overline{\text{MS}}}(\mu, x, b_T, P^z) \equiv \int db^z e^{ib^z x P^z} P^z \hat{B}_{\gamma^4}^{\overline{\text{MS}}}(\mu, b^z, b_T, P^z), \quad (\text{D2})$$

of the form

$$\begin{aligned} \tilde{B}^{\text{fit}}(\mu, x, b_T, P^z) &= \left[C_{\text{ns}}^{\text{TMD}}(\mu, x P^z) + \frac{\lambda_1 \Lambda_{\text{QCD}}^2}{(x P^z)^2} \right] \left(\frac{(2x P^z)^2}{\zeta_0} \right)^{\frac{1}{2} \gamma_\zeta(\mu, b_T)} \\ &\times F(x, b_T, \mu, \zeta_0) \left[1 + \frac{\lambda_2}{(x P^z b_T)^2} \right], \end{aligned} \quad (\text{D3})$$

where γ_ζ , F , λ_1 and λ_2 are free parameters and ζ_0 can be chosen freely. For each x , the model can be fit to $\tilde{B}_{\gamma^4}^{\overline{\text{MS}}}$ (and separately to $\tilde{B}_{\gamma^3}^{\overline{\text{MS}}}$) for all choices of P^z and b_T simultaneously, and the Collins-Soper kernel extracted as the fit parameter γ_ζ .

The results of this procedure yield results for the Collins-Soper kernel which are not more consistent with a constant in x than the results without the correction applied. A global fit at discretized x values is of poor quality, with $\chi^2/\text{d.o.f.} \gtrsim 2$. There are a range of reasons that the model form above may not a good description of the numerical data; for example, the assumption that the $1/(x P^z b_T)^2$ corrections are proportional to the leading power contribution in Eq. (D1), may not be a good approximation. This approach is thus not taken in the main analysis presented here, but may be worthwhile to consider for future studies with larger values of P^z where the power corrections will be suppressed relative to those in the current work.

FIG. 16. Examples of fits to ratios of three and two-point functions $\mathcal{R}_\Gamma(t, \tau, b^\mu, a, \eta, P^z)$ defined in Eq. (11), performed as described in the text. The shaded bands matching the color of each set of points show 68% bootstrap confidence intervals of the fits from the fit range that has the highest weight in the weighted average that determines the final result, which is indicated by the gray horizontal bands. These bands show the total uncertainty on the bare quasi beam functions, including both the statistical uncertainty and the systematic uncertainty which arises from variation of the results between different fit range choices.

FIG. 17. Examples of the bare quasi beam functions $B_{\gamma^4}^{\text{bare}}$ determined as described in Sec. III A (note that $B_{\gamma^4}^{\text{bare}}$ for $b_T = 0.12$ fm and $\eta = 1.68$ fm is shown in Fig. 3 in the main text).
