(Dated: October 28, 2021)

Obtaining a high-quality interaction model together with associated uncertainties is an essential task for neutrino experiments studying oscillations, nuclear scattering processes, or both. As a primary input to the MicroBooNE experiment's next generation of neutrino cross-section measurements and its flagship investigation of the MiniBooNE low-energy excess, we present a new tune of the charged-current pionless (CC0 π) interaction cross section via the two major contributing processes – charged-current quasielastic and multi-nucleon interaction models – within version 3.0.6 of the GENIE neutrino event generator. Parameters in these models are tuned to muon neutrino CC0 π cross-section data obtained by the T2K experiment, which provides an independent set of neutrino interactions with a neutrino flux in a similar energy range to MicroBooNE's neutrino beam. Although the fit is to muon neutrino data, the information carries over to electron neutrino simulation because the same underlying models are used in GENIE. A number of novel fit parameters were developed for this work, and the optimal parameters were chosen from existing and new sets. We choose to fit four parameters, that have not previously been constrained by theory or data. Thus, this will be called a theory-driven tune. The result is an improved match to the T2K CC0 π data with more well-motivated uncertainties based on the fit.

I. INTRODUCTION

A fundamental challenge in a large variety of accelerator experiments is to have a Monte Carlo simulation of the apparatus. For neutrino experiments, a key aspect is the neutrino interaction modeling [1]. For MicroBooNE [2], this is true both for the low-energy excess (LEE) search (based on the findings of MiniBoone [3]) and neutrino-argon scattering cross-section measurements. MicroBooNE uses a liquid argon target exposed to Fermilab's Booster Neutrino Beam (BNB), which has a mean neutrino energy of 0.8 GeV [4]. This makes the LEE search sensitive to nuclear effects such as multi-nucleon correlations and medium corrections. Cross-section measurements require a model that can provide a reliable estimate of the contribution of background events in a selection. Although selection cuts that decrease the number of background events and data-driven estimations are highly desirable, problems with background very often remain and the model-data correspondence must be close enough to trust the efficiency estimation. MicroBooNE's LEE search, on the other hand, has the critical requirement of a model that provides a baseline estimate for most non-LEE contributions to the event yields and estimated uncertainties. The model also correlates uncertainties between different samples of selected events. Achieving significant improvement in the understanding of both the central-value model and its related uncertainties is the most important goal of this work.

The MicroBooNE data set contains a significant number of charged-current quasielastic (CCQE) interactions,

as well as charged-current *2 particle, 2 hole* (CC2p2h) interactions in which the neutrino interacts with a correlated pair of nucleons. Resonant (RES) interactions, particularly resonant pion production, also form a considerable portion of the interactions collected by MicroBooNE (although these interactions tend to be at higher energies than CCQE or CC2p2h are therefore of less concern for MicroBooNE's electron-like LEE searches) and deep inelastic scattering (DIS) also occurs in smaller proportions at even higher energies. MicroBooNE has adopted GENIE [5] v3.0.6 G18_10a_02_11a as its core event generator at this time. This version of GENIE uses new models from the Valencia group [6–8] for CCQE and CC2p2h processes. The introduction of new models presents the problem of choosing features of the model to test. We develop a theory-driven set of parameters for this purpose where the parameters are chosen with respect to the lack of understanding in the underlying theory.

The treatment of nuclear dependence (or *A*-dependence) is important to this work because the existing data are largely for carbon targets and the MicroBooNE detector is almost totally composed of argon. Because GENIE is required to simulate interactions with the wide variety of nuclei used in experiments, it needs a simple nuclear model. The local Fermi gas (LFG) model provides a reasonable description of the momentum density for many nuclei. Additional medium corrections are applied to account for some of the dependence on nucleus. Neutrinos interact weakly within nuclei; therefore, interaction locations can be chosen according to spatial density for which data from electron scattering are used.

In this article, we present a tune of the GENIE [5] v3.0.6 G18_10a_02_11a CCQE and CC2p2h models to T2K CC0 π cross-section data [9]. The main purpose of this work is to provide an important input to the ν_e -focused MicroBooNE LEE analyses [10–13]. One of the

* microboone_info@fnal.gov

primary goals there is to use the ν_μ data to constrain the ν_e model with robust uncertainties and covariances. The goal is to propagate features properly across channels and this fit is the basis for that exercise. With this method, no additional fits to MicroBooNE data are needed or desired.

Although we tune underlying model parameters of these specific processes, the aim of this work is to improve the prediction of the overall $CC0\pi$ cross-section, and thereby improve the model predictions and uncertainties used in MicroBooNE analyses. The signal choice of $CC0\pi$ means no mesons in the final state; experiments use this choice because it has less model dependence than true $CCQE$ (which cannot be directly measured in a neutrino experiment). It then includes $CCQE$, $CC2p2h$, and some pion production (where the pion is absorbed in the residual nucleus) events. The choice of the data set to study here is an important decision that is particular to the MicroBooNE experiment. Although choices of target and beam energy must be considered, the emphasis is on external data sets with similar beam energy because the set of interactions required grows in complexity as beam energy increases. T2K data are used for this tuning work because the neutrino flux is in a very similar energy range to MicroBooNE. T2K measurements use a CH target and MicroBooNE uses an argon target. ArgoNeuT data [14] uses an argon target, but is at a higher energy and has significant statistical uncertainty. MINERvA published $CC0\pi$ data [15, 16] for a CH target but has a high proportion of RES and DIS interactions because the neutrino energies sampled are higher. Restricting the study to neutrino energies below 2 GeV limits consideration to the $CCQE$ and $CC2p2h$ models.

Tuning to external data allows us to avoid any potential biases from double-fitting to MicroBooNE data in any subsequent analyses. MiniBooNE $CC0\pi$ data [17] has provided an important basis for understanding interaction mechanisms in this energy range. Because it uses the same BNB beamline as MicroBooNE, that data is not used for the purpose of tuning models for MicroBooNE. The main issue is potential correlations between the neutrino flux in the two measurements; accounting for this possibility is beyond the scope of this work. However, comparisons of the nominal and tuned GENIE predictions with MiniBooNE data are a powerful tool to evaluate the tuned models, and therefore are shown in Secs. II and IV B. Concerns about double-counting systematic uncertainties apply even more strongly to use of MicroBooNE data. Comparisons of the final fit with MicroBooNE data are presented in Sec. IV A.

This work was required because the default GENIE v3.0.6 G18_10a_02_11a model configuration was found to under-predict cross-section data from various experiments for charged-current interactions that produce no charged or neutral pions above detection threshold. This is known as the $CC0\pi$ channel, and is dominated by $CCQE$ and $CC2p2h$ interactions. This is discussed further in Sec. II.

The features of GENIE that are important for this fitting exercise are presented in Sec. II. The data chosen for tuning and selection of parameters needed to properly tune the model for MicroBooNE are described in Sec. III. Fit results are presented in Sec. IV along with comparisons to other relevant data. A full description of MicroBooNE's adopted set of neutrino cross-section model uncertainties is given in Sec. V, and the conclusions from this study are summarized in Sec. VI.

II. GENIE MODELS

The latest version of GENIE (v3) [18] has a variety of model sets available to allow users to make the best choice for their particular analysis. The GENIE v3.0.6 G18_10a_02_11a model set includes the full Valencia model [6–8] for the local Fermi gas nucleon momentum distribution, $CCQE$, and $CC2p2h$ interactions. This adds the RPA correction (random phase approximation which is a description of long-range nucleon-nucleon correlations) and the Coulomb interaction of the outgoing muon. It also includes improved agreement with a significantly expanded data set for the A -dependence of final state interactions (FSI) along with updated form factors [19] and diagrams for the pion production process [20–22]. A new tune to neutrino-proton and neutrino-deuterium cross-section data [23] has been applied. These features represent significant enhancements for neutrino energies sampled by MicroBooNE over the historical default model from GENIE v2.12.2 (used by previous MicroBooNE analyses [24–27]).

It should be noted that the Valencia models as implemented in GENIE v3 are somewhat different than those in the original publications. The $CC2p2h$ model had a restriction on the 3-momentum transfer [8] which has little effect at lower neutrino energies. The $CCQE$ model [7] applied a simple binding energy correction by subtracting it from the muon energy. GENIE used a more detailed method of decreasing the effective mass of the struck nucleon [18, 28]. This feature will have an important impact on the analysis presented here.

The updated models have been validated against both inclusive and exclusive bubble-chamber experiments, and provide a significantly improved description of $CC0\pi$ cross-section data from MiniBooNE [17] compared to the GENIE v2.12.2 models. The relativistic Fermi gas nuclear model and Llewellyn-Smith QE model used in GENIE v2.12.2 are more appropriate for measurements at a higher beam energy than the BNB energies. Fig. 1 shows a comparison of MiniBooNE $CC0\pi$ data [17] with simulations from these two models. GENIE v3.0.6 G18_10a_02_11a more closely matches the data and will be the basis for the fit we describe in this document. However, it is also clear that GENIE v3.0.6 G18_10a_02_11a underpredicts the data in both angular bins shown ($-0.1 < \cos(\theta_\mu) < 0.0$ and $0.9 < \cos(\theta_\mu) < 1.0$) where θ_μ is the lab angle of the muon with respect to the best

estimate of the neutrino direction. A similar underprediction can be seen when comparing to CC0 π cross-section data from T2K [9] in Fig. 2, as well as in data selections in MicroBooNE, such as that shown in Fig. 10(a). The underproduction of MicroBooNE data is the primary motivation for this tuning work in the context of the LEE search.

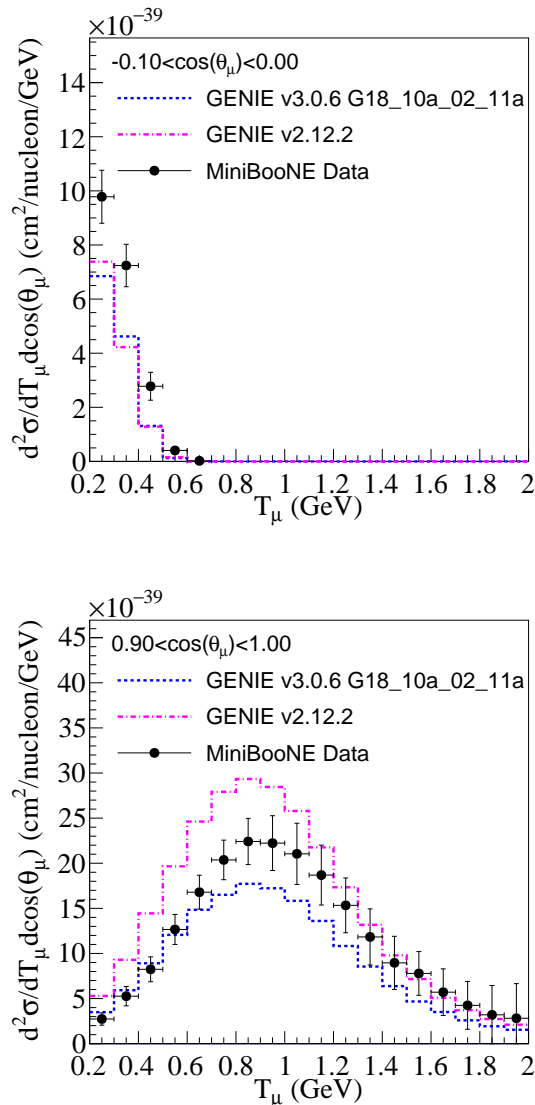

FIG. 1. MiniBooNE flux-averaged CC0 π -like differential cross section [17] for muon kinetic energy T_μ compared with GENIE v2.12.2 and v3.0.6 G18_10a_02_11a simulations for $-0.1 < \cos\theta_\mu < 0.0$ (top) and $0.9 < \cos\theta_\mu < 1.0$ (bottom). Uncertainties on the data points are the shape uncertainties reported by the collaboration. These bins show the underprediction of GENIE v3.0.6 G18_10a_02_11a compared to data for forwards-going and backwards-going muons.

The choice to tune specifically the CCQE and CC2p2h models in this work is motivated by several factors. The largest difference between data and simulation in many

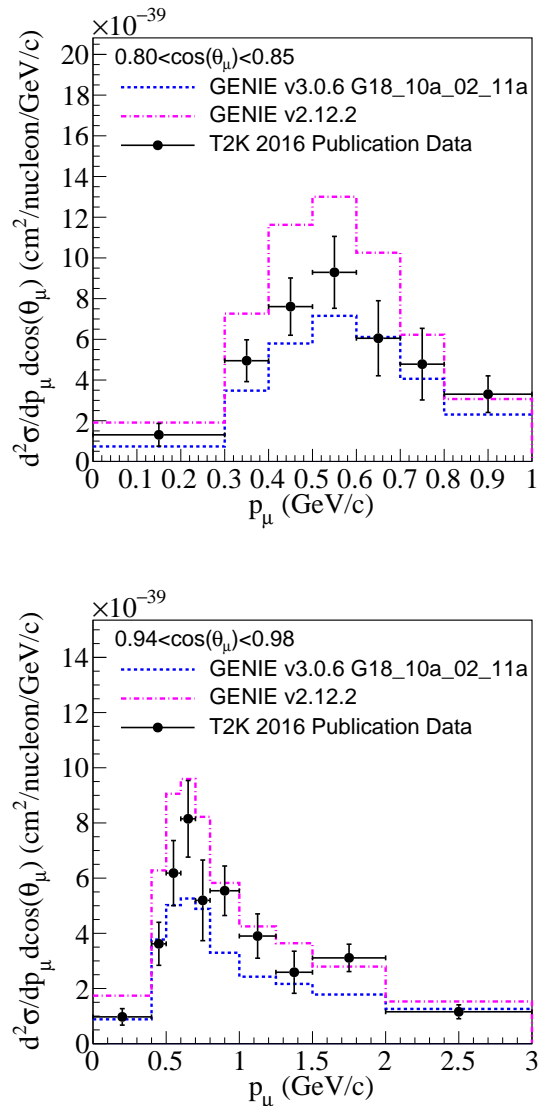

FIG. 2. T2K flux-averaged CC0 π cross section [9] as a function of muon momentum for $0.80 < \cos\theta_\mu < 0.85$ (top) and $0.94 < \cos\theta_\mu < 0.98$ (bottom) for GENIE v2.12.2 and v3.0.6 G18_10a_02_11a simulations.

MicroBooNE analyses is seen at low visible energy (see, for example, Fig. 10(a)) where these interactions dominate. The lack of consensus about optimal choice of these models in the theoretical community [1, 29–31] strongly drives the parameter choices in this theory-driven fitting exercise. Tuning other channels (e.g. resonant pion production) has lower priority for MicroBooNE at this time, mainly because the contribution of these channels is less relevant for MicroBooNE’s electron-like LEE searches due to the energy range and the effective π^0 rejection achieved by these analyses. However, the work presented here may be extended to include tuning of other channels in the future.

III. FITTING METHOD

Fits to T2K $CC0\pi$ cross-section data [9] are performed to tune parameters within the GENIE v3.0.6 G18_10a_02_11a CCQE and CC2p2h models using the GENIE reweighting package v1.0.4. The main goal is to mitigate the underprediction observed in both MicroBooNE and MiniBooNE data. The tuning was performed using the NUISANCE software package [32].

A. T2K Data Set

The choice of the single data set to include in a fit is important as the data set must be as close as possible to the MicroBooNE data and contain a high proportion of CCQE and CC2p2h interactions. The inclusion of more data sets would have complicated the fit because of the incompatibilities that can be exposed [33]. It was also important to limit the fit to data at neutrino energies compatible with MicroBooNE because of the growing complexity of models needed to describe data properly as the energy increases [34].

We perform fits to T2K $CC0\pi$ cross section data, published in 2016 [9]. These results come from an analysis that requires an inclusive muon measurement. A later analysis of the same data includes results based on proton multiplicity [35]; for these fits the 2016 inclusive muon-based data are sufficient [9]. The paper includes two analyses, which both use the same data events but apply different selection cuts and extract the cross section using different methods:

- **Analysis 1:** Uses a binned likelihood fit performed simultaneously in four signal and two control regions to extract the cross section. A 2D double-differential cross section as a function of muon momentum (p_μ) and angle ($\cos\theta_\mu$) is provided in the full phase space.
- **Analysis 2:** Uses d’Agostini unfolding to extract the cross section. A 2D double-differential cross section as a function of muon momentum (p_μ) and angle ($\cos\theta_\mu$) is provided in the restricted phase space where $p_\mu > 0.2$ GeV and $\cos\theta_\mu > 0.6$.

For the work presented in this article, we fit to “Analysis 1” from the paper, both because of the broader phase space of the “Analysis 1” result and because d’Agostini unfolding is known to produce undercoverage of uncertainties.

Figure 3 shows the complete T2K $CC0\pi$ analysis 1 data compared to GENIE v3.0.6 G18_10a_02_11a and GENIE v2.12.2. The data are presented in a double-differential cross section as a function of muon momentum (p_μ) and angle ($\cos\theta_\mu$). We see the general pattern that the more recent GENIE prediction is below the T2K data, as we have also seen in MicroBooNE simulation.

The highest bin in muon momentum in each $\cos\theta$ bin is excluded in the fitting procedure because very high-momentum muons are not significant in the MicroBooNE analysis. In addition, the very small cross sections and small absolute uncertainties on the data in these bins can drive the fit in an undesirable way. This reduces the number of bins in the data fit from 67 (including high-muon momentum bins) to 58.

NUISANCE allows use of the published bin-to-bin covariance matrix in the fitting process; this is generally regarded as the correct way to fit the data. Unfortunately, attempts to fit the T2K data with the full covariance matrix proved problematic, resulting in a significant and unphysical reduction of the cross section across all of the bins. Multiple hypotheses have been considered to explain this observation. We note that a recent publication in which NuWro models are fit to T2K and MINERvA data sees a similar effect when fitting the MINERvA data [31] and attributes it to Peelle’s Pertinent Puzzle [36].

To avoid these problems, we proceed with fits that do not use the full covariance matrix, but instead use only diagonal elements – corresponding to the error bars on each data point drawn in Fig. 3 – and do not consider correlations between bins. We find that this fitting method gives satisfactory results.

B. Parameter Choice

When using the MINUIT fitting formalism, the choices of parameters to fit are limited because of the difficulty of finding a global minimum with reasonable uncertainties, especially when parameters are highly correlated. In addition, parameters should be chosen to reflect the underlying physics. This means choosing parameters that clearly show a particular physical effect that is not already constrained by data. For example, the CC2p2h contribution is uncertain and makes its study very useful to a variety of researchers.

The decision on parameters to avoid is also important. Although many other fit exercises use the Fermi momentum as a free parameter [37], we ignored it because it is already well-known from electron scattering and any significant differences between electron and neutrino probes are unlikely. Although the MicroBooNE LEE analysis is sensitive to protons in the final state, we do not use any FSI parameters for protons because the T2K 2016 data [9] contains only information on the muon. This is a limitation of this analysis; future work may find it beneficial to add FSI parameters in a fit to measurements of proton kinematics in the T2K data [35].

The reweighting package provided with GENIE allows tuning of the CCQE model via the parameter MaCCQE (which affects both shape and absolute normalization) and tuning of the CC2p2h model via an absolute normalization parameter. These are obvious choices to include in our tuning. We also consider a number of other

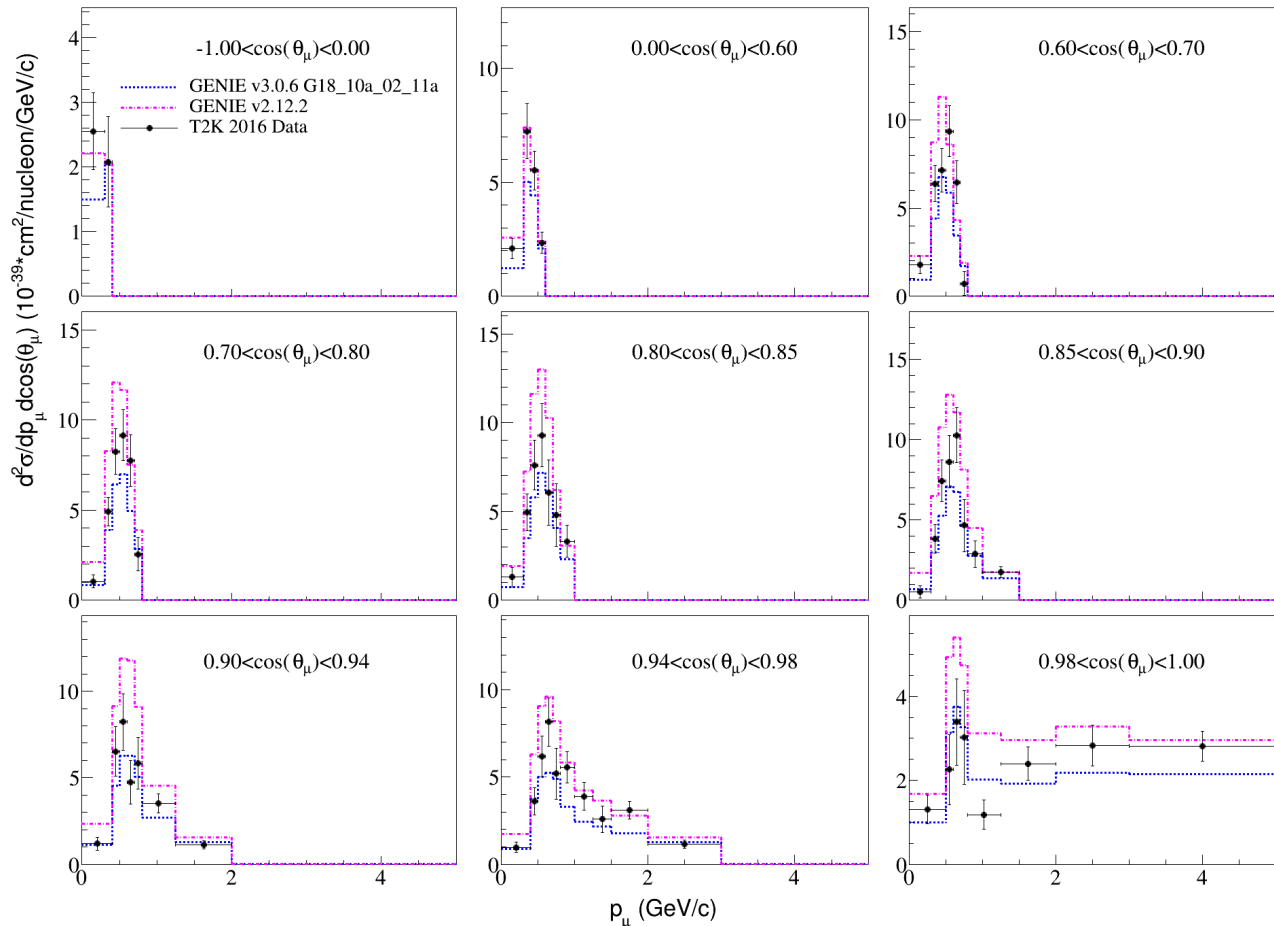

FIG. 3. Comparison of nominal GENIE v3.0.6 G18-10a_02-11a ($\chi^2=115.31/67$ bins) and GENIE v2.12.2 ($\chi^2=284.31/67$ bins) to T2K flux-averaged CC0 π cross section measurement analysis 1 as a function of p_μ in bins of $\cos(\theta_\mu)$. The calculation of χ^2 uses only the uncertainties on the diagonals of the T2K CC0 π data set. While only bins of $p_\mu < 5$ GeV are plotted, all bins with data up to $p_\mu = 30$ GeV are included in the χ^2 calculations.

parameters that we expect might have an effect on this data set: some available in the GENIE reweighting package and some that were developed and added to GENIE for this work. Sec. III B 1 lists the parameters that were chosen to include in the fit to T2K data, and Sec. V A details additional new parameters that were developed for the MicroBooNE interaction uncertainty evaluation, but ultimately not included in the fits presented here.

1. Fit Parameters

MaCCQE: Axial mass in the dipole form factor used in the CCQE cross section calculation. Increasing this parameter’s value has the effect of increasing the normalization of CCQE interactions, as well as changing the shape of the cross section as a function of Q^2 , where Q is the four-momentum transfer to the nucleus.

CCQE RPA: GENIE v3.0.6 G18_10a_02_11a uses the

Valencia RPA (Random Phase Approximation) calculation to correct the CCQE cross section for nucleon-nucleon long range correlations. This manifests itself predominantly as a suppression of the CCQE cross section at low Q^2 . There exists a large body of evidence in support of such a suppression, but calculations differ on its exact strength (including theoretical approximations used in the Valencia prediction), which is not currently well-constrained by data. A new GENIE reweighting parameter has been developed for this work that extrapolates linearly from the nominal RPA model (Valencia) to a model in which the RPA correction is turned off completely. Moving the parameter’s value in the opposite direction strengthens the RPA suppression. Figure 4 illustrates the effect of applying the parameter to a sample of simulated ν_μ CCQE events generated using a ^{40}Ar target and the MicroBooNE flux. The low- Q^2 portion of the event distribution shows the expected suppression in the nominal model (black) relative to the “RPA correction

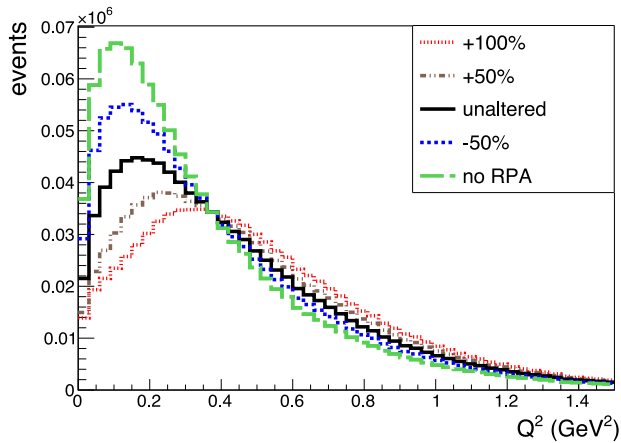

FIG. 4. GENIE v3.0.6 prediction of the true Q^2 distribution for ν_μ CCQE scattering on ^{40}Ar in MicroBooNE. The black histogram shows the untuned result for the G18_10a_02_11a model set, which includes Valencia RPA corrections to the CCQE cross section. The other histograms show alterations to the strength of the untuned CCQE RPA correction calculated via reweighting.

off” model (green). The other histograms show further reweighting-based variations of the RPA strength which follow the expected trend.

Figure 5 and Table I show the impact of RPA corrections on predictions for CC0 π events at forward muon scattering angles (low Q^2) in T2K, changing between the untuned prediction (100% of the nominal RPA strength) and the “RPA correction off” prediction. The effect on the T2K distribution is significant and consistent with what we would expect; the overall effect of including RPA corrections is to improve the fit in one angle bin and make it worse in the other bin. Because of the large impact on the CCQE cross section and thus on the T2K prediction, we include this RPA parameter in the fits.

TABLE I. χ^2 for GENIE v3.0.6 G18_10a_02_11a with and without the Valencia CCQE RPA corrections for T2K CC0 π data as shown in Fig. 5. Only the diagonal terms in the covariance matrix are used in the χ^2 calculation.

χ^2	$0.94 < \cos(\theta_\mu) < 0.98$	$0.98 < \cos(\theta_\mu) < 1.00$
RPA Correction	23.0/11 bins	16.2/9 bins
No RPA Correction	14.8/11 bins	35.9/9 bins

CC2p2h Normalization: This parameter changes the overall absolute normalization of the CC2p2h cross section. A parameter value of 1 corresponds to the default normalization of CC2p2h interactions in GENIE v3.0.6 G18_10a_02_11a. A larger value increases the average cross section with no change in shape.

CC2p2h Shape: At present, there are substantial differences between alternative theoretical predictions of lepton kinematics on CC2p2h scattering. To account for this, a parameter developed for this work changes the shape of the inclusive CC2p2h differential cross sec-

tion between the Valencia calculation [8] (the nominal model in our version of GENIE v3.0.6 G18_10a_02_11a, dial value = 0) and the GENIE Empirical model [38] (an alternative available in other GENIE configurations, dial value = 1). A linear interpolation is performed which allows for continuous variations of the dial on the interval [0, 1]. The overall normalization of the cross-section is left unaltered. Fig. 6 illustrates the effect of the CC2p2h shape dial variations on the distribution of the leptonic energy and momentum transfer for simulated CC2p2h events in MicroBooNE. The two distinct peaks seen for

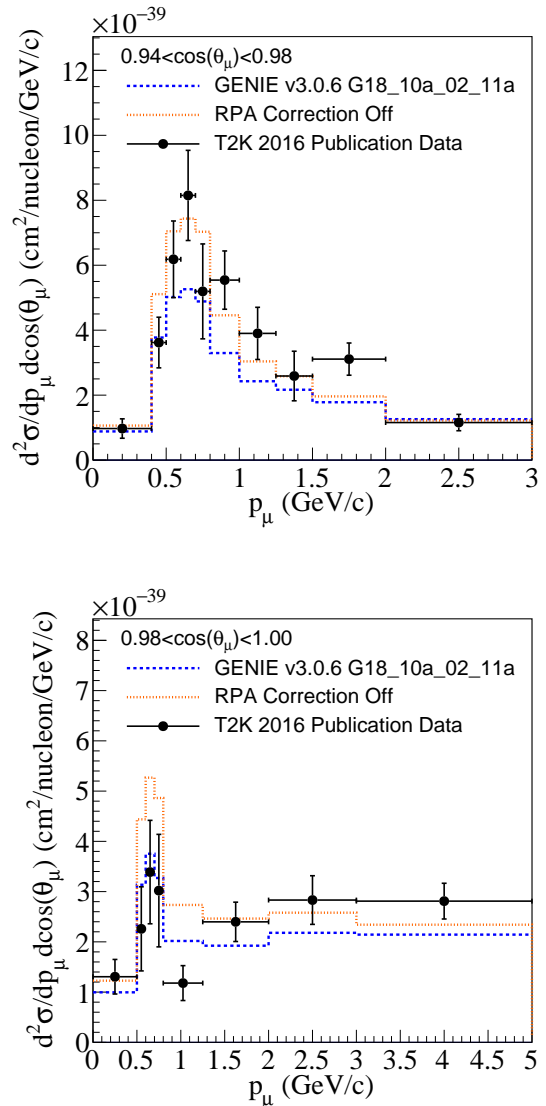

FIG. 5. T2K flux-averaged CC0 π analysis 1 data as a function of muon momentum for $0.94 < \cos(\theta_\mu) < 0.98$ (top) and $0.98 < \cos(\theta_\mu) < 1.00$ (bottom) compared to the nominal GENIE v3.0.6 G18_10a_02_11a prediction and the prediction with no CCQE RPA corrections. Both plots are zoomed in on a lower range of muon momentum for readability, although all bins are included in the χ^2 calculations in Table I.

the Valencia calculation (top plot) are replaced by a single peak (middle plot, dial value = 0.5) as the distribution is reshaped to resemble the GENIE Empirical model prediction (bottom plot) more closely. A similar kinematic distribution with a single peak is predicted by other CC2p2h models, e.g., SuSAv2-MEC [39].

Figure 7 shows the effect of changing the CC2p2h Shape dial from 0 (nominal) to 1 on the predicted CC0 π cross section at T2K. Although the CC2p2h shape change is subtle in some regions of phase space (top plot), in others it is an important effect (bottom plot). The sensitivity to shape of the muon angle-energy distribution is further corroborated in the χ^2 values reported in Table II. The CC2p2h shape parameter has a significant impact for MicroBooNE. Since the CC2p2h cross section shape is very much unknown, we include this parameter in our tuning.

TABLE II. χ^2 for GENIE v3.0.6 G18_10a_02_11a with the Valencia CC2p2h shape and Empirical CC2p2h shape for T2K CC0 π data as shown in Fig. 7. Only the diagonal terms from the data set covariance matrix are used for the χ^2 calculation.

χ^2	$0.60 < \cos(\theta_\mu) < 0.70$	$0.98 < \cos(\theta_\mu) < 1.00$
Valencia CC2p2h	21.9/7 bins	16.2/9 bins
Empirical CC2p2h	20.6/7 bins	12.8/9 bins

The final parameterization for this tuning work consists of four parameters to be fit: MaCCQE, CC2p2h Normalization, CCQE RPA strength, and CC2p2h shape.

IV. FIT RESULTS

We fit four parameters (MaCCQE, CC2p2h Normalization, CCQE RPA Strength, and CC2p2h Shape) to the T2K CC0 π cross, section data, neglecting off-diagonal terms in the T2K data covariance matrix and the highest muon momentum bins (as described in Sec. III A). Table III shows the results of three fits, adding in a parameter each time, such that the final row on the table shows the result of the full four-parameter fit (referred to in this article as the “MicroBooNE Tune”). The fitted parameter values in this line are one of the primary results of this analysis. Post-fit correlations between the parameters are shown in Fig. 8, and the tuned model is compared to the T2K data in Fig. 9. Agreement between data and simulation is measured as a χ^2 value across the whole data set. As a result of the fit, the total χ^2 is reduced from 115.3 to 63.8 (almost a factor of two) for the 67 bins in the data set.

The fit results show increases in both MaCCQE (which in large part increases the CCQE cross section) and the CC2p2h cross-section normalization. It favors a slight decrease in CCQE RPA strength (85% of nominal), albeit with a value consistent within a 1σ uncertainty of the Valencia prediction (100%). Interestingly, the fit prefers a CC2p2h shape in lepton kinematics that matches the

Empirical CC2p2h model over the Valencia prediction, although the fit uncertainty is close to the entire range of the parameter, indicating that the preference is not strong.

In Fig. 8, we find fairly strong anti-correlations between MaCCQE and CC2p2h normalization, because increasing MaCCQE increases the CCQE cross-section normalization (with some additional changes in shape). Strong anti-correlations are also seen between the CC2p2h normalization and RPA strength parameters, which is to be expected because both have importance at forward muon angles. These anti-correlations suggest ambiguities in the tuning procedure, where different fitted parameters can have similar effects on the prediction. Therefore, one cannot assume that the central-value result of this tune has the correct ratio of contributions from the CCQE and CC2p2h processes. However, this tune does successfully adjust the overall rate and shape of the prediction in lepton kinematics for CC0 π interactions. Ambiguities between individual interaction processes can be correctly accounted for if the correlation matrix is taken into account in the treatment of uncertainties. The correlations between the CC2p2h normalization and shape parameters are small, consistent with the design of these parameters to be orthogonal.

Tests of the robustness of the fit are important. The variation of parameters in Table III gives some indication of how choices of parameters impact the fit results. The variation of fit results as the number of parameters increases is not significant. The best-fit values for MaCCQE and CC2p2h normalization are fairly constant within uncertainties, with and without the shape parameters. The fitted value of CC2p2h normalization changes depending on the fitted value of RPA strength, which is consistent with the large anti-correlations between these parameters seen in the four-parameter fit covariance matrix.

As another test of robustness, different parameters were chosen (e.g. CCQE normalization vs. MaCCQE and different formulations of the shape parameters) with minimal change in the output. In addition, alternate fits with different starting values, both small and random, give almost identical fit values and uncertainties. This gives confidence that the choice of fit parameters was robust.

The uncertainties shown in Table III are the post-fit uncertainties given by MINUIT. MicroBooNE analyses adopt uncertainties that cover the results of all three fits presented in Table III and incorporate prior expectations about the sensitivity of T2K to these parameters: an uncertainty of 0.1 GeV on the parameter MaCCQE, 0.5 on the CC2p2h normalization, 40% on the CCQE RPA strength, and an uncertainty that covers the full allowed range of the parameter for CC2p2h Shape: 1_{-1}^{+0} .

TABLE III. Tuned parameter values and uncertainties after fitting to T2K CC0 π data for the nominal simulation and three tunes that build to the final four parameter tune. Note that post-fit χ^2 values are quoted here only for the 58 bins included in the fit (excluding the highest muon momentum bin in each $\cos\theta$ bin). In the text and figures, pre- and post-fit χ^2 comparisons are also quoted for the full T2K data set of 67 bins.

	MaCCQE fitted value	CC2p2h Norm. fitted value	CCQE RPA Strength fitted value	CC2p2h Shape fitted value	T2K χ^2/N_{bins}
Nominal (untuned)	0.961242 GeV	1	100%	0	106.7/58
Fit MaCCQE + CC2p2h Norm.	1.14 ± 0.07 GeV	1.61 ± 0.19	100% (fixed)	0 (fixed)	71.8/58
Fit MaCCQE + CC2p2h Norm. + CCQE RPA Strength	1.18 ± 0.08 GeV	1.12 ± 0.38	(64 \pm 23)%	0 (fixed)	69.7/58
Fit MaCCQE + CC2p2h Norm. + CCQE RPA Strength + CC2p2h Shape	1.10 ± 0.07 GeV	1.66 ± 0.19	(85 \pm 20)%	$1_{-0.74}^{+0}$	52.5/58

A. “MicroBooNE Tune” Comparison to MicroBooNE Data

Because the aim of this tuning work is to support MicroBooNE analyses, it is important to compare the “MicroBooNE Tune” to MicroBooNE data. While the T2K data are in a similar energy range to MicroBooNE, they are on a different nuclear target. Therefore it is imperative to check that the fitted result within uncertainties can predict MicroBooNE’s measured argon-target interactions. Comparisons of the tuned and untuned GENIE v3 models to MicroBooNE data are provided in this section for generic neutrino scattering, ν_μ CC inclusive events, and exclusive one-muon, one-proton ($1\mu 1p$) final states consistent with CCQE kinematics. No attempt is made to be comprehensive. As is the case for any neutrino interaction model, the suitability of the “MicroBooNE Tune” (and its associated uncertainties) for any specific analysis must be determined on a case-by-case basis. Further data-driven model constraints will often be essential for achieving sufficient precision. However, based on the overall improvement seen in the description of MicroBooNE data across many event selections and observables, the collaboration has adopted the “MicroBooNE Tune” described herein as the base neutrino interaction model for all current analyses, including those investigating the MiniBooNE LEE [10–13, 40] and neutrino-argon cross sections [41, 42].

Figure 10 shows the events selected in the MicroBooNE detector using the generic neutrino detection described in Ref. [43], plotted as a function of visible energy. The same selected data events are shown in both panels, but the simulation uses untuned GENIE v3.0.6 G18_10a.02_11a in Fig. 10(a) and the simulation computed with the “MicroBooNE Tune” is applied in Fig. 10(b). The tune increases the normalization of the simulation, decreasing the data/simulation ratio from 1.12 (untuned) to 1.01 (“MicroBooNE Tune”).

Figure 11 shows GENIE v3.0.6 G18_10a.02_11a and the “MicroBooNE Tune” central value (neglecting uncertainties on the predictions) compared to the double-differential cross section for CC inclusive interactions measured in the MicroBooNE detector as a function of lepton momentum and $\cos(\theta_\mu)$ [44]. Table IV contains a comparison of χ^2 values for the complete data set and binned in angle. As seen elsewhere, a major effect of the tune is to increase the normalization of the prediction. Overall we see in Table IV that χ^2/n_{bins} increases from 2.51 (untuned GENIE prediction) to 3.35 (“MicroBooNE Tune”). However, in both cases we find that the large χ^2/n_{bins} value is driven by the highest muon momentum bins for $\cos(\theta_\mu)$ approaching 1. In the highest muon momentum bin in the $0.86 \leq \cos(\theta_\mu) \leq 0.94$ angular bin, the measurement sits below both predictions and has a very small uncertainty. Removing this bin from the comparison gives an overall χ^2 of 69.7 (GENIE v3) or 90.2 (“MicroBooNE Tune”) for 41 bins. It also reduces the χ^2 in the $0.86 \leq \cos(\theta_\mu) \leq 0.94$ angular bin to 6.2 (GENIE v3) or 8.3 (“MicroBooNE Tune”), noting that the χ^2 for individual $\cos(\theta_\mu)$ shown in Table IV do not include correlations with other angular bins. We find that the tuning has provided a better description of the data in some regions of phase space, notably at moderate muon production angles and momenta. However, there remains room for improvement in the description at high muon momentum and at very forward-going scattering angles.

Comparisons of the GENIE v2.12.10 default model, untuned GENIE v3.0.6 G18_10a.02_11a, and the “MicroBooNE Tune” to additional MicroBooNE ν_μ CC inclusive cross-section measurements from Ref. [42] are shown in Fig. 12. When the theoretical uncertainties on each model prediction are neglected, the overall agreement between the data and the “MicroBooNE Tune” is found in plots (a) and (b) to be comparable to or better than the two alternative GENIE models studied. For plot (c), the

TABLE IV. χ^2 for the results of this work in Fig. 11 relative to MicroBooNE CC inclusive double-differential data using the full covariance matrix of the data set for χ^2 calculations. Included are both χ^2 values for the full data set and for each slice of $\cos(\theta_\mu)$. The per-slice χ^2 values reported here do not include correlations between different slices.

χ^2	GENIE v3.0.6 G18_10a_02_11a	MicroBooNE Tune
Full Data Set	105.41/42 bins	140.55/42 bins
$-1.00 < \cos(\theta_\mu) < -0.50$	3.50/5 bins	3.47/5 bins
$-0.50 < \cos(\theta_\mu) < 0.00$	2.80/5 bins	3.07/5 bins
$0.00 < \cos(\theta_\mu) < 0.27$	4.54/5 bins	4.15/5 bins
$0.27 < \cos(\theta_\mu) < 0.45$	2.95/4 bins	2.61/4 bins
$0.45 < \cos(\theta_\mu) < 0.62$	2.37/4 bins	2.09/4 bins
$0.62 < \cos(\theta_\mu) < 0.76$	7.73/4 bins	8.36/4 bins
$0.76 < \cos(\theta_\mu) < 0.86$	10.89/5 bins	7.92/5 bins
$0.86 < \cos(\theta_\mu) < 0.94$	34.36/5 bins	43.90/5 bins
$0.94 < \cos(\theta_\mu) < 1.00$	7.60/5 bins	12.41/5 bins

measurement of the differential cross section as a function of energy transfer ($d\sigma/d\nu$), the χ^2/dof value for the tune is slightly higher than untuned GENIE v3 and substantially higher than GENIE v2. Nevertheless, detailed studies of the tuned model, reported in Refs. [11, 42], demonstrate that it provides a reliable description of MicroBooNE data in the low- ν region when theoretical uncertainties are taken into account.

As an example of the performance of the tuned model when confronted with a MicroBooNE measurement of a highly exclusive event topology, Fig. 13 compares the untuned (top panel) and tuned (bottom panel) GENIE model predictions to the reconstructed neutrino energy distribution obtained for the $1\mu 1p$ constraint sample used in the quasielastic ν_e LEE search [13]. The selection used here obtains a highly pure sample of ν_μ CCQE events by checking the kinematic consistency of the $1\mu 1p$ final state with a two-body CCQE hypothesis. Application of the “MicroBooNE Tune” substantially improves the level of GENIE model agreement with these data: a ratio of 1.23 ± 0.13 between the integrated data and the untuned model is reduced to 1.08 ± 0.13 with the tune, and the combined Neyman-Pearson chi-square [45] metric for goodness-of-fit improves from $\chi_{\text{CNP}}^2 = 1.68/\text{bin}$ to $\chi_{\text{CNP}}^2 = 1.31/\text{bin}$ [13]. Similar levels of improvement are seen for other kinematic distributions obtained using the same data set.

B. “MicroBooNE Tune” Comparison to MiniBooNE Data

We next compare the result of this tuning to data from the MiniBooNE experiment. Because this article presents a tune of the CCQE and CC2p2h parameters, we compare to measured CCQE-like cross section data [17], shown in Fig. 14. The “CCQE-like” signal definition used

by the MiniBooNE collaboration in [17] is consistent with what has been termed “CC0 π ” in this article: any interaction in which one muon, any number of nucleons, and no other particles are produced.

Figure 14 shows the comparison of tuned and untuned GENIE to the extracted CC0 π double-differential cross-section measurement from MiniBooNE [17] as a function of lepton kinetic energy and $\cos(\theta_\mu)$. Note that χ^2 goodness-of-fit metrics cannot be calculated between the prediction and this data set because the measurement is published without a bin-to-bin covariance matrix. Visually, we see overall improved agreement when using the “MicroBooNE Tune”. More specifically, we see very good agreement for high energy muons, but the tuned model still underpredicts the data for low-energy muons. The original Valencia publications [6] had very good visual agreement with this data, although required a normalization shift of $\sim 10\%$. Using the GENIE version of the Valencia model [8] and the “MicroBooNE Tune”, no normalization shift is needed and thus the overall agreement is better. However, the ability to describe these low energy features are not as good as the original Valencia model [6] despite the use of an improved binding energy technique in GENIE. The application of a constant binding energy in GENIE (derived from (e,e’) data at higher energies [46]) may still be a problem. A more realistic treatment would have binding energy depending on kinematics or the use of a spectral function, neither of which is included yet in GENIE.

It is interesting to note that we do not see a similar underprediction when comparing to the T2K data. In fact, attempts to tune to this MiniBooNE data has resulted in a prediction that is in tension with the T2K data, so we believe this represents an underlying tension between the two data sets.

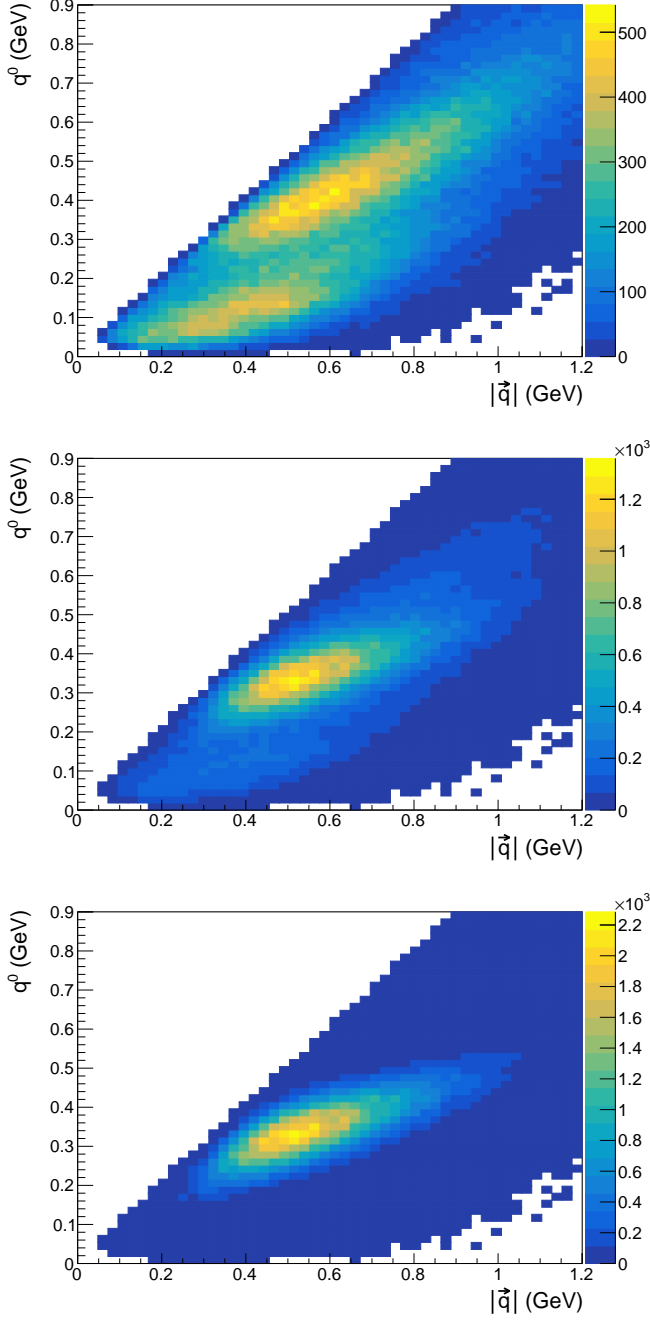

FIG. 6. Joint distribution (with arbitrary normalization) of the energy transfer (q^0) and magnitude of the three-momentum transfer ($|\vec{q}|$) for simulated ν_μ CC2p2h events on ^{40}Ar in MicroBooNE. Top: Valencia model prediction (CC2p2h shape dial at 0). Middle: Intermediate prediction (CC2p2h Shape dial at 0.5). Bottom: GENIE empirical model prediction (CC2p2h shape dial at 1).

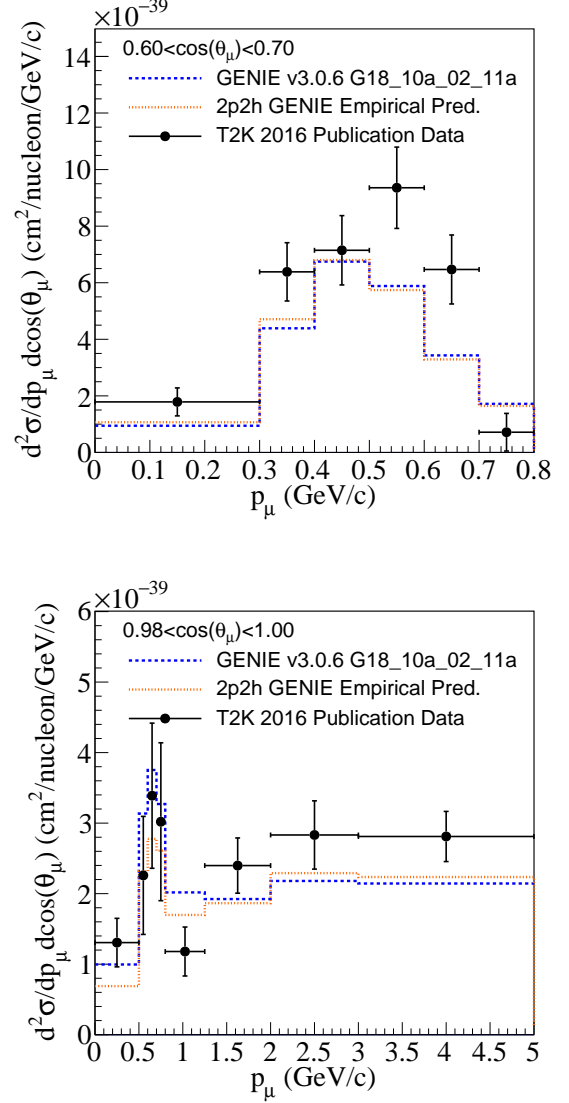

FIG. 7. T2K flux-averaged CC0 π analysis 1 cross-section measurement as a function of muon momentum for $\cos(\theta_\mu)$ between $0.60 < \cos(\theta_\mu) < 0.70$ (top) and $0.98 < \cos(\theta_\mu) < 1.00$ (bottom) compared to the nominal GENIE v3.0.6 G18_10a_02_11a prediction and the prediction with the GENIE empirical CC2p2h shape. Both plots are zoomed in on a lower range of muon momentum for readability, although all bins are included in the χ^2 calculations in Table II.

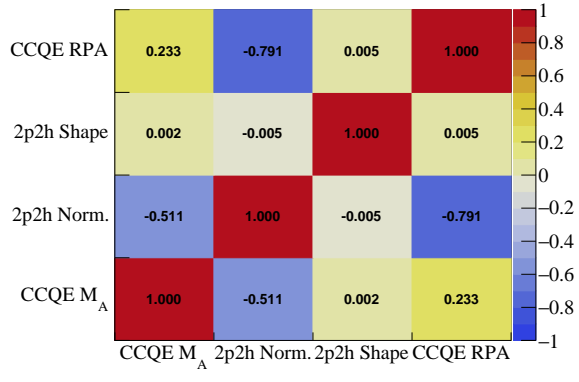

FIG. 8. Correlations between parameters after fitting to T2K $CC0\pi$ data.

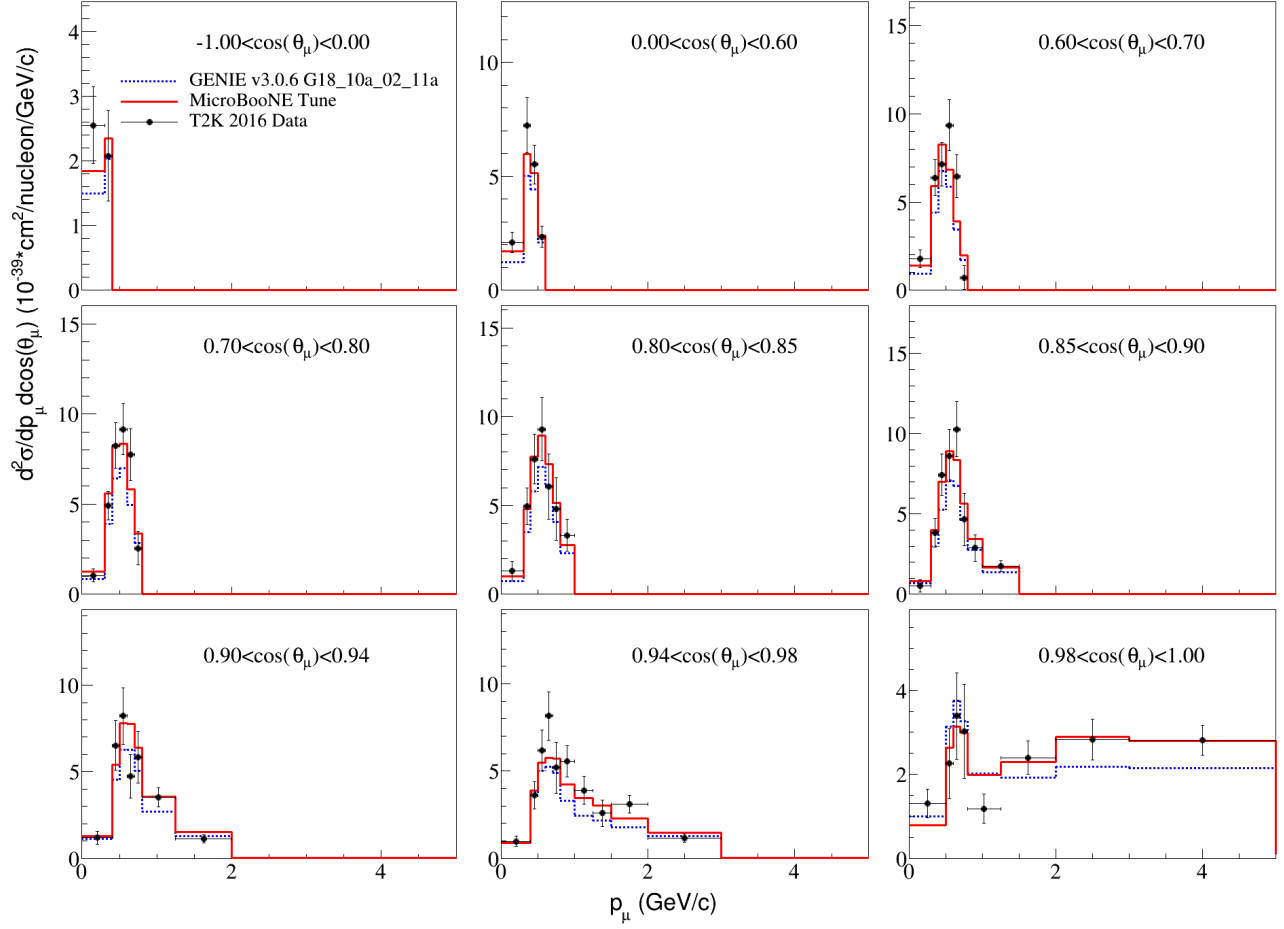

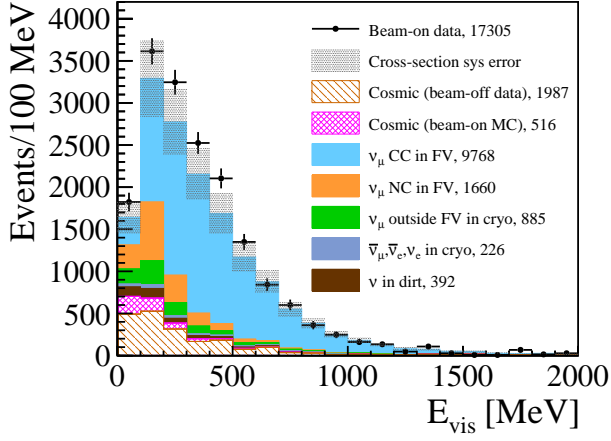

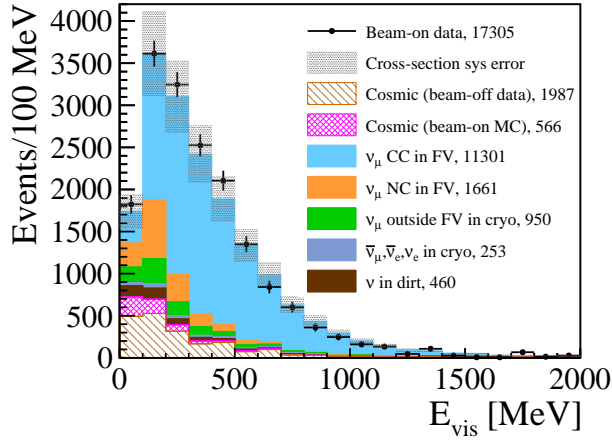

FIG. 9. T2K flux-averaged CC0 π differential cross section of lepton momentum and $\cos(\theta_l)$ compared to GENIE v3.0.6 G18.10a_02.11a ($\chi^2=115.31/67$ bins) and the MicroBooNE tune ($\chi^2=63.77/67$ bins) to T2K CC0 π data. Only the diagonal entries in the covariance matrix are used for the χ^2 evaluation. While only bins of $p_\mu < 5$ GeV are plotted, all bins with data up to $p_\mu = 30$ GeV are included in the χ^2 calculations.

(a) Simulated neutrino interactions predicted by GENIE v3.0.6 G18_10a_02_11a

(b) Simulated neutrino interactions predicted by the “MicroBooNE tune” applied to GENIE v3.0.6 G18_10a_02_11a

FIG. 10. Total visible energy of events selected in the MicroBooNE detector using the generic neutrino detection described in [43], compared to MicroBooNE simulation before and after the “MicroBooNE Tune” has been applied. The gray hashed area indicates uncertainties on the cross-section model only (including uncertainties on the tuned parameters, the new uncertainties presented in Sec. V A, and other uncertainties as recommended by the GENIE collaboration). The tuned model shows significantly better agreement with the data.

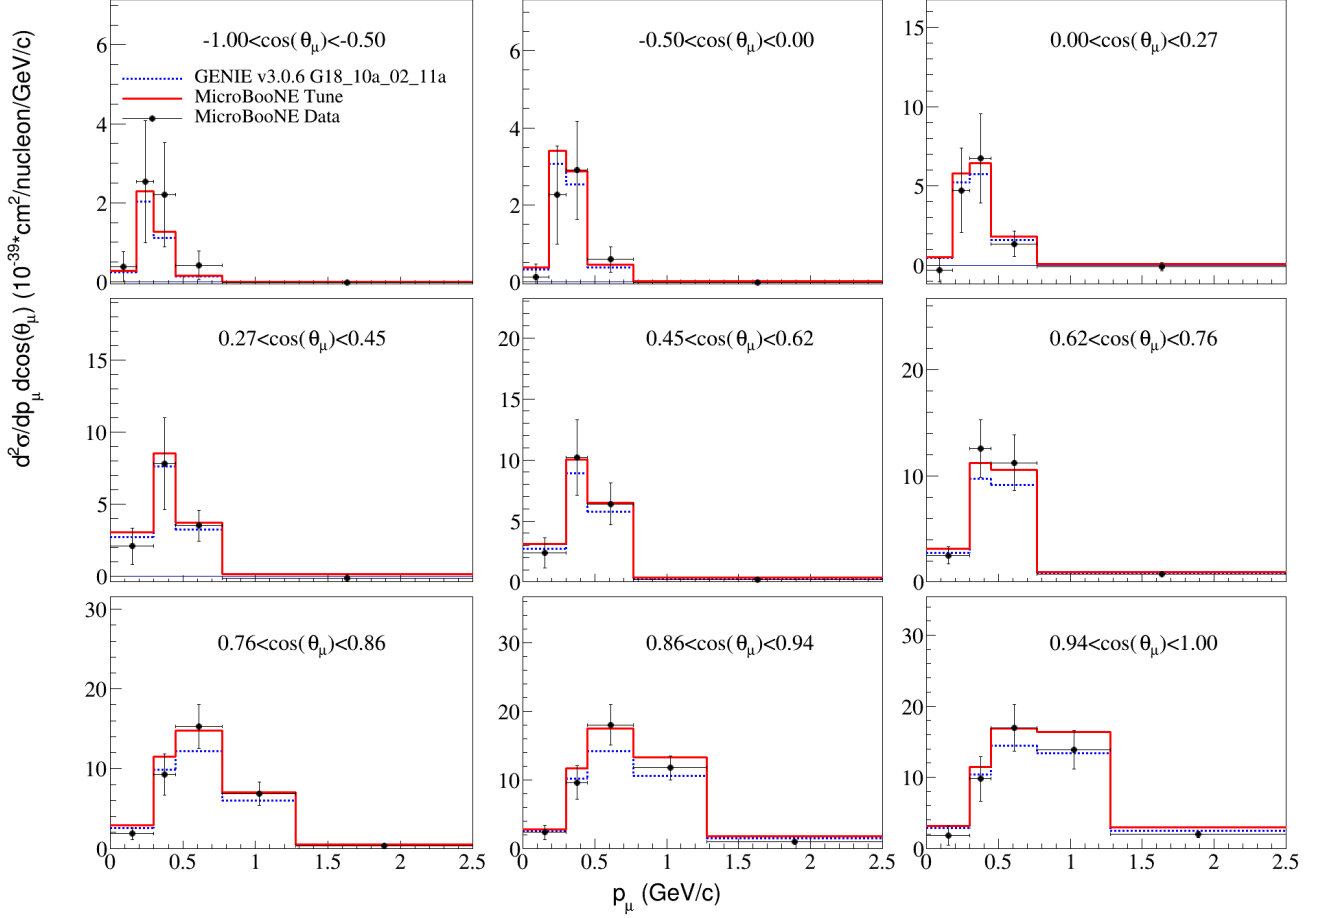

FIG. 11. MicroBooNE flux-averaged ν_μ CC inclusive double-differential cross section as a function of muon momentum and $\cos(\theta_\mu)$ [44], compared to GENIE v3.0.6 G18_10a_02_11a and the MicroBooNE tune central value to T2K CC0 π data.

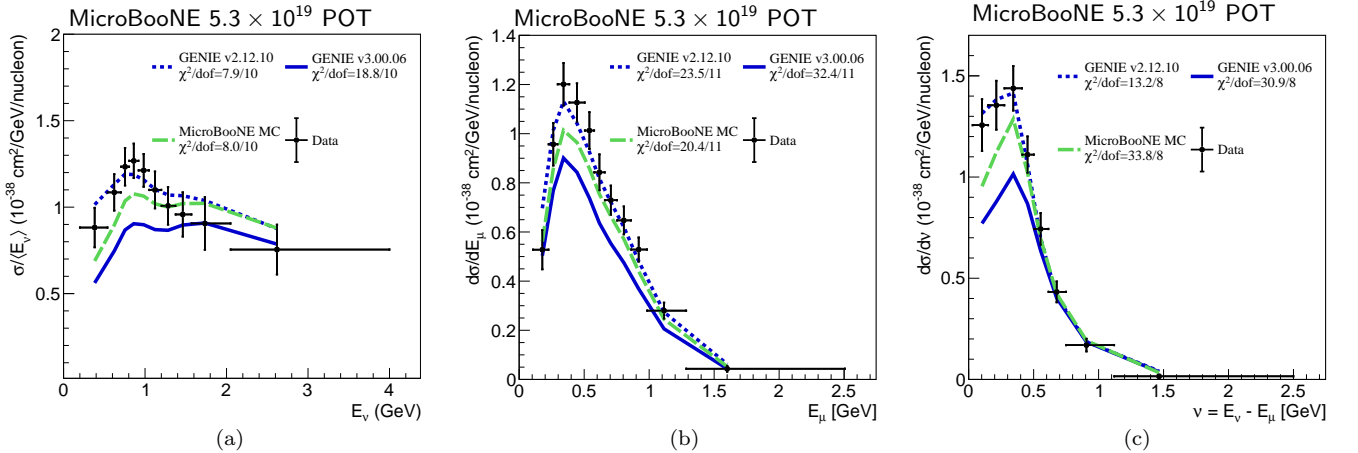

FIG. 12. Comparison of the GENIE v2.12.2 default model (dashed blue) and both the untuned (solid blue) and tuned (dashed green) GENIE v3.0.6 G18_10a_02_11a models to MicroBooNE measurements [42] of the ν_μ -argon CC inclusive cross section as a function of (a) neutrino energy, (b) muon energy, and (c) energy transfer. The data in plot (a) are divided by the bin-center neutrino energy. Chi-squared values are calculated while neglecting uncertainties on the model predictions.

(a) Simulated neutrino interactions predicted by GENIE v3.0.6 G18_10a_02_11a

(b) Simulated neutrino interactions predicted by the “MicroBooNE tune” applied to GENIE v3.0.6 G18_10a_02_11a

FIG. 13. Reconstructed neutrino energy of $1\mu 1p$ events selected as input to a constraint for the MicroBooNE $1e1p$ LEE analysis described in Ref. [13]. The bottom panel is taken directly from that publication and uses the “MicroBooNE Tune” of GENIE, while the top panel provides a similar comparison to the untuned GENIE v3.0.6 G18_10a_02_11a prediction. Significantly better agreement with the data is achieved with the tuned GENIE model.

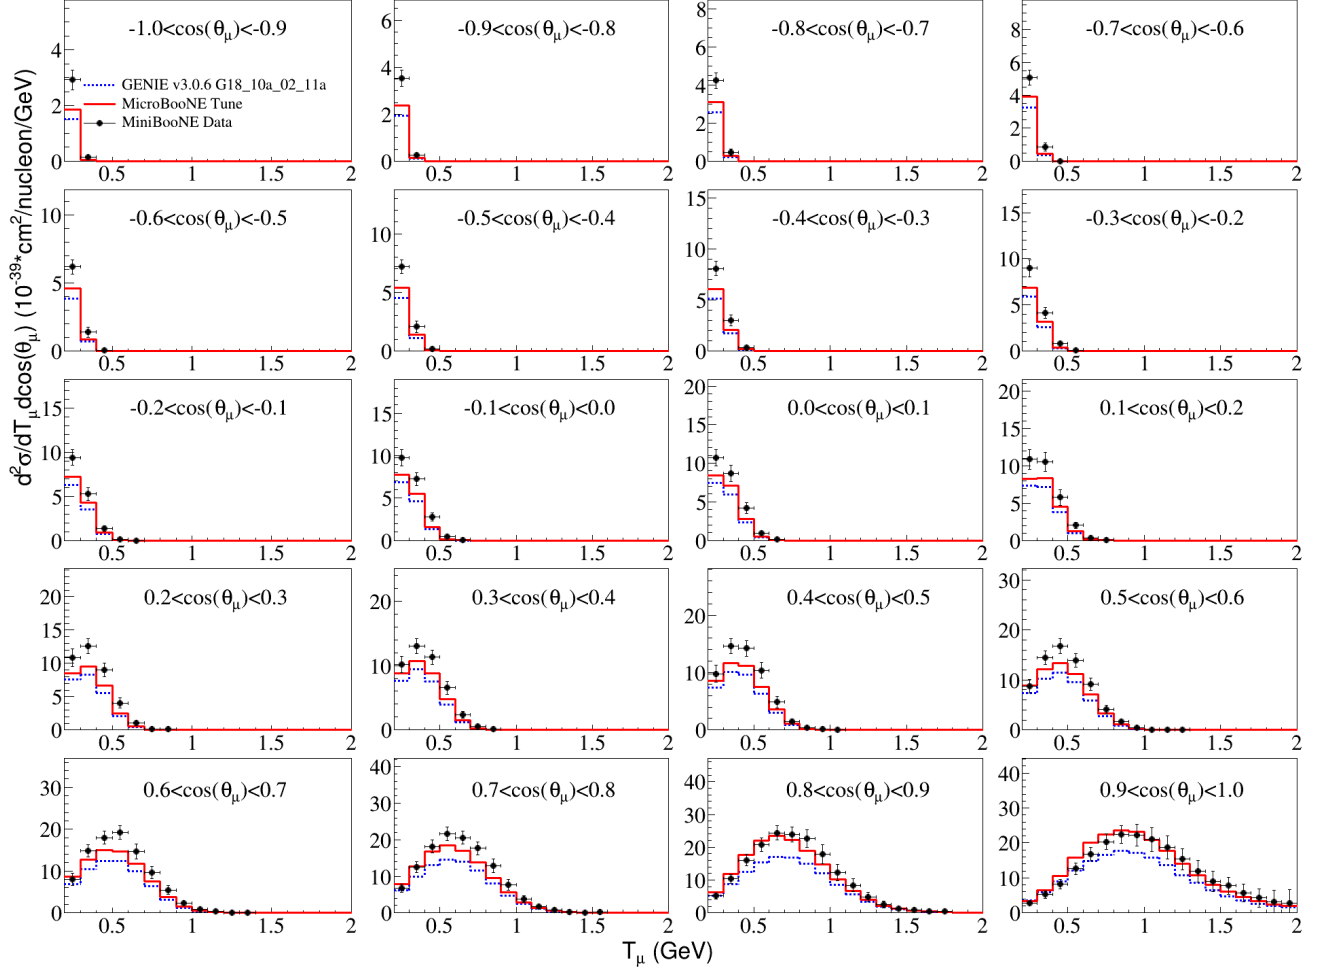

FIG. 14. MiniBooNE flux-averaged CCQE-like double-differential cross section as a function of lepton kinetic energy and $\cos(\theta_\mu)$ [17] compared to GENIE v3 and the MicroBooNE tune. Uncertainties on the data points are the shape uncertainties reported by the collaboration.

V. INTERACTION MODEL UNCERTAINTIES

The analysis presented in the preceding sections obtained refined values of four cross-section model parameters describing the $CC0\pi$ channel, which is dominant in MicroBooNE. A complete treatment of neutrino interaction model uncertainties, however, requires a consideration of many additional degrees of freedom. This section documents the full set of neutrino cross-section systematic uncertainties adopted in current MicroBooNE analyses. With the exception of CCQE uncertainties related to second-class currents (see Sec. VB), these are implemented by adding MicroBooNE-specific enhancements to the Reweight package [47] distributed with GENIE v3.0.6. These will be contributed by MicroBooNE for inclusion in the upcoming v3.2.0 release of GENIE.

The GENIE Reweight code provides a standard framework for evaluating model uncertainties via event *reweighting*: the impact of a model parameter variation on an existing sample of simulated events is approximated by assigning a numerical weight w to each event equal to the likelihood ratio

$$w = L'/L. \quad (1)$$

Here L is the likelihood of generating the event under the original GENIE configuration and L' is the corresponding likelihood calculated after one or more interaction model parameters have been altered from their original values. Uncertainties on distributions calculated using the events may then be evaluated by comparing results obtained with different sets of event weights.

A typical uncertainty quantification method used by MicroBooNE is the *multiple universe* approach: a covariance matrix V_{ij} describing the uncertainty on a vector of predicted event counts n_i is constructed via the formula

$$V_{ij} = \frac{1}{N} \sum_{k=1}^N (n_i^k - n_i^{CV})(n_j^k - n_j^{CV}). \quad (2)$$

Here V_{ij} is the covariance matrix element of interest, n_i^{CV} is the predicted number of events in the i th bin under the nominal (or *central-value*) GENIE model configuration, and n_i^k is the corresponding event count calculated under an alternate configuration labeled as the k th alternate *universe*. The result is averaged over a total of N alternate universes.

MicroBooNE analyses consider a wide variety of cross-section model variations when preparing alternate-universe predictions n_i^k for use with this method. Section VA describes new parameters (and their associated uncertainties) developed by MicroBooNE to address missing degrees of freedom in the reweighting tools released with GENIE v3.0.6. These are supplemented with an external calculation of CCQE model uncertainties related to second-class currents as described in Sec. VB. A full inventory of systematic uncertainties on the GENIE-based cross-section model is then documented in Sec. VD and Appendix A.

A. Additional Parameters Developed for MicroBooNE Interaction Uncertainty Evaluation

While current MicroBooNE analyses adopt the recommended GENIE v3.0.6 parameter uncertainties in most cases, several new parameters were developed to assess additional uncertainties beyond the default set. Three new parameters (RPA_CCQE, NormCCMEC, and XSecShape_CCMEC) were already discussed in the context of the tune to T2K $CC0\pi$ data presented in the previous sections. The following paragraphs describe the remaining new parameters which are used for systematic uncertainty evaluation but were excluded from the fit to external data.

Coulomb_CCQE: The Valencia CCQE model accounts for the Coulomb interaction between the residual nucleus and the outgoing lepton using a procedure similar to the *modified effective momentum approximation* proposed by Engel [48]. This involves the use of an effective value k_{eff} of the outgoing lepton momentum computed via

$$E_{\text{eff}} = E - V_C(r) \quad k_{\text{eff}} = \sqrt{E_{\text{eff}}^2 - m^2} \quad (3)$$

where E is the lepton total energy, m is its mass, and $V_C(r)$ is the local nuclear Coulomb potential at the initial radial position r of the struck nucleon. An approximate uncertainty on this correction may be assessed by scaling the value of the nuclear Coulomb potential $V_C(r)$. The Coulomb_CCQE parameter applies this scaling with a recommended fractional uncertainty of $\pm 30\%$. The impact of the Coulomb corrections at neutrino energies relevant for MicroBooNE is typically small.

DecayAngMEC: At present, all 2p2h models implemented in GENIE are inclusive, i.e., they predict the kinematics of the outgoing lepton only [8]. A two-nucleon hadronic final state is obtained in the simulation by recourse to a rough approximation called the *nucleon cluster model* [38]. Under this approach, the leptonic four-momentum transfer is imparted to a pair of two nucleons sampled independently from the nuclear ground state distribution and treated as a single object. A decay of the final-state pair is then simulated to produce two outgoing nucleons. In the default GENIE treatment of this decay, the angular distribution is isotropic in the rest frame of the pair. The DecayAngMEC parameter adjusts this behavior. A parameter value of 0 corresponds to the default isotropic distribution, while a value of 1 yields an angular dependence proportional to $\cos^2 \theta$, where the polar angle θ is measured with respect to the 3-momentum transfer \mathbf{q} . Due to the lack of theoretical guidance for the alternate angular distribution, this specific form was chosen as a significant deviation from isotropy which is invariant under exchange of the two nucleons. Intermediate parameter values on the interval $[0, 1]$ linearly interpolate between the two distributions. An uncertainty corresponding to the full difference between DecayAngMEC values of 0 and 1 is adopted.

FracPN_CCMEC: Charged-current 2p2h interactions may occur with an initial pair of nucleons that share the same third component of isospin (nn for neutrinos, pp for antineutrinos) or that differ (pn). The **FracPN_CCMEC** parameter adjusts the fraction of these events involving an initial pn pair relative to the default prediction of the Valencia CC 2p2h model. A fractional uncertainty of $\pm 20\%$ is adopted subject to the constraint that the pn fraction must lie on the interval $[0, 1]$.

FracDelta_CCMEC: In contrast to other theoretical treatments of CC 2p2h interactions, the Valencia calculation predicts two distinct peaks in the joint distribution of energy and momentum transfer (see the top panel of Fig. 6). These arise from two classes of Feynman diagrams, one of which involves an internal Δ line while the other does not. The **FracDelta_CCMEC** parameter adjusts the relative strength of these two contributions to the CC 2p2h cross section. An uncertainty of $\pm 30\%$ on the nominal fraction of CC 2p2h interactions that proceed via an internal Δ is assessed, subject to the constraint that the fraction remains within the interval $[0, 1]$.

Although changes to this parameter were expected to leave the total CC 2p2h event rate unchanged, numerical limitations were found that lead to missing strength when a downward variation is applied. These limitations involve occasional very large event weights and inconsistencies in the GENIE implementation of the cross sections themselves, e.g., the internal Δ contribution sometimes exceeds the total cross section. The main impact of these issues on MicroBooNE analyses is expected to be a small overestimation of the systematic uncertainty on the normalization of CC 2p2h events.

ThetaDelta2NRad: An enhanced rate of neutrino-induced production of single photons is a proposed explanation for the anomalous excess of electron-like low-energy events seen by MiniBooNE [49]. Radiative decays of Δ baryons ($\Delta \rightarrow N + \gamma$) are a major source of single photons at MicroBooNE energies and are thus of particular interest. In addition to the existing GENIE uncertainty on the branching ratio for radiative Δ decay, the new **ThetaDelta2NRad** parameter is used to assess an uncertainty on the angular distribution for this process. The implementation is similar to the one for the parameter (**DecayAngMEC**) describing the two-nucleon angular distribution in 2p2h events: a **ThetaDelta2NRad** value of 0 corresponds to isotropic decays, while a value of 1 yields an angular distribution proportional to $\cos^2 \theta$. An uncertainty calculated by taking the full difference between these two extremes is adopted.

NormCCCOH and **NormNCCOH:** The event reweighting tools distributed with GENIE v3.0.6 allow for variations of two parameters in the coherent pion production (COH) cross section: the axial mass (**MaCOHpi**) and the effective nuclear radius (**ROCOHpi**). However, technical limitations in the implementation of the Berger-Sehgal COH model used in G18.10a.02.11a lead to incompatibility with those weight calculators. New parameters which apply a constant scale factor to the CC

(**NormCCCOH**) and NC (**NormNCCOH**) coherent pion production cross section are adopted instead, each with a $\pm 100\%$ uncertainty.

NormNCMEC: A similar normalization-only uncertainty of $\pm 100\%$ is assessed on the GENIE Empirical model of the NC 2p2h cross section.

B. Second-class current form factors

Violations of charge conjugation or time reversal symmetry in quasielastic neutrino-nucleon scattering can give rise to new terms in the differential cross section proportional to the *second-class current* (SCC) form factors F_V^3 and F_A^3 . While the size of the SCC component of the CCQE cross section is limited by measurements of beta decay and related processes, a nonvanishing contribution can lead to noticeable differences in the predicted cross sections for ν_e and ν_μ [50]. Separate systematic uncertainties on the possible contributions of the F_V^3 and F_A^3 terms in the CCQE cross section are assessed for MicroBooNE analyses via a dedicated weight calculator implemented within the LArSoft software framework [51]. Event weights are evaluated based on the ratio of a CCQE differential cross section calculated using the NEUT [52] neutrino event generator (which includes the SCC form factors) and a similar one calculated with GENIE (which does not). Possible SCC effects for interaction modes other than CCQE are neglected.

C. Final-state interaction reweighting

The empirical model used in GENIE v3.0.6 G18.10a.02.11a for hadronic final-state interactions is called *hA2018* and represents an updated version of the historical default treatment *hA* used in GENIE v2 [18, 53]. An *effective cascade* approach is employed: each hadron emerging from the primary neutrino interaction vertex may rescatter a maximum of one time inside the nucleus, and the specific reinteraction mode (charge exchange, inelastic, etc.) is sampled using ratios of energy- and A -dependent cross sections. The *hA* FSI models are specifically designed to allow for straightforward uncertainty quantification via reweighting. A key feature of the reweighting strategy is the *unitarity constraint*. Each change is balanced by changes in other channels to make the overall fraction of events affected by FSI constant. Thus, all inclusive event distributions (i.e., those that are not sensitive to final hadron multiplicities and kinematics) are expected to be invariant under FSI model variations [54].

Internal validations of the “MicroBooNE Tune” revealed some minor inconsistencies in the *hA2018* reweighting tools included with GENIE v3.0.6. These lead to violations of the aforementioned unitarity constraint and thus to potentially inaccurate model uncertainties. The specific issues identified in the weight cal-

culators are (1) the elastic scattering reinteraction mode was removed from the FSI model in the hA \rightarrow hA2018 update, but this change is not fully applied in GENIE Reweight; (2) the model parameters and hadron starting positions used to calculate mean free paths in Reweight are not completely identical to those used during event generation; and (3) the mass number (A) and proton number (Z) of the nucleus are not updated to account for prior knockout when reweighting events with multiple primary hadrons. Studies performed by all current MicroBooNE low-energy excess analyses indicate that these problems have a negligible impact on the final results.

D. Systematics budget

Table V summarizes the ways in which the neutrino interaction model and uncertainties used by MicroBooNE analyses differ from the default GENIE v3.0.6 G18_10a_02_11a configuration. These differences fall into two categories: CCQE and CC2p2h parameters that were tuned as described in this article (and therefore have different central values and uncertainties from the default recommendation), and new parameters developed by MicroBooNE for the evaluation of additional model uncertainties. For completeness, a full list of parameters for which MicroBooNE analyses adopt the GENIE recommendations unaltered is given in Appendix A.

E. “MicroBooNE Tune” Total Cross Sections with Uncertainties

The electron-like LEE searches in MicroBooNE will search specifically for electron neutrino interactions. Therefore it is important to also examine the impact of the “MicroBooNE Tune” on the ν_e CC cross section. The modeling of electron and muon neutrinos in GENIE uses the same underlying model parameters, such that the tune – while derived from fitting to muon-neutrino cross-section data – is also applied to the electron neutrino prediction, with uncertainties as previously described. The top (bottom) panel of Fig. 15 shows predictions for the total charged-current cross section for electron (muon) neutrino-argon scattering obtained using the results of our tuning procedure and full treatment of systematic uncertainties. This is plotted as a black line as a function of neutrino energy in the region below 1 GeV where our tune has the largest impact. The gray band indicates the full one-sigma uncertainty for the MicroBooNE standard analysis on the cross-section prediction. A comparison is made to the GENIE v3.0.6 G18_10a_02_11a model used as the basis for the tune (dashed blue) and the historical default model from GENIE v2.12.2 (dot-dashed pink). The most significant changes from GENIE v3.0.6 to the new fit come at neutrino energies below 600 MeV.

Parameter	“MicroBooNE Tune”		
	Central value	+1 σ	-1 σ
MaCCQE ^a	1.10 GeV	+0.1 GeV	-0.1 GeV
RPA_CCQE ^b	85%	+40%	-40%
NormCCMEC	166%	+50%	-50%
XSecShape_CCMEC	Empirical ^c	N/A	Valencia ^d
Coulomb_CCQE	Nominal	+30%	-30%
DecayAngMEC	Isotropic	Alternative ^e	N/A

FracDelta_CCMEC	Valencia	+30%	-30%
NormNCMEC	Nominal	+100%	-100%
ThetaDelta2NRad	Isotropic	Alternative ^e	N/A
NormCCCOH	Nominal	+100%	-100%
NormNCCOH	Nominal	+100%	-100%

^a The GENIE default value for this parameter is 0.961242 ± 0.03 GeV

^b Variations are not capped at 100%

^c Nominal prediction of the GENIE Empirical CC 2p2h model

^d Nominal prediction of the Valencia CC 2p2h model

^e An angular distribution proportional to $\cos^2 \theta$. See the description of this parameter in Sec. V A

TABLE V. Summary of parameters for which MicroBooNE analyses adopt a different central value and/or uncertainty than recommended in the GENIE v3.0.6 G18_10a_02_11a model set.

VI. SUMMARY AND CONCLUSIONS

This paper introduces a new tune of the GENIE event generator [5] that is suitable for MicroBooNE LEE and cross section analyses. New parameters designed to focus on the most uncertain parts of existing models within GENIE were developed for this purpose.

The T2K inclusive CC0 π data [9] was the basis for this fit for a variety of reasons. Since there was a strong desire to make this underlying model independent of MicroBooNE data, no internal data was used in the fit. In addition, MiniBooNE data was excluded from the fit to avoid use of a data set that used the same neutrino beam as MicroBooNE. However, the MiniBooNE CC0 π data [17] was used as a consistency check.

The GENIE G18_10a model set was chosen as the basis for the fit because it provides the best description of data in this kinematic region among available GENIE configurations. It includes the local Fermi gas momentum distribution and the Valencia CCQE [7] and CC2p2h [8] models as implemented in GENIE v3.0.6. As discussed in the text, the implementation in GENIE was somewhat different than what was used in comparisons [6] to Mini-

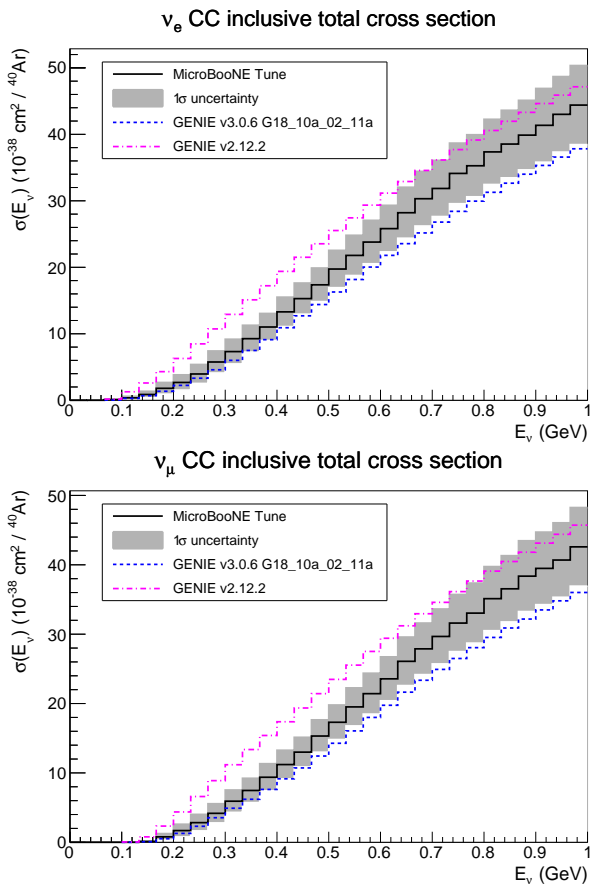

FIG. 15. Predictions from the “MicroBooNE Tune” for the CC inclusive total cross section for electron (top) and muon (bottom) neutrino-argon scattering.

BooNE data [17].

Parameters for fitting were chosen according to relevance to the MicroBooNE data and the level of theoretical understanding: the CCQE axial mass, the strength of RPA corrections, the normalization of the CC2p2h cross section, and the shape of the CC2p2h cross section. In particular, CC2p2h and RPA modeling show significant variation among theoretical calculations [1].

When these parameters were fit to T2K CC0 π data, both the CCQE normalization and the CC2p2h normalization was increased. The CC2p2h shape parameter had a weak preference for the one-peak (Empirical) shape which is traditional in electron scattering modeling. This sensitivity to CC2p2h shape was not apparent in previous calculations [6]. Although there is a preference for a large RPA contribution as in the Valencia CCQE model [7], the constraint is not strong. The final fit is shown in Fig. 9 with the parameter correlations in Fig. 8.

The interpretation of these fit results should be carefully considered. The fit parameter values only make sense in the context of the modelling parameters and data set used. Given the small number of parameters used, the results indicate directions rather than an ac-

tual measurement.

The result of the “MicroBooNE Tune” is a reduction in the T2K data-simulation χ^2 agreement by a factor of 2, with better agreement in both normalization and shape. Although the final fit parameters also produce a better fit to the MiniBooNE data than GENIE v3.0.6, it is not a good match to those results. The biggest discrepancies come at the lowest muon momenta. Within the confines of the model used, we find that the T2K and MiniBooNE data sets are incompatible.

Nevertheless, the primary goal of producing a parameterization of relevant muon neutrino cross section data has been achieved. This results in an overall improvement for the description of MicroBooNE data as discussed in Sec. IV A. Since the same models are used for muon and electron neutrino CCQE and CC2p2h interactions, this information applies to both flavors and will provide a solid basis for MicroBooNE’s searches for physics beyond the Standard Model using electron neutrinos. In addition, the accuracy of the dependence on nucleus (A -dependence) within GENIE has been demonstrated. This work will also provide the basis for further studies of MicroBooNE cross sections [25, 26, 44] and other [14] data for heavier targets in the future.

The uncertainty band derived from this work is as important as, perhaps even more-so than, the central-value prediction. The cross-section model can be further constrained experimentally through use of background-enriched and sideband samples, but those procedures rely on a well-motivated quantification of systematic uncertainties in order to work effectively. In particular, this work motivates new uncertainties on parameters for which we previously had no or extremely weak prior uncertainties such as the strength of RPA corrections and the modeling of CC 2p2h interactions.

VII. ACKNOWLEDGEMENTS

This document was prepared by the MicroBooNE collaboration using the resources of the Fermi National Accelerator Laboratory (Fermilab), a U.S. Department of Energy, Office of Science, HEP User Facility. Fermilab is managed by Fermi Research Alliance, LLC (FRA), acting under Contract No. DE-AC02-07CH11359. MicroBooNE is supported by the following: the U.S. Department of Energy, Office of Science, Offices of High Energy Physics and Nuclear Physics; the U.S. National Science Foundation; the Swiss National Science Foundation; the Science and Technology Facilities Council (STFC), part of the United Kingdom Research and Innovation; the Royal Society (United Kingdom); and The European Union’s Horizon 2020 Marie Skłodowska-Curie Actions. Additional support for the laser calibration system and cosmic ray tagger was provided by the Albert Einstein Center for Fundamental Physics, Bern, Switzerland. We also acknowledge the contributions of technical and scientific staff to the design, construction, and operation

of the MicroBooNE detector as well as the contributions of past collaborators to the development of MicroBooNE analyses, without whom this work would not have been possible.

Appendix A: List of Parameters and Uncertainties

Table VI lists all model parameters from GENIE v3.0.6 G18_10a_02_11a for which the central value and uncertainty are adopted unaltered as part of the “MicroBooNE Tune” described in this paper. Parameters which have been added or altered by MicroBooNE are listed separately in Table V.
