An FD that would look down on the earth's atmosphere from space orbit to view a much larger area than ground based instruments is an active area of R&D. Prototypes that have been built and flown in orbit include the pioneering TUS instrument [24], [25] operated 2016-2018 onboard the Lomonosov satellite. The JEM-EUSO collabration has flown prototype FD telescopes on two stratospheric balloon flights [26] and [27] with a third in preparation. The Mini-EUSO [28] FD is recording terrestial UV emission by looking down through a 25 cm diameter UV window from inside the International Space Station. The Probe of Extreme Multimessenger Astrophysics (POEMMA) project has completed a detailed conceptual design study for a twin-satellite mission [29] that would observe UHECRs and PeV scale cosmogenic tau neutrinos.

36.2.2 *Atmospheric Cherenkov telescopes for high-energy gamma ray astronomy*

Revised August 2019 by J. Holder (Delaware U.; Delaware U., Bartol Inst.).

A wide variety of astrophysical objects are now known to produce high-energy γ-ray photons. Leptonic or hadronic particles, accelerated to relativistic energies in the source, produce γ-rays typically through inverse Compton boosting of ambient photons or through the decay of neutral pions produced in hadronic interactions. At energies below ∼30 GeV, γ-ray emission can be efficiently detected using satellite or balloon-borne instrumentation, with an effective area approximately equal to the size of the detector (typically < 1 m^2). At higher energies, a technique with much larger effective collection area is desirable to measure astrophysical γ-ray fluxes, which decrease rapidly with increasing energy. Atmospheric Cherenkov detectors achieve effective collection areas of $>10^5$ m^2 by employing the Earth's atmosphere as an intrinsic part of the detection technique.

As described in Chapter 30, a hadronic cosmic ray or high energy γ-ray incident on the Earth's atmosphere triggers a particle cascade, or air shower. Relativistic charged particles in the cascade generate Cherenkov radiation, which is emitted along the shower direction, resulting in a light pool on the ground with a radius of ∼130 m. Cherenkov light is produced throughout the cascade development, with the maximum emission occurring when the number of particles in the cascade is largest, at an altitude of ∼10 km for primary energies of 100 GeV–1 TeV. Following absorption and scattering in the atmosphere, the Cherenkov light at ground level peaks at a wavelength, $\lambda \approx 300$–350 nm. The photon density is typically ∼100 photons/m^2 for a 1 TeV primary, arriving in a brief flash of a few nanoseconds duration. This Cherenkov pulse can be detected from any point within the light pool radius by using large reflecting surfaces to focus the Cherenkov light on to fast photon detectors (Fig. 36.4).

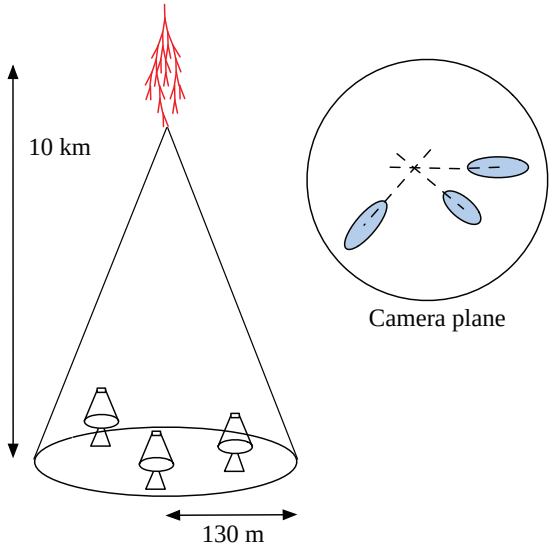

Figure 36.4: A schematic illustration of an imaging atmospheric Cherenkov telescope array. The primary particle initiates an air shower, resulting in a cone of Cherenkov radiation. Telescopes within the Cherenkov light pool record elliptical images; the intersection of the long axes of these images indicates the arrival direction of the primary, and hence the location of a γ-ray source in the sky

Modern atmospheric Cherenkov telescopes, such as those built and operated by the VERITAS [30], H.E.S.S. [31] and MAGIC [32] collaborations, consist of large (> 100 m^2) segmented mirrors on steerable altitude-azimuth mounts. A camera made from an array of photosensors is placed at the focus of each mirror and used to record a Cherenkov image of each air shower. In these imaging atmospheric Cherenkov telescopes, single-anode photomultipliers tubes (PMTs) have traditionally been used (2048, in the case of H.E.S.S. II), but silicon devices now feature in more modern designs. The telescope cameras typically cover a field-of-view of $3 - 10^\circ$ in diameter. Images are recorded at kHz rates, the vast majority of which are due to showers with hadronic cosmic-ray primaries. The shape and orientation of the Cherenkov images are used to discriminate γ-ray photon events from this cosmic-ray background, and to reconstruct the photon energy and arrival direction. γ-ray images result from purely electromagnetic cascades and appear as narrow, elongated ellipses in the camera plane. The long axis of the ellipse corresponds to the vertical extension of the air shower, and points back towards the source position in the field-of-view. If multiple telescopes are used to view the same shower ("stereoscopy"), the source position is simply the intersection point of the various image axes. Cosmic-ray primaries produce secondaries with large transverse momenta, which initiate sub-showers. Their images are consequently wider and less regular than those with γ-ray primaries and, since the original charged particle has been deflected by Galactic magnetic fields before reaching the Earth, the images have no preferred orientation.

The measurable differences in Cherenkov image orientation and morphology provide the background discrimination which makes ground-based γ-ray astronomy possible. For point-like sources, such as distant active galactic nuclei, modern instruments can reject over 99.999% of the triggered cosmic-ray events, while retaining up to 50% of the γ-ray population. In the case of spatially extended sources, such as Galactic supernova remnants, the background rejection is less efficient, but the technique can be used to produce γ-ray maps of the emission from the source. The angular resolution depends upon the number of telescopes which view the

image and the energy of the primary γ-ray, but is typically less than 0.1° per event (68% containment radius) at energies above a few hundred GeV.

The total Cherenkov yield from the air shower is proportional to the energy of the primary particle. The image intensity, combined with the reconstructed distance of the shower core from each telescope, can therefore be used to estimate the primary energy. The energy resolution of this technique, also energy-dependent, is typically 15–20% at energies above a few hundred GeV. Energy spectra of γ-ray sources can be measured over a wide range, depending upon the instrument characteristics, source properties (flux, spectral slope, elevation angle, *etc.*), and exposure time. The effective energy range is typically from 30 GeV to 100 TeV and peak sensitivity lies in the range from 100 GeV to a few TeV.

The first astrophysical source to be convincingly detected using the imaging atmospheric Cherenkov technique was the Crab Nebula [33], with an integral flux of 2.1×10^{-11} photons cm^{-2} s^{-1} above 1 TeV [34]. Modern imaging atmospheric Cherenkov telescopes have sensitivity sufficient to detect sources with less than 1% of the Crab Nebula flux in a few tens of hours. The TeV source catalog now consists of over 200 sources (see e.g. Ref. [35]). A large fraction of these were detected by scanning the Galactic plane from the southern hemisphere with the H.E.S.S. telescope array [36]. Recent reviews of the field include [37] and [38], and a historical overview can be found in [39].

Major upgrades of the existing telescope arrays have recently been completed, including the addition of a 28 m diameter central telescope to H.E.S.S. (H.E.S.S. II). Development is also underway for the next generation instrument, the Cherenkov Telescope Array (CTA), which will consist of a northern and a southern hemisphere observatory, with a combined total of more than 100 telescopes [40]. Telescopes of three different sizes are planned, spread over an area of > 1 km^2, providing wider energy coverage, improved angular and energy resolutions, and an order of magnitude improvement in sensitivity relative to existing imaging atmospheric Cherenkov telescopes. Baseline telescope designs are similar to existing devices, but exploit technological developments such as dual mirror optics and silicon photo-detectors.

36.3 Large neutrino detectors

36.3.1 *Deep liquid detectors for rare processes*

Revised August 2021 by K. Scholberg (Duke U.) and C.W. Walter (Duke U.).

Deep, large detectors for rare processes tend to be multi-purpose with physics reach that includes not only solar, reactor, supernova and atmospheric neutrinos, but also searches for baryon number violation and lepton number violation, searches for exotic particles and beyond-the-standard-model physics, and neutrino and cosmic-ray astrophysics in different energy regimes. The detectors may also serve as targets for long-baseline neutrino beams for neutrino oscillation physics studies. In general, detector design considerations can be divided into high- and low-energy regimes, for which background and event reconstruction issues differ. The high-energy regime, from about 100 MeV to a few hundred GeV, is relevant for proton decay searches, atmospheric neutrinos and high-energy astrophysical neutrinos. The low-energy regime (a few tens of MeV or less) is relevant for supernova, solar, reactor and geological neutrinos.

Large water Cherenkov and scintillator detectors (see Table 36.2) usually consist of a volume of transparent liquid viewed by photomultiplier tubes (PMTs) (see Sec 35.2); the liquid serves as active target. PMT hit charges and times are recorded and digitized, and triggering is usually based on coincidence of PMT hits within a time window comparable to the detector's light-crossing time. Because photosensors lining an inner surface represent a driving cost that scales as surface area, very large volumes can be used for comparatively reasonable cost. Some detectors are segmented into subvolumes individually viewed by PMTs, and may include other detector elements (*e.g.*, tracking detectors). Devices to increase light collection, *e.g.*, reflectors or waveshifter plates, may be employed. A common configuration is to have at least one concentric outer layer of liquid material separated from the inner part of the detector to serve as shielding against ambient background. If optically separated and instrumented with PMTs, an outer layer may also serve as an active veto against entering cosmic rays and other background events. The PMTs for large detectors typically range in size from 20 cm to 51 cm diameter, and typical quantum efficiencies are in the 20–25% range for scintillation and water-Cherenkov photons. PMTs with higher quantum efficiencies, 35% or higher, have recently become available. The active liquid volume requires purification and there may be continuous recirculation of liquid. For large homogeneous detectors, the event interaction vertex is determined using relative timing of PMT hits, and energy deposition is determined from the number of recorded photoelectrons. A "fiducial volume" is usually defined within the full detector volume, some distance away from the PMT array. Inside the fiducial volume, enough PMTs are illuminated per event that reconstruction is considered reliable, and furthermore, entering background from the enclosing walls is suppressed by a buffer of self-shielding. PMT and detector optical parameters are calibrated using laser, LED, or other light sources. Quality of event reconstruction typically depends on photoelectron yield, pixelization and timing.

Because in most cases one is searching for rare events, large detectors are usually sited underground to reduce cosmic-ray-related background (see Chapter 30). The minimum depth required varies according to the physics goals [41].

36.3.1.1 *Liquid scintillator detectors*

Past and current large underground detectors based on hydrocarbon scintillators include LVD, MACRO, Baksan, Borexino, KamLAND and SNO+; JUNO is a future detector. Experiments at nuclear reactors include CHOOZ, Double CHOOZ, Daya Bay, and RENO. Organic liquid scintillators (see Section 35.3) for large detectors are chosen for high light yield and attenuation length, good stability, compatibility with other detector materials, high flash point, low toxicity, appropriate density for mechanical stability, and low cost. They may be doped with waveshifters and stabilizing agents. Popular choices are pseudocumene (1,2,4-trimethylbenzene) with a few g/L of the PPO (2,5-diphenyloxazole) fluor, and linear alkylbenzene (LAB), with light yield $\sim 10^4$ photons/MeV. In a typical detector configuration there will be active or passive regions of undoped scintillator, non-scintillating mineral oil or water surrounding the inner neutrino target volume. A thin vessel or balloon made of nylon, acrylic or other material transparent to scintillation light may contain the inner target; if the scintillator is buoyant with respect to its buffer, ropes may hold the balloon in place. For phototube surface coverages in the 20–40% range, yields in the few hundreds of photoelectrons per MeV of energy deposition can be obtained. Typical energy resolution is about $5-7\%/\sqrt{E(\mathrm{MeV})}$ [42,43], and typical position reconstruction resolution is a few tens of cm at $\sim$ 1 MeV, scaling as $\sim N^{-1/2}$, where N is the number of photoelectrons detected.

Shallow detectors for reactor neutrino oscillation experiments require excellent muon veto capabilities. For $\bar{\nu}_e$ detection via inverse beta decay on free protons, $\bar{\nu}_e + p \to n + e^+$, the neutron is captured by a proton on a $\sim$180 μs timescale, resulting in a 2.2 MeV γ ray, observable by Compton scattering and which can be used as a tag in coincidence with the positron signal. The positron annihilation γ rays may also contribute. Inverse beta decay tagging may be improved by addition of Gd at $\sim$0.1% by mass, which for natural isotope abundance has a $\sim$49,000 barn cross-section for neutron capture (in contrast to the 0.3 barn cross-section for capture on free protons). Gd capture takes $\sim$30 μs, and is followed by a cascade of γ rays adding up to about 8 MeV. Gadolinium doping of scintillator requires specialized formulation to ensure adequate attenuation length and stability.

Scintillation detectors have an advantage over water Cherenkov detectors in the lack of Cherenkov threshold and the high light yield. However, scintillation light emission is nearly isotropic, and therefore directional capabilities are relatively weak. Liquid scintillator is especially suitable for detection of low-energy events. Radioactive backgrounds are a serious issue, and include long-lived cosmogenics such as ^{14}C. To go below a few MeV, very

Table 36.2: Properties of large detectors for rare processes. If total target mass is divided into large submodules, the number of subdetectors is indicated in parentheses. Projects with first data expected in 2023 or later are indicated in italics.

†Measurements made before 2003 only considered data from the 43 cm PMTs.
‡SNO+ ran with water fill from May 2017 to July 2019.
§The effective Daya Bay coverage is 12% with top and bottom reflectors.
¶The effective Kamiokande III coverage was 25% with light collectors.
‖A second staged module is being investigated.
**Additional photosensor modules and PMTs are planned.
††The effective SNO coverage was 54% with light collectors.
‡‡Photodetector technology and coverage varies according to TPC type and is not yet fully determined.

careful selection of materials and purification of the scintillator is required (see Section 36.6). Fiducialization and tagging can reduce background. One can also dissolve neutrinoless double beta decay ($0\nu\beta\beta$) isotopes in scintillator. This has been realized by KamLAND-Zen, which deployed a 1.5 m-radius balloon containing enriched Xe dissolved in scintillator inside KamLAND, and ^{130}Te is planned for SNO+.

36.3.1.2 *Water Cherenkov detectors*

Very large imaging water detectors reconstruct ten-meter-scale Cherenkov rings produced by charged particles (see Section 35.5). The first such large detectors were IMB and Kamiokande. The only currently existing instance of this class of detector, with fiducial mass of 22.5 kton and total mass of 50 kton, is Super-Kamiokande (Super-K, SK). Hyper-Kamiokande (Hyper-K) plans at least one, and possibly two, detectors with 187-kton fiducial mass. For volumes of this scale, absorption and scattering of Cherenkov light are non-negligible, and a wavelength-dependent factor $\exp(-d/L(\lambda))$ (where d is the distance from emission to the sensor and $L(\lambda)$ is the attenuation length of the medium) must be included in the integral of Eq. (35.6) for the photoelectron yield. Attenuation lengths on the order of 100 meters have been achieved.

Cherenkov detectors are excellent electromagnetic calorimeters, and the number of Cherenkov photons produced by an e/γ is nearly proportional to its kinetic energy. For massive particles, the number of photons produced is also related to the energy, but not linearly. For any type of particle, the *visible energy* $E_{\rm vis}$ is defined as the energy of an electron which would produce the same number of Cherenkov photons. The number of collected photoelectrons depends on the scattering and attenuation in the water along with the photo-cathode coverage, quantum efficiency and the optical parameters of any external light collection systems or protective material surrounding them. Event-by-event corrections are made for geometry and attenuation. For a typical case, in water $N_{\rm p.e.} \sim 15\,\xi\,E_{\rm vis}({\rm MeV})$, where ξ is the effective fractional photosensor coverage. Cherenkov photoelectron yield per MeV of energy is relatively small compared to that for scintillator, *e.g.*, $\sim$ 6 pe/MeV for Super-K with a PMT surface coverage of $\sim$ 40%. In spite of light yield and Cherenkov threshold issues, the intrinsic directionality of Cherenkov light allows individual particle tracks to be reconstructed. Vertex and direction fits are performed using PMT hit charges and times, requiring that the hit pattern be consistent with a Cherenkov ring.

High-energy ($\sim$100 MeV or more) neutrinos from the atmosphere or beams interact with nucleons; for the nucleons bound inside the ^{16}O nucleus, nuclear effects must be considered both at the interaction and as the particles leave the nucleus. Various event topologies, with final-state particles contained, exiting, or entering the detector, can be distinguished by their timing and fit patterns, and by presence or absence of light in a veto. At high energies, multi-photoelectron hits are likely and the charge collected by each PMT (rather than the number of PMTs firing) must be used; the energy resolution in this case is approximately $2\%/\sqrt{\xi\,E_{\rm vis}({\rm GeV})}$. The absolute energy scale in this regime can be known to $\sim$2–3% using cosmic-ray muon energy deposition, Michel electrons and π^0 from atmospheric neutrino interactions. Typical vertex resolutions for GeV energies are a few tens of cm [44]. Angular resolution for determination of the direction of a charged particle track is a few degrees. For a neutrino interaction, because some final-state particles are usually below Cherenkov threshold, knowledge of direction of the incoming neutrino direction itself is generally worse than that of the lepton direction, and dependent on neutrino energy.

Multiple particles in an interaction (so long as they are above Cherenkov threshold) may be reconstructed, allowing for the exclusive reconstruction of final states. In searches for proton decay,

multiple particles can be kinematically reconstructed to form a decaying nucleon. High-quality particle identification is also possible: γ rays and electrons shower, and electrons scatter, which results in fuzzy rings, whereas muons, pions and protons make sharp rings. These patterns can be quantitatively separated with high reliability using maximum likelihood methods [45]. Sources of background for high energy interactions include misidentified cosmic muons and anomalous light patterns when the PMTs sometimes "flash" and emit photons themselves. The latter class of events can be removed using its distinctive PMT signal patterns, which may be repeated. More information about high energy event selection and reconstruction may be found in reference [46].

In spite of the fairly low light yield, large water Cherenkov detectors may be employed for reconstructing low-energy events, down to *e.g.* $\sim$ 4-5 MeV for Super-K [47]. Low-energy neutrino interactions of solar neutrinos in water are predominantly elastic scattering off atomic electrons; single electron events are then reconstructed. At solar neutrino energies, the visible energy resolution ($\sim 30\%/\sqrt{\xi\, E_{\rm vis}(\mathrm{MeV})}$) is about 20% worse than photoelectron counting statistics would imply. Using an electron LINAC and/or nuclear sources, approximately 0.5% determination of the absolute energy scale has been achieved at solar neutrino energies. Angular resolution is limited by multiple scattering in this energy regime (25–30°). At these energies, radioactive backgrounds become a dominant issue. These backgrounds include radon in the water itself or emanated from detector materials, and γ rays from the rock and detector materials. In the few to few tens of MeV range, radioactive products of cosmic-ray-muon-induced spallation are troublesome, and are removed by proximity in time and space to preceding muons, at some cost in dead time. Gadolinium doping using 0.2% $Gd_2(SO_4)_3$ has now been initiated for Super-K to improve selection of low-energy $\bar{\nu}_e$ and other events with accompanying neutrons [48].

The Sudbury Neutrino Observatory (SNO) detector [49] is the only instance of a large heavy water detector. In addition to an outer 1.7 kton of light water, SNO contained 1 kton of D_2O, giving it unique sensitivity to neutrino neutral current ($\nu_x + d \to \nu_x + p + n$), and charged current ($\nu_e + d \to p + p + e^-$) deuteron breakup reactions. The neutrons were detected in three ways: via capture on deuterons, via capture on dissolved ^{35}Cl, and via specialized ^{3}He counters.

36.3.1.3 *Noble liquid detectors*

Noble liquids scintillate and can be used as the active medium for particle detection. Detectors employing argon and xenon are also used as time-projection chambers (TPCs), either as dual-phase low-energy recoil detectors, or as track-imaging detectors. Noble-liquid detectors with low energy (few to few tens of keV) capability for detecting electronic and nuclear recoils are employed for dark matter and other rare event searches and are described in Sec. 36.4. These detectors can also be employed for some of the same physics (baryon number violation, astrophysical neutrino transient searches, etc.) as for the other large detectors described here, especially as they approach tens of ton scale and higher (e.g., DARWIN, DarkSide-20, ARGO). Track-imaging time-projection chambers, which are described in detail Section 36.4, have a dynamic range reaching down to the few to few tens of MeV scale, enabling sensitivity to e.g., solar and supernova burst neutrinos. Surface LArTPCs have significant cosmic backgrounds, but may still have sensitivity to astrophysical transients such as supernova burst neutrinos. DUNE will be sufficiently deep to have sensitivity to steady-state low-energy neutrino sources such as solar neutrinos.

36.3.2 *Neutrino telescopes*

Revised November 2021 by U.F. Katz (Erlangen U.) and C. Spiering (DESY, Zeuthen).

The primary goal of neutrino telescopes (NTs) is the detection of astrophysical neutrinos, in particular those which are expected to accompany the production of high-energy cosmic rays in astrophysical accelerators. NTs in addition address a variety of other fundamental physics issues like the indirect search for dark matter, studies of neutrino oscillations, searches for exotic particles like magnetic monopoles or study of cosmic rays and their interactions [50–52]. Electromagnetic radio frequency detectors for high energy neutrinos are discussed in "Radio emission from (ultra-) high energy particle showers" section 36.3.3.

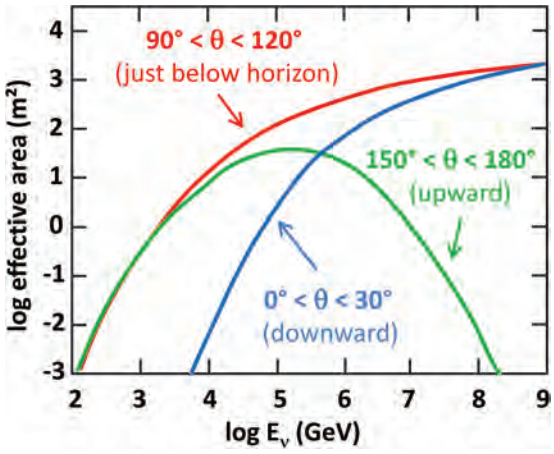

Figure 36.5: Average over the effective ν_μ and $\bar{\nu}_\mu$ areas for IceCube as an example of a cubic-kilometre NT, as a function of neutrino energy for three intervals of the zenith angle θ. The values shown here correspond to a specific event selection for point source searches.

NTs are large-volume arrays of "optical modules" (OMs) installed in open transparent media like water or ice, at depths that completely block the daylight. The OMs are sensitive to individual photons of the Cherenkov light induced by charged secondary particles produced in reactions of high-energy neutrinos in or around the instrumented volume. The time of photon-induced signals ("hits") is registered with a precision of a few nanoseconds. The neutrino energy, E_ν, and direction can be reconstructed from the hit pattern recorded. NTs typically target an energy range $E_\nu \gtrsim 100\,\mathrm{GeV}$; sensitivity to lower energies is achieved in dedicated setups with denser instrumentation.

In detecting cosmic neutrinos, three sources of backgrounds have to be considered: (i) *atmospheric neutrinos* from cosmic-ray interactions in the atmosphere, which can be separated from cosmic neutrinos on a statistical basis, or, for down-going neutrinos, by vetoing accompanying muons; (ii) down-going punch-through *atmospheric muons* from cosmic-ray interactions, which are suppressed by several orders of magnitude with respect to the ground level due to the large detector depths and can be further reduced by selecting upward-going or high-energy neutrinos or by self-veto methods; (iii) random backgrounds due to photomultiplier (PMT) dark counts, ^{40}K decays (mainly in sea water) or bioluminescence (only water). Note that atmospheric neutrinos and muons allow for investigating neutrino oscillations and cosmic ray anisotropies, respectively.

In the last decade, it has become obvious that a precise measurement of the energy-zenith-distribution of atmospheric neutrinos in the energy range from a few to about 100 GeV may allow for determining the neutrino mass hierarchy by exploiting matter-induced oscillation effects in the Earth [53, 54].

Neutrinos can interact with target nucleons N through charged current ($\overset{(-)}{\nu}_\ell N \to \ell^\mp X$, CC) or neutral current ($\overset{(-)}{\nu}_\ell N \to \overset{(-)}{\nu}_\ell X$, NC) processes. A CC reaction of a $\overset{(-)}{\nu}_\mu$ produces a muon track and a hadronic particle cascade, whereas all NC reactions and CC reactions of $\overset{(-)}{\nu}_e$ produce particle cascades only. CC interactions of $\overset{(-)}{\nu}_\tau$ can have either signature, depending on the τ decay mode. Of particular interest is the so-called double-bang signature, where the τ decays sufficiently far away from the primary interaction to create a second, distinguishable cascade (typically at PeV energies and above). In most astrophysical models, neutrinos are expected to be produced through the $\pi/K \to \mu \to e$ decay chain, *i.e.*, with a flavour ratio $\nu_e : \nu_\mu : \nu_\tau \approx 1 : 2 : 0$. For sources outside the solar system, neutrino oscillations turn this ratio to $\nu_e : \nu_\mu : \nu_\tau \approx 1 : 1 : 1$ upon arrival on Earth.

The total neutrino-nucleon cross section is about $10^{-34}\,\mathrm{cm}^2$ at $E_\nu = 20\,\mathrm{TeV}$ and rises roughly linearly with E_ν below this energy and as $E_\nu^{0.3-0.5}$ above, flattening out towards high energies. The CC:NC cross-section ratio is about 2:1. At energies above several TeV, neutrino absorption in the Earth becomes noticeable; for vertically upward-moving neutrinos (zenith angle $\theta = 180°$), the survival probability is $74\,(27, < 2)\%$ for $10\,(100, 1000)\,\mathrm{TeV}$. The energy transferred to the final-state lepton varies between 0 and 100% of E_ν, with a mean of 50% (65%) for neutrinos (antineutrinos) at 100 GeV and 75% for both neutrinos and antineutrinos at 10 PeV.

The final-state lepton follows the initial (anti)neutrino direction with an average mismatch angle of about $\langle\phi_{\nu\ell}\rangle \approx 1°/(E_\nu/\mathrm{TeV})^{0.55}$, with a steeper decrease beyond 10 TeV, reaching 0.005° at 1 PeV [55]. These values indicate the intrinsic kinematic limit to the angular resolution of NTs. For CC $\overset{(-)}{\nu}_\mu$ reactions at energies above about 10 TeV, the angular resolution is dominated by the muon reconstruction accuracy of a few times 0.1° at most. For muon energies $E_\mu \gtrsim 1\,\mathrm{TeV}$, the increasing light emission due to radiative processes allows for reconstructing E_μ from the measured Cherenkov light intensity with an accuracy of $\sigma(\log E_\mu) \approx 0.3$; at lower energies, E_μ can be estimated from the length of the muon track if it is contained in the detector. These properties make CC $\overset{(-)}{\nu}_\mu$ reactions the prime channel for the identification of individual astrophysical neutrino sources.

Hadronic and electromagnetic particle cascades at the relevant energies are 5–20 m long, *i.e.*, short compared to typical OM spacings. The total amount of Cherenkov light provides a direct measurement of the cascade energy with an accuracy of about 20% at energies above 10 TeV and 10% beyond 100 TeV for events contained in the instrumented volume. Except for double-bang events, the neutrino flavour and reaction mechanism can, however, be determined on a statistical basis at best, and neutrinos from NC reactions or τ decays may carry away significant "invisible" energy. Above 100 TeV, the average directional reconstruction accuracy of cascades is better than 10 (2) degrees in polar ice (sea water), the difference being due to the inhomogeneity of the ice and stronger light scattering in ice. These features, together with the small background of atmospheric $\overset{(-)}{\nu}_e$ and $\overset{(-)}{\nu}_\tau$ events, makes the cascade channel particularly interesting for searches for a diffuse, high-energy excess of extraterrestrial over atmospheric neutrinos. Cascade events can also be used to complement the muon channel in searches for point sources or transient signals, albeit with inferior angular accuracy compared to muon tracks.

The detection efficiency of a NT is quantified by its effective area, *e.g.*, the fictitious area for which the full incoming neutrino flux would be recorded (see Figure 36.5). The increase with E_ν is due to the rise of neutrino cross section and muon range, while neutrino absorption in the Earth causes the decrease at large θ for large E_ν. Identification of downward-going neutrinos requires strong cuts against atmospheric muons, hence the cut-off towards low E_ν at low θ. Due to the small cross section, the effective area is many orders of magnitude smaller than the geometrical dimension of the detector; a $\overset{(-)}{\nu}_\mu$ with 1 TeV can, *e.g.*, be detected with a probability of the order 10^{-6} if the NT is on its path.

Due to the long muon range, CC interactions of up-going $\overset{(-)}{\nu}_\mu$ can be detected from far outside the instrumented volume. This method also works for horizontal neutrinos up to about 10° above the horizon (depth dependent), where the background from atmospheric muons become prohibitive. Alternatively, one can select events that start inside the instrumented volume and thus remove incoming muons that generate early hits in the outer layers of the detector. Such a veto-based event selection is sensitive to neutrinos of all flavours from all directions, albeit with a reduced efficiency since a part of the instrumented volume is sacrificed for the veto. Such a muon veto, or vetoing events with a coincident signal in the surface array, also rejects down-going atmospheric neutrinos that are accompanied by muons from the same air shower and thus reduces the atmospheric-neutrino background. Actually, the breakthrough in detecting high-energy cosmic neutrinos was first achieved with this technique.

Note that the fields of view of NTs at the South Pole and in the Northern hemisphere are complementary for each reaction channel and neutrino energy.

36.3.2.1 *The Projects*

Table 36.3 lists past, present and future neutrino telescope projects and their main parameters.

36.3.2.2 *Properties of media*

The efficiency and quality of event reconstruction depend strongly on the optical properties (absorption and scattering length, intrinsic optical activity) of the medium in the spectral range of bialkali photocathodes (300–550 nm). Large absorption lengths result in a better light collection, large scattering lengths in superior angular resolution. Deep-sea sites typically have effective scattering lengths of $> 100\,\mathrm{m}$ and, at their peak transparency around 450 nm, absorption lengths of 50–65 m. The absorption length for Lake Baikal is 22–24 m. The properties of South Polar ice vary strongly with depth; at the peak transparency wave length (400 nm), the scattering length is between 5 and 75 m and the absorption length between 15 and 250 m, with the best values in the depth region 2200–2450 m and the worst ones in the layer 1950–2100 m.

Noise rates measured by PMTs with a diameter of 25 cm in deep polar ice are about 0.5 kHz per PMT and almost entirely due to radioactivity in the OM components. The corresponding rates in sea water are typically 60 kHz, mostly due to ^{40}K decays. Bioluminescence activity can locally cause rates on the MHz scale for seconds; the frequency and intensity of such "bursts" depends strongly on the sea current, the season, the geographic location, and the geometry of the detector elements. Experience from ANTARES shows that these backgrounds are manageable without a major loss of efficiency or experimental resolution.

36.3.2.3 *Technical realisation*

Optical modules (OMs) and PMTs: An OM is a pressure-tight glass sphere housing one or several PMTs with a time resolution in the nanosecond range, and in most cases also electronics for control, HV generation, operation of calibration LEDs, time synchronisation and signal digitisation.

Hybrid PMTs with 37 cm diameter have been used for NT-200, conventional hemispheric PMTs with 20 cm diameter for AMANDA and with 25 cm diameter for ANTARES, IceCube and Baikal-GVD. A novel concept has been chosen for KM3NeT. Each OM (43 cm) is equipped with 31 PMTs (7.5 cm), plus control, calibration and digitisation electronics. Advantages are that (i) the overall photocathode area exceeds that of a 25 cm PMT by more than a factor of 3; (ii) the individual readout of the PMTs results in a very good separation between one- and two-photoelectron signals which is essential for online data filtering and random background suppression; (iii) the hit pattern on an OM provides directional information; (iv) no mu-metal shielding against the Earth magnetic field is required. Figure 36.6 shows the OM designs of IceCube and KM3NeT.

Readout and data filtering: In current NTs the PMT data are digitised in situ: for ANTARES and Baikal-GVD in special electronics containers close to the OMs, for IceCube and KM3NeT inside the OMs. For IceCube, data are transmitted via electrical cables of up to 3.3 km length, depending on the location of the strings and the depth of the OMs; for ANTARES, KM3NeT and Baikal-GVD optical fibre connections have been chosen (several 10 km for the first two and 4 km for GVD).

The full digitised waveforms of the IceCube OMs are transmitted to the surface for pulses appearing in local coincidences on a string; for other pulses, only time and charge information is provided. For ANTARES (time and charge) and KM3NeT (time and time over threshold), all PMT signals above an adjustable threshold are sent to shore.

The raw data are subsequently processed on online computer farms, where multiplicity- and topology-driven filter algorithms are applied to select event candidates. The filter output data rate is about 10 GByte/day for ANTARES and of the order 1 TByte/day for IceCube (100 GByte/day transferred via satellite) and KM3NeT.

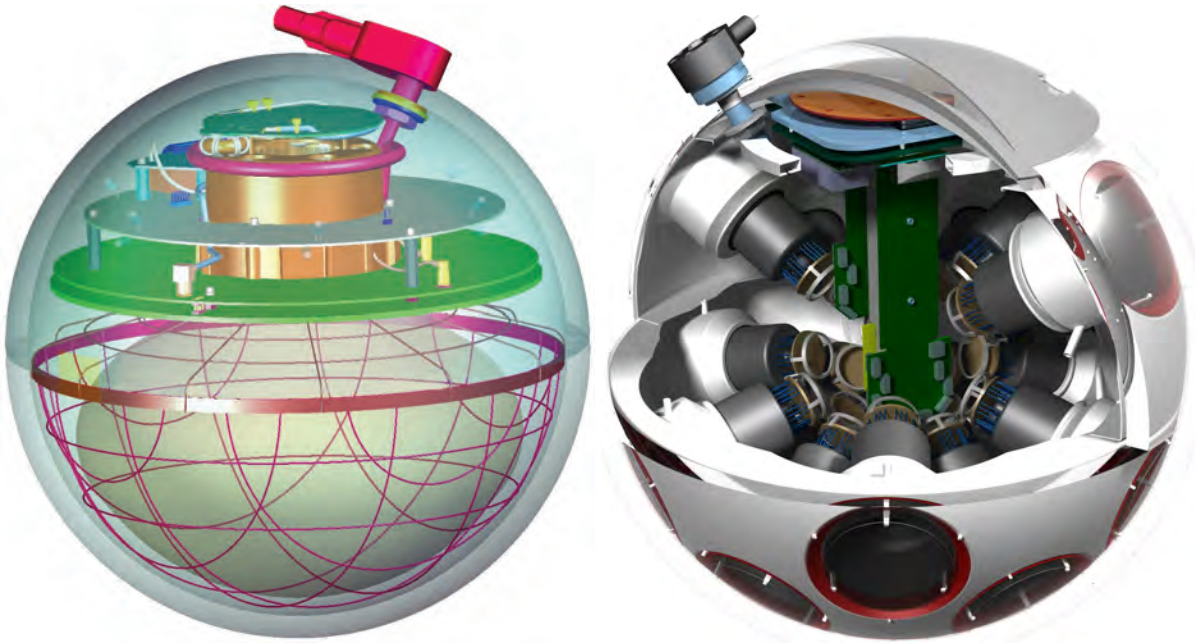

Figure 36.6: Schematic views of the digital OMs of IceCube (left) and KM3NeT (right).

Table 36.3: Past, present and future NT projects and their main parameters. The milestone years give the times of project start, of first data taking with partial configurations, of detector completion, and of project termination. Projects with first data expected past 2022 are indicated in italics. The size refers to the largest instrumented volume reached during the project development. See [52] for references to the different projects where unspecified.

Experiment	Milestones	Location	Size (km^3)	Remarks
DUMAND	1978/–/–/1995	Pacific Ocean		Terminated due to technical/funding problems
NT-200	1980/1993/1998/2015	Lake Baikal	10^{-4}	First proof of principle
GVD [56]	2012/2015/–/–	Lake Baikal	0.5–1.5	High-energy ν astronomy first 8 clusters installed
NESTOR	1991/–/–/–	Med. Sea		2004 data taking with prototype
NEMO	1998/–/–/–	Med. Sea		R&D project, prototype tests
AMANDA	1990/1996/2000/2009	South Pole	0.015	First deep-ice NT
ANTARES	1997/2006/2008/–	Med. Sea	0.010	First deep-sea NT
IceCube [57]	2001/2005/2010/–	South Pole	1.0	First km^3-sized detector

P-ONE [60]	2018/–/–/–	Pacific Ocean	$\mathcal{O}(1)$	Possible future NT, R&D phase

Calibration: For efficient event recognition and reconstruction, the OM timing must be synchronised at the few-nanosecond level and the OM positions and orientations must be known to a few 10 cm and a few degrees, respectively. Time calibration is achieved by sending time synchronisation signals to the OM electronics and also by light calibration signals emitted in situ at known times by LED or laser flashers (ANTARES, KM3NeT). Precise position calibration is achieved by measuring the travel time of light calibration signals sent from OM to OM (IceCube) or acoustic signals sent from transducers at the sea floor to receivers on the detector strings (ANTARES, KM3NeT, Baikal-GVD). Absolute pointing and angular resolution can be determined by measuring the "shadow of the moon" (*i.e.*, the directional depletion of muons generated in cosmic-ray interactions). IceCube and ANTARES have both shown that they have angular resolution below 1°, confirming MC calculations which indicate a precision of $\approx 0.5°$ for energies above 10 TeV. For KM3NeT, simulations indicate that sub-degree precision in the absolute pointing can be

reached within a few weeks of operation.

Detector configurations: IceCube [57] (see Figure 36.7) consists of 5160 Digital OMs (DOMs) installed on 86 strings at depths of 1450 to 2450 m in the Antarctic ice; except for the DeepCore region, string distances are 125 m and vertical distances between OMs 17 m. 324 further DOMs are installed in IceTop, an array of detector stations on the ice surface above the strings. DeepCore is a high-density sub-array at large depths (*i.e.*, in the best ice layer) at the centre of IceCube.

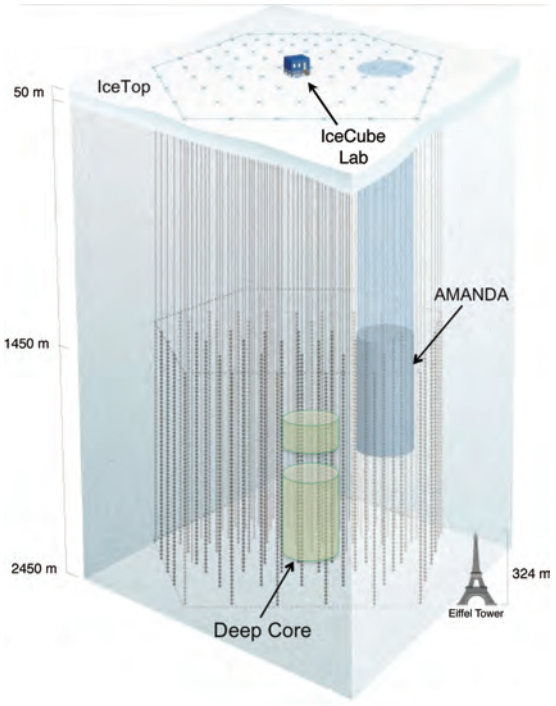

Figure 36.7: Schematic view of the IceCube neutrino observatory comprising the deep-ice detector including its nested dense part DeepCore, and the surface air shower array IceTop. The IceCube Lab houses data acquisition electronics and the computer farm for online processing. Operation of AMANDA was terminated in 2009.

The NT200 detector in Lake Baikal at a depth of 1100 m consisted of 8 strings attached to an umbrella-like frame, with 12 pairs of OMs per string. The diameter of the instrumented volume was 42 m, its height 70 m. Meanwhile (2021), the Baikal collaboration has installed the first eight clusters of a future cubic-kilometre array, GVD [56]. A first phase, covering a volume of about 0.7 km^3, will consist of 14 clusters, each with 288 OMs at 8 strings; its completion is scheduled for 2024. A next stage could cover up to 1.5 km^3.

ANTARES (see [52] and references therein) comprises 12 strings with lateral distances of 60–70 m, each carrying 25 triplets of OMs at vertical distances of 14.5 m. The OMs are located at depths of 2.1–2.4 km, starting 100 m above the sea floor. An additional string holds devices for calibration and environmental monitoring. A system to investigate the feasibility of acoustic neutrino detection has also been implemented.

KM3NeT will consist of building blocks of 115 strings each, with 18 OMs per string. Operation of prototypes and the first strings deployed have successfully verified the KM3NeT technology [61]. In the upcoming phase 2.0 of its staged implementation, KM3NeT aims at two building blocks for neutrino astronomy, with vertical distances between OMs of 36 m and a lateral distance between adjacent strings of 90 m (ARCA, for *Astroparticle Research with Cosmics in the Abyss*) and at one block for the measurement of the neutrino mass hierarchy, with vertical distances between OMs of 9 m and a lateral distance between adjacent strings of about 20 m (ORCA, for *Oscillation Research with Cosmics in the Abyss*) [54]. The installation of ARCA near Capo Passero, East of Sicily (depth 3440 m) and of ORCA near Toulon (depth 2450 m) is ongoing and as of now (August 2021) for each of both six strings have been deployed and are continuously operated. Completion of the full ARCA (ORCA) arrays is planned for 2026 (2025). The possibility of directing a neutrino beam from the Protvino accelerator to ORCA (P2O) is also under study [62].

P-ONE (*Pacific Ocean Neutrino Experiment*) [60] is a new initiative in an early R&D phase, envisaging a large NT in the Pacific Ocean off the Canadian coast. It is intended to use an existing deep-sea cable infrastructure and to optimise the sensitivity for horizontal neutrinos with energies of about 100 TeV and beyond.

36.3.2.4 *Results*

Atmospheric neutrino fluxes have been precisely measured with AMANDA ($\overline{\nu}_\mu$), with IceCube and ANTARES ($\overline{\nu}_\mu$, $\overline{\nu}_e$) and have recently also been detected with KM3NeT ($\overline{\nu}_\mu$); the results are in agreement with predicted spectra.

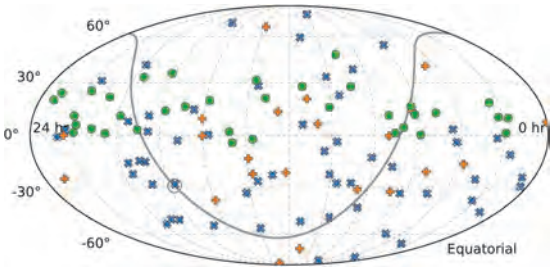

Figure 36.8: Arrival directions of IceCube candidate events for cosmic neutrinos in equatorial coordinates. The plot contains 82 HESE events, with shower-like events marked as blue × and muon tracks as orange +, and in addition 36 through-going muons tracks with an energy deposit exceeding 200 TeV (green circles). Approximately 40% of the events are expected to originate from atmospheric backgrounds. The grey curve denotes the Galactic Plane and the grey circle the Galactic Centre (from [63]).

In 2013, an excess of track and cascade events between 30 TeV and 1 PeV above background expectations was reported by IceCube; this analysis used the data taken in 2010 and 2011 and for the first time employed containment conditions and an atmospheric muon veto for suppression of down-going atmospheric neutrinos (High-Energy Starting Event analysis, HESE). The observed excess reached a significance of 5.7σ in a subsequent analysis of 3 years of data [64] and increased in significance since then. The excess is therefore interpreted to be due to an astrophysical neutrino flux. A consistent observation has also been made by ANTARES [65], albeit with much lower significance. The skymap of HESE and high-energy through-going muon events (see Figure 36.8) does not indicate statistically significant event clusters, nor deviations from an isotropic cosmic neutrino flux. Meanwhile the energy range of IceCube analyses has been extended down to about 10 TeV and the high-energy excess confirmed; also, events with through-going muons showed a corresponding excess of cosmic origin. In [66], the various analyses have been combined. Assuming the cosmic neutrino flux to be isotropic, flavour-symmetric and ν-$\overline{\nu}$-symmetric at Earth, the all-flavour spectrum is well described by a power law with normalisation $6.7^{+1.1}_{-1.2} \times 10^{-18}\,\mathrm{GeV}^{-1}\mathrm{s}^{-1}\mathrm{sr}^{-1}\mathrm{cm}^{-2}$ at 100 TeV and a spectral index -2.50 ± 0.09 for energies between 25 TeV and 2.8 PeV. A spectral index of -2, an often quoted benchmark value, is disfavoured with a significance of 3.8σ.

Multi-messenger observations triggered by a high-energy IceCube neutrino event in 2017 (see Figure 36.9 for an event display), together with a neutrino excess from the same celestial direction in the 2014/15 archival IceCube data, yielded evidence for a first neutrino signal related to a known astronomical object, the blasar[2] TXS 0506+056 [67, 68]. Multi-messenger investigations in conjunction with gravitational waves, ultra-high-energy cosmic rays or gamma-ray observations have not revealed further,

[2] An Active Galactic Nucleus with a relativistic jet outflow pointing to the observer.

similarly significant neutrino signals to date. Also, no further astrophysical neutrino sources were found in a recent combined IceCube/ANTARES search for steady sources [69].

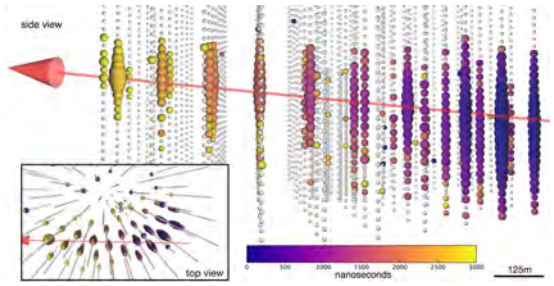

Figure 36.9: Display of the event IceCube-170922A, consistent with a neutrino from the blasar TXS 0506+056. The deposited energy is 24 TeV, the most probable neutrino energy is 290 TeV. The colour code indicates the signal timing (blue: early; yellow: late), the size of the coloured circles is a logarithmic measure of the light intensity registered per DOM. The arrow indicates the reconstructed neutrino direction, corresponding to a zenith angle of $5.7^{+0.5}_{-0.3}$ degrees below horizon. Figure from [67].

IceCube has reported an energy-dependent anisotropy of cosmic-ray induced muons, a measurement of the neutrino-nucleon cross section using neutrino absorption in Earth, and the observation of a cascade event consistent with the process $\overline{\nu}_e + e^- \to W^- \to$ hadrons (Glashow resonance).

No indications for neutrino fluxes from dark matter annihilations or for other exotic phenomena have been found.

At lower energies, down to 10 GeV, IceCube/DeepCore, ANTARES and meanwhile also KM3NeT have identified clear signals of oscillations of atmospheric neutrinos. The closely spaced OMs of DeepCore allow for selecting a very pure sample of low-energy $\overset{(-)}{\nu}_\mu$ (6–56 GeV) that produce upward moving muons inside the detector. The neutrino energy is determined from the energy of the hadronic shower at the vertex and the muon range. Fits to the energy/zenith-dependent deficit of muon neutrinos provide constraints on the oscillation parameters $\sin^2\theta_{23}$ and Δm^2_{23}. The analysis of the same dependence for cascade-like events provides a $\sim 3\sigma$ evidence for ν_τ appearance – an important measurement to test the unitarity of the PMNS matrix [70].

See [71–73] for summaries of status, recent results and future plans of IceCube, ANTARES, KM3NeT, and GVD.

36.3.2.5 *Plans beyond 2021*

Within the future IceCube-Gen2 project, it is planned to extend the sensitivity of IceCube towards both higher and lower energies. To increase the detector sensitivity at high energies, a large-volume extension is envisaged, combined with a radio array for highest-energy neutrinos and a surface array providing also a powerful veto against atmospheric events [58, 59]. A substantially denser instrumentation of a sub-volume of DeepCore will be achieved with 7 closely spaced strings to be deployed in 2024/25 (the IceCube Upgrade), aiming to cover a low-energy program, to better calibrate the existing IceCube detector and the archival data, and to test new technologies. More information on the future extensions of GVD and KM3NeT and on P-ONE are given above, in Table 36.3 and in [54, 72].

36.3.3 *Radio emission from (ultra-)high energy particle showers*

Revised October 2021 by S.R. Klein (NSD LBNL; UC Berkeley) and A. Nelles (DESY, Zeuthen; Erlangen U.).

Coherent radio-frequency (RF) electromagnetic radiation is an attractive signature to search for particle cascades produced by interactions of high-energy particles. RF signatures have been used to study both cosmic-ray air showers and to search for neutrino-induced showers. This article will discuss the radio signal generation, the relevant energy regime and the application in detectors. Air showers are discussed in more detail in two recent reviews [74, 75]. At lower energies, incoherent optical Cherenkov radiation is frequently used, as discussed in "Neutrino telescopes" section 36.3.2. This article uses the general definitions and properties of neutrino telescopes as described in 36.3.2.

36.3.3.1 *Signal generation and its characteristics*

As discussed in the "Passage of Particles Through Matter" review Sec. 34 the electromagnetic component of a high energy shower gives rise to radio emission. For the signal generation itself the type of primary particle is irrelevant. However, the signal medium is important. It must be non-conducting (and non-absorptive at RF frequencies). The different shower length scales (radiation length, X_0) between air and the solid materials used for neutrino searches leads to surprisingly large differences in shower development. Due to the interaction with the medium the shower contains more electrons than positrons, which results in a net charge excess and leads to coherent Cherenkov emission, also known as Askaryan effect [76–78]. In air, during propagation through the geomagnetic field, the relative motion of electrons and positrons is affected, which leads to a varying transverse current, usually referred to as the geomagnetic effect [74]. Both effects may be described more generally as being due to radiation from a time-varying net charge [79]. Their relative importance is governed by the density of the medium, as the electric field scales as the net charge excess, and a lower density allows the geomagnetic effect to gain importance. Thus, in solid materials the emission from the Askaryan effect dominates, but it is a $< 20\%$ correction in air showers.

Coherent radiation is possible at wavelengths longer than the instantaneous thickness of the shower along an observer's line of sight. Since air showers have a larger extent than showers in solid media, their coherent radiation appears at lower frequencies.

High-frequency radiation is concentrated around the Cherenkov angle θ_C. Viewed directly on the Cherenkov cone, the electric field strength, $\epsilon_{\rm Ch}$ at a frequency f from an electromagnetic shower from a ν_e with energy E_ν in ice may be roughly parameterized as [80, 81]

$$\epsilon_{\rm Ch}(V/{\rm mMHz}) = 2.53\times10^{-7}\,\frac{E_\nu}{1{\rm TeV}}\,\frac{f}{f_c}\left[\frac{1}{1+(f/f_c)^{1.44}}\right]. \quad (36.3)$$

The electric field strength increases linearly with frequency, up to a cut-off frequency f_c, which is set by the transverse size of the shower [82, 83]. The maximum wavelength c/f_c is roughly the Moliere radius divided by $\cos(\theta_C)$ where θ_C is the Cherenkov angle. The cutoff frequencies depend on the density (which affects the Moliere radius). They are about 1 GHz in ice, about 3 GHz in the lunar regolith, and below 100 MHz in air.

Near f_c, radiation is narrowly concentrated around θ_C [82, 83]. At lower frequencies, the limited length of the emitting region leads to a broadening in emission angle around the Cherenkov cone. Away from θ_C, the electric field from Eq. (36.3) is reduced by [80],

$$\frac{\epsilon}{\epsilon_{\rm Ch}} = \exp\left(-\frac{1}{2}\,\frac{(\theta-\theta_C)^2}{(2.2^\circ\times[1{\rm GHz}/f])^2}\right). \quad (36.4)$$

The angular distribution of the signal around θ_C can be parameterized by a Gaussian peak modulated by a $\sin\theta$. In both ice and the lunar regolith, θ_C is about 56°, in air only 1°. Close to θ_C, the 1 GHz maximum frequency in ice/regolith leads to a generated pulse width of ≈ 1 nsec.

These equations are appropriate for ice. More general parameterizations can be found in [81, 84].

More accurate calculations of the predicted radio signal, in particular air showers are not easily parameterized, but require detailed Monte Carlo simulations. For air showers, these are built on microscopic air shower simulations, calculate the emission from all individual particles in the shower development and add them for different observer positions [74]. For neutrinos, most approaches calculate (directly or from a parameterization) the Askaryan signal from a shower profile. The signal is then propagated through the medium and into an antenna model [81].

At energies above 10^{16} eV in ice, the Landau-Pomeranchuk-Migdal effect lengthens electromagnetic showers, by reducing the

cross-sections for bremsstrahlung and pair production [85]. The lengthening of the shower leads to a narrowing of the radio emission around the Cherenkov cone, and a reduction in high-frequency emission away from the cone [81]. At higher energies, this leads to two separate components of the Askaryan radiation from a neutrino interaction: an un-altered component from the hadronic portion of the shower and an angularly narrowed component from the LPM-lengthened electromagnetic shower. The width of the narrowed component scales as $E_\nu^{1/3}$. If these two components can be observed separately, they could, in principle, be combined to determine the inelasticity of the neutrino interaction [86], allowing for improved measurements of low$-x$ parton distributions and searches for beyond-standard-model interactions.

Similarly, energetic outgoing $\mu^\pm$ and $\tau^\pm$ from neutrino interactions will dominantly lose energy via stochastic pair production and photonuclear interactions. These secondary particles will produce electromagnetic showers that can be detected by radio detectors, if they are above threshold energy. This will enable multiple detections of the same particle track and thus present interesting reconstruction opportunities [87].

At still higher energies, above 10^{20} eV, the LPM effect strengthens, and the electromagnetic shower splits into multiple subshowers with significant separation. When these separations become large enough, the subshowers will effectively become independent radiators, with the total emission showing substantial event-by-event variation, depending on the division into subshowers [85]. Because of this, many experiments that study higher energy (well above 10^{20} eV) neutrinos focus on the hadronic shower from the struck nucleus. This contains an average of only about 20% of the energy, but with fewer large fluctuations.

36.3.3.2 *Energy regime of radio detectors*

The electric field amplitude is linearly proportional to the shower energy. Since the signal is a radio wave, the field amplitude decreases as $1/R$, plus potential absorption in the intervening medium, while the energy fluence decreases as $1/R^2$, again, plus potential absorption. The detection threshold depends on the distance to the antenna and the bandwidth and noise characteristics of the antenna and detector. For an antenna located in the detection medium, at a distance of 1 km the typical threshold is around 10^{17} eV. For stand-off (remote sensing) detectors, the threshold rises roughly linearly with the distance. These thresholds can be reduced by using directional antennas and/or combining the signals from multiple antennas using beam-forming techniques.

RF detectors are used to search for energetic neutrinos from three types of sources: astrophysical objects (*i.e.* extending measurements of the neutrino energy spectrum observed at TeV to PeV energies upward in energy), cosmogenic neutrinos associated with cosmic-ray-cosmic microwave background radiation (CMBR) interactions, and neutrinos from beyond-standard-model physics. These types are very roughly associated with energies below 10^{18} eV, the energy range 10^{18} to 10^{20} eV, and above 10^{20} eV.

Cosmogenic neutrinos are produced when ultra-high energy (UHE) protons with energy $E > 5\times10^{19}$ eV interact with photons from the CMBR, infrared light from old stars, and other extragalactic background light. These protons are excited to a Δ^+ resonance which may decay via $\Delta^+ \to n\pi^+$, leading to neutrinos with energies above 10^{18} eV [88, 89]. The cosmogenic neutrino signal depends heavily on the fraction of UHE cosmic-rays that are protons. For a 100% proton composition (disfavored by most data [90]), observing a cosmogenic neutrino signal of at least a few events per year requires a solid or liquid detector with an active volume of about 100 km^3.

To reach the effective volumes necessary to observe the expected low fluxes of UHE neutrinos, common, naturally occurring, non-conducting solid (or potentially liquid) media, with a long absorption length for radio waves are needed. Optical Cherenkov and acoustical detectors are limited by short (< 100 m) attenuation lengths [91] so would require a prohibitively expensive number of sensors. The radio detection technique has been used to detect air showers, targeting neutrinos as well as cosmic rays, and to search for neutrino showers in ice, salt domes and the lunar regolith.

36.3.3.3 *Reconstruction of particle energy and direction and background suppression*

Since radio detectors view the interaction from afar, the reconstruction techniques differ from optical neutrino telescopes.

Radio detection is a calorimetric measurement, thus provides good energy estimates of the shower energy. The energy fluence (integrated pulse power) of the signal scales quadratically with shower energy. It also depends on the distance to the shower, through potential attenuation losses and the usual $1/R$ loss in electric field amplitude. The arrival times in antennas and a spherical wave approximation can be used to determine the interaction vertex, although some uncertainty due to the viewing angle with respect to the Cherenkov angle may remain, if not corrected for by using the frequency information. If the radio signal travels through media where the index of refraction varies (like the firn of glacial ice), then ray-tracing techniques may be required to follow the signal back to the interaction point. For buried antennas, the bending of the signal trajectories due to the index of refraction creates an opportunity. For some geometries, there may be two paths to the detector: a 'direct' path, with minor bending, and a second where the signal is bent beyond horizontal, bouncing off the surface before reaching the antenna. By measuring the time difference between the two paths, the distance to the interaction vertex may be determined; this greatly simplifies the energy determination [92,93]. For most neutrino interactions (except for ν_e charged-current interactions), the shower energy is less than the neutrino energy. The uncertainty on the interaction inelasticity is a major contributor to the uncertainty in the neutrino energy, along with uncertainties on the distance between the antenna(s) and the interaction vertex [94].

Reconstruction of the neutrino arrival direction depends on several aspects of the signal. First, the direction from the antenna to the interaction site must be determined. This can be done by using the relative timing from separated antennas, or using beam-forming techniques with multi-element arrays. For air showers, the signal arrival direction is (almost) equal to the particle arrival direction, with corrections being obtainable by fitting a hyperbolic wavefront [74, 75].

For showers in solid/liquid media, the arrival direction with respect to the interaction point - antenna vector is determined from two additional angles. The frequency spectrum can be used to determine the angle between signal arrival direction and Cherenkov cone according to Eq. (36.4) [95]. The second angle can be determined from the polarization of the signal. The radio signal is produced with a linear polarization in the plane containing both the particle direction and the radio wave direction. These two angles can be combined to determine the direction, subject to a (usually) four-fold ambiguity, due to uncertainty as to whether the antenna is inside or outside the Cherenkov cone, and because the particle direction can be flipped 180° without affecting the observed signal. Often, some of these solutions can be rejected because they correspond to long path lengths through the Moon or the Earth, where the neutrino would be absorbed.

Spectral information is crucial for the reconstruction and background rejection. However, large bandwidth antennas typically disperse (i.e. broaden) the pulses. As long as the dispersion can be compensated for and backgrounds controlled, a large bandwidth detector is the most sensitive.

All radio experiments must contend with background. Common sources are anthropogenic noise, antenna/preamp noise, charge generated by blowing snow, lightning, and, at low frequencies, radiation from the Milky Way. While narrowband noise impacts triggering and contaminates signal quality, impulsive backgrounds could mimic a signal. One of the major issues for radio-detection experiments is anthropogenic noise. Most anthropogenic noise has distinctive characteristics (such as being narrow-band, and coming from near the horizon) which makes it relatively easy to reject during data analysis, via narrow-band filters and other techniques [74]. However, these factors complicate triggering and reduce data purity. This is even an issue in Antarctica, where communication radios and passing satellites can mimic showers, at least at the trigger level. The need to limit anthropogenic noise has led most experimental groups to select remote locations for

their detectors. Still, experiments have used approaches to reduce trigger-level noise, and/or to reject background at the analysis level. For example, for multi-element arrays, the threshold drops as the square root of number of antennas, since the signal adds in-phase while the backgrounds add with random phases [96].

Most dedicated air shower experiments have used radio antennas in combination with at least one other detector technology, such as scintillation counters, if the site quality is not sufficient and/or computing power on autonomous stations is limited. One exception is ARIANNA, which is located in an uninhabited part of Antarctica, enabling them to efficiently self-trigger on air showers [97].

Lunar experiments (discussed below) use different techniques to reduce the anthropogenic background. Some experiments use multiple antennas, separated by at least hundreds of meters; by requiring a coincidence within a small time window, anthropogenic noise can be rejected. With good enough timing, beam-forming techniques can be used to further reduce the background. An alternative approach is to use beam forming with multiple feed antennas viewing a single reflector, to ensure that the signal points back to the moon.

Due to the similarity in the radio emission of air showers and neutrino showers, the more abundant cosmic rays can act as background to neutrino searches. In-ice detectors need to suppress in-air emission that is refracted into the ice, emission that is created from developing air showers continuing in the ice, as well as from stochastic energy-losses of atmospheric muons. Lunar experiments may faces challenges in separating neutrino interactions from cosmic ray interactions.

36.3.3.4 *Recent experiments*

Figure 36.10 shows some current limits from neutrino searches, including from prototype arrays. Except for LOFAR, which is fully operational, projected limits from future experiments are not shown in the figure.

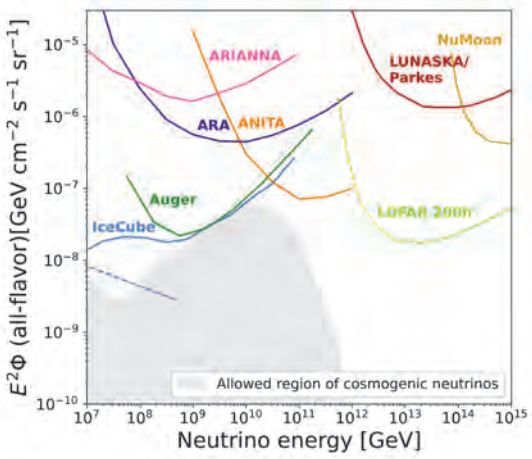

Figure 36.10: Representative 3-flavor (summed, assuming equal fluxes of each flavor) differential (over one decade in energy) limits from different experiments and prototype experiments. Shown are limits from the IceCube ultra-high energy ν search [98], the Auger search for earth-skimming ν_τ [99], the LUNASKA/Parkes [100] and NuMoon lunar searches [101], the ANITA balloon experiment [102], ARA [103] and ARIANNA prototypes [104], along with projections for the LOFAR array [105]. The dashed blue line is the extrapolation of the IceCube through-going ν_μ flux measured at lower energies (few 10s of TeV to 10 PeV), with spectral index $\alpha = -2.28$ [106]. Because of the long extrapolation, this should only be treated as a rough reference. The ARA and ARIANNA limits are from prototype arrays, and indicate the energy range that might be covered, with far higher sensitivity by larger arrays. The shaded area is the allowed region for cosmogenic neutrinos, from a recent global analysis that included the measured cosmic-ray spectrum and composition [107].

i. *Ice*

The most common dense medium transparent to radio waves is ice. Natural ice is an attractive medium for neutrino detection with radio attenuation lengths from over 300 m to 1 km [108]. The attenuation length varies with frequency and ice temperature, with higher attenuation in warmer ice. Although glacial ice is mostly uniform, the top $\approx$ 100 m of ice, the 'firn,' exhibits a gradual transition from packed snow at the surface (typically $\rho = 0.35$ g/cm^3) to solid ice ($\rho = 0.92$ g/cm^3) below [109]. The thickness of the firn varies with location; it is thicker in central Antarctica than in the coastal ice sheets or in Greenland. The varying density has several implications.

The index of refraction depends linearly on the density, so radio waves curve downward in the firn. This bending reduces the effective volume of surface or aerial antennas. A surface antenna cannot see near-surface interactions at large horizontal distances. There are also indications that the increase in firn density is non-monotonic [110, 111]. This leads to non-monotonic changes in index of refraction which may create waveguides that trap a small fraction of the radio energy and propagate it horizontally.

In one type of experiment, antennas mounted on high-altitude balloons observe the ice from above. Radio signals from in-ice neutrino interactions propagate to the surface, traverse the ice-air interface, and then travel to the balloon. The surface roughness of the ice can affect signals as they transition from the ice to the atmosphere. The best known example, ANITA, has made four flights around Antarctica, floating at an altitude around 35 km [112]. Its 32/40/48 (depending on the flight) dual-polarization horn antennas scanned the surrounding ice, out to the horizon (650 km away). Because of the small angle of incidence, ANITA could use polarization information to separate signals from background; ν signals should be vertically polarized, while most background from cosmic-ray air showers should be horizontally polarized.

As with all radio-detection experiments, ANITA had to contend with anthropogenic backgrounds. The ANITA collaboration uses their multiple antennas as a phased array to achieve good pointing accuracy, with a resolution of 0.2-0.4° in elevation, and 0.5-1.1° in azimuth. They rejected all events that pointed toward known or suspected areas of human activity. ANITA has set the most stringent flux limits yet on neutrinos with energies above 10^{20} eV [102]. The ANITA experiment has also reported several anomalous events, matching cosmic ray signals, but with unexpected polarization signature, which the collaboration has indicated might be from Earth-skimming ν_τ [113, 114]. However, this interpretation is controversial.

Because of the significant source-detector separation, ANITA is most sensitive at energies above 10^{19} eV. A lower energy threshold requires a smaller antenna-target separation.

Other ice based experiments use antennas located within the active volume, allowing them to reach thresholds around 10^{17} eV, or lower with phased array antennas. This approach was pioneered by the RICE experiment [115] which buried 18 half-wave dipole antennas in holes drilled for AMANDA at the South Pole, at depths from 100 to 300 m. The hardware was sensitive from 200 MHz to 1 GHz. Each antenna fed an in-situ preamplifier which transmitted the signals to surface digitizing electronics.

More recently, two groups have deployed prototype arrays which have explored different detector concepts. The Askaryan Radio Array (ARA) deployed surface and buried antennas at the South Pole [116], while the Antarctic Ross Iceshelf Antenna Neutrino Array (ARIANNA) installed surface antennas on the Ross Ice Shelf [104], about 110 km north of McMurdo station. ARIANNA offered the possibility of detecting downward-going ν, from the radio waves reflected off the ice-sea water interface on the bottom of the Ross Ice Shelf, while ARA took advantage of the colder, deeper ice at the South Pole, with its longer radio attenuation length. ARA buried antennas up to 200 m deep to be able to observe a larger portion of ice, due to the refraction of the signal in the firn. In contrast, ARIANNA deployed antennas just below the surface, allowing them to use high-gain, but large log periodic dipole antennas. Recently, phased-array trigger techniques have been demonstrated that can reduce the energy threshold by a

factor of several [96, 117].

Both experiments use stations which operate independently, spaced far enough to maximize sensitivity, but where only a small fraction of neutrino events will be visible in multiple stations. Each station includes multiple antennas, which will be sensitive to both horizontal and vertical polarization. The expected angular resolution is a few degrees [95].

In 2021, the Radio Neutrino Observatory Greenland (RNO-G) started deploying stations at Summit Station. RNO-G is planned to consist of 35 stations, which employ ARIANNA-style surface antennas, an ARA-style phased array and deep antennas, and draw heavily on ANITA's electronics heritage [118].

ii. *The Moon*

Because of its large size and non-conducting regolith, and the availability of large radio-telescopes, the Moon is an attractive target [119]. Conventional radio-telescopes are quite well suited to lunar neutrino searches, with natural beam widths not too dissimilar from the size of the Moon. Still, there are experimental challenges. The attenuation length is typically estimated to be 9m/f(GHz) [120], so only near-surface interactions can be studied. The composition of the lunar regolith is not well known, and there are significant uncertainties due to this uncertainty. One big limitation of lunar experiments is that the 385,000 km target-antenna separation leads to energy thresholds above 10^{20} eV.

The effective volume probed by experiments depends on the geometry, which itself depends on the frequency range used. At high frequencies f, the electric field strength is high, leading to a lower energy threshold, but the sensitive volume is limited because the Cherenkov cone only points toward the Earth for a narrow range of geometries. Lower frequency radiation is more isotropic, so the effective volume is larger, but, because the electric field is weaker, the energy threshold is higher. The $1/f$ dependence of the attenuation length in the lunar regolith further increases the effective volume at low frequencies. The frequency range affects the energy dependence of the sensitivity. As can be seen in Fig. 36.10, a low-frequency experiment like NuMoon (which covered 115-180 MHz) has good sensitivity, but only above about 10^{14} GeV, while Lunaska/Parkes, which observed in the range 1200-1500 MHz, has a higher flux limit, but is sensitive above about $10^{12.5}$ GeV.

Current limits and projected sensitivities are sensitive to many details. A recent review [121] compared different radio-detection experiments using a common framework, and found some significant shifts in sensitivities due to, e.g. different assumptions about lunar composition and inelasticities.

With modern technology, it is increasingly viable to search over very broad frequency ranges [122]. One technical challenge is due to dispersion (frequency dependent time delays) in the ionosphere. Dispersion can be largely removed with a de-dispersion filter, using either analog circuitry or post-collection digital processing.

iii. *Air*

Radio detection in air is sensitive to all particles inducing air showers. Radio-detection can be used to determine the energy of cosmic rays, as done by e.g. the Auger and Tunka-Rex experiments [123, 124]. Radio signals can also be used to infer the altitude for shower-maximum, where the shower contains the most particles, as done by e.g. the LOFAR and Tunka-Rex collaborations [124, 125]. This altitude is sensitive to the cosmic-ray composition. Reconstructing the particle arrival direction is much easier in air since the Cherenkov angle, and thus the radio wavefront, aligns with the axis to 1°. Radio-detection is also useful for energy cross-calibrations between different experiments and may be able to provide an independent energy scale calibration for air shower arrays [126].

One variation on the radio-detection approach is to look for radio emission from Earth-skimming ν_τ. Although ν_τ are much less commonly produced than ν_μ and ν_e, over astrophysical distances, oscillations lead to a $\nu_e : \nu_\mu : \nu_\tau$ ratio near $1 : 1 : 1$, for almost all non-exotic acceleration and propagation mechanisms [127].

If the ν_τ traverse the Earth and interact while traveling upward, near the surface, the resulting $\tau^\pm$ may exit the Earth before decaying. 83% of the time, the decay produces a hadronic or electromagnetic shower in the atmosphere [128]. Experiments have searched for these upgoing showers, and for the resulting optical Cherenkov and coherent RF radiation. The threshold energy dependence for these searches depends on several factors, notably including the average $\tau^\pm$ decay length, which increases linearly with energy; the Pierre Auger observatory sets stringent limits on the neutrino flux at energies above 10^{17} eV [99].

36.3.3.5 *Future experiments*

Looking ahead, RNO-G [118] will continue deployment until 2024 and reach the largest yearly sensitivity of any radio array thus far. Further out, the proposed IceCube Gen2 expansion includes a substantial radio array component [59], which will be sensitive to both neutrinos from the ice and air showers from cosmic rays. PUEO, a successor of ANITA has been funded and is scheduled for its first flight in 2024 [129].

In the near future, several large radio detector arrays should reach significantly lower energies for lunar neutrino detection. The LOFAR array is taking data with 36 detector clusters spread over Northern Europe [105]. In the longer term, the Square Kilometer Array (SKA) with its 1 km^2 effective area will push thresholds down to near 10^{20} eV [122]. The SKA will also study air showers.

A number of dedicated prototype ν_τ radio-detection experiments exist. The GRAND Collaboration recently proposed to deploy a 10,000 antenna array, eventually growing to 200,000 antennas spread over 200,000 km^2. Its stations are simple autonomous units that sample the 30-100 MHz range using antennas optimized for near-horizontal signals [130]. The first phase GRAND-proto 300 is scheduled for deployment in 2021. The Pierre Auger Collaboration is currently upgrading their surface array to include radio antennas at all water Cherenkov detectors. This array will improve the sensitivity of the instrument to horizontal showers, both for composition sensitivity for cosmic rays and for the detection of Earth skimming neutrinos [131].

36.4 Large time-projection chambers for rare event detection

Revised October 2019 by T. Shutt (SLAC).

Rare event searches require detectors that combine large target masses and low levels of radioactivity, and that are located deep underground to eliminate cosmic-ray related backgrounds. Past and present efforts include searches for the scattering of particle dark matter, neutrinoless double beta decay, and the measurement of solar neutrinos, while next generation experiments will also probe coherent scattering of solar, atmospheric and diffuse supernova background neutrinos. Large time project chambers (TPCs) [132], adapted from particle collider experiments, have emerged as a leading technology for these efforts. Events are measured in a central region confined by a field cage and usually filled with a liquid noble element target. Ionization electrons are drifted (in the z direction) to an anode region by use of electrode grids and field shaping rings, where their magnitude and $x - y$ location is measured. In rare event searches (with no external trigger available) scintillation generated at the initial event site is also measured, and the time difference between this prompt signal and the later-arriving charge signal gives the event location in z for a known electron drift speed. Thus, 3D imaging is a achieved in a monolithic central volume. The relatively slow readout due to the drift of charges ($\sim 1/2$ ms/m at 1 kV/cm) [133] is not a major pile-up concern in low background experiments. Noble elements have relatively high light yields (comparable to or exceeding the best inorganic scintillators), and the charge signal can be amplified by multiplication or electroluminescence. Radioactive backgrounds are distinguished by event imaging, the separate measurements of charge and light, and scintillation pulse shape. For recent reviews of noble element detectors, see [134–137].

Methods for achieving very low radioactive backgrounds are discussed in general in section 35.6. The basic architecture of large TPCs is very favorable for this application because gas or liquid targets can be relatively easily purified, while the gener-

ally more radioactive readout and support materials are confined to the periphery. The 3D imaging of the TPC then allows self shielding in the target material, which is quite powerful when the target is large compared to mean scattering lengths of order $\sim$ 10 cm for $\sim$ MeV neutrons and gammas from radioactivity. Most recent experiments have immersed the TPCs in hermetic water shields to eliminate external radioactive backgrounds, and several are also using an active scintillator inner layer to further veto backgrounds from detector materials. While other target fluids are possible, almost all recent efforts have used Xe and Ar. In LHe and LNe the mobility of electrons is $\sim 10^3$ times lower than in the heaver noble elements due to the formation "bubbles" around electrons. [138, 139] It is worth noting that scintillation and electron drift are possible in a number of organic fluids, possibly providing a route to economical large detectors, but with much reduced performance compared to noble elements.

In noble element targets, all non-noble impurities are readily removed (e.g., by chemical reaction in a commercial getter) so that only radioactive noble isotopes are a significant background concern. Xe, Ne and He have have no long lived radioactive isotopes (apart from the ^{136}Xe, discussed below, and the very long-lived ^{124}Xe [140]). Kr has $\sim$ 0.3 MBq/kg of the beta emitter ^{85}Kr created by nuclear fuel reprocessing [141], making it unusable as a target, while the $\sim$ 1 Bq/kg level of the beta emitter ^{39}Ar [142] is a nuisance for Ar-based experiments. Both of these can be backgrounds in other target materials, as can Rn emanating from detector components. Relatively low background materials are available for most of the structures surrounding the central target, with the exception of radioactive glasses and ceramics usually present in PMTs, feedthroughs and electrical components. Very low background PMTs with synthetic quartz windows, available over the last 15 years (see, e.g., [143]), have been a key enabling technology for dark matter searches. Radio-clean SiPMs and related Si-based photon detectors are increasingly being used in cases where their dark rates (which are significantly higher than PMTs) can be tolerated.

An important technical challenge in liquid detectors is achieving the high voltages needed for electron drift and measurement. In general, quench gases which stabilize charge gain and speed electron transport in wire chambers cannot be used, since these absorb and/or quench scintillation light and can trap electrons. It is also important to suppress low-level emission of electrons and associated photons which can otherwise swamp low energy signals. Drift of electrons over meter scales with minimal loss from attachment on trace levels of dissolved impurities (e.g., O_2) has so far required continuous circulating purification.

36.4.1 *Dark matter and other low energy signals*

A major goal of low background experiments is detection of WIMP (Weakly Interacting Massive Particle) dark matter through scattering on nuclei in a terrestrial detector (for a recent review, see [144]). Energy transfers are generally small, a few tens of keV at most. Liquid noble TPCs distinguish single nuclear recoils (NR) from dark matter from the dominant background of electron recoils (ER) from gamma rays and beta decays by rejecting multiple scatters, and, as described below, based on both the ratio of charge to light and the scintillation pulse shape. Neutrons are a NR background, but are present at much lower rates than gammas and betas, and also undergo significant multiply scattering. To detect small charge signals, a dual phase technique is used wherein electrons from interactions in the liquid target are drifted to the liquid surface and extracted with high field ($\sim$ 5 kV/cm) into the gas phase where they create an amplified electroluminescence signal which is usually measured by an array of PMTs located just above the liquid. (While both charge multiplication and electroluminescence are possible in liquid, they require very high fields created by very small electron structures and thus have not seen widespread adoption. For recent progress see [145]) This technique readily measures single electrons with $\sim$ cm $x-y$ resolution.

The measurement of the initial scintillation signal, by contrast, suffers from loss upon reflection from the TPC walls, and inefficiency in the readout, and usually limits the energy threshold. In LXe, the $\sim$ 178 nm wavelength is just long enough to be transmitted through high purity synthetic quartz PMTs windows, and, remarkably, PTFE immersed in LXe has $\sim$ 97% reflectivity. [146] The $\sim$ 128 nm scintillation light of LAr requires waveshifting (usually using TPB) both for reflectivity (usually on PTFE) and for efficient measurement. With both liquids, a second sensor array at the bottom of the TPC is used to maximize light collection, and total photon efficiencies have been in the 10-15% range. Typical raw yields for ER are several tens of electrons and photons per keV, and, in LXe, a NR threshold of $\sim$ 5 keV has been achieved [147].

The microscopic processes leading to signals in liquid nobles are complex. Energy deposited by an event generates pairs of free electron and ions, and also atoms in their lowest excited state. The latter rapidly form excimers which de-excite by emitting light. Excimers arise in both triplet and singlet states which have the same energy but different decay times. In an event track, some fraction of electrons recombine with ions, while the rest escape and are measured. Each recombined ion creates an additional excimer, and hence another photon. Finally, some part of the energy is lost as heat - a small fraction for ER but a dominant and energy dependent fraction for NR. The branching into these various modes depends on drift field, energy, and particle type, requiring extensive calibrations. These have largely been carried out for LXe (see, e.g., [148]), and have been incorporated into the NEST Monte Carlo framework. [149]

This complexity also gives rise to discrimination between ER and NR: for the same visible energy, the slower NR create short, denser tracks and generate a higher fraction of initial excitons, leading to a smaller ratio of measured charge to light. NR also generate a higher ratio of short-lived singlet state to long-lived triplet states than ER, so that the scintillation signal itself gives pulse shape discrimination (PSD). Charge/light discrimination has been well mapped in LXe, and, remarkably, is very high (>99.9%) below $\sim$10 keV for NR. [147] It has only recently been measured in LAr [150], and has not yet played an important role in LAr based experiments. Qualitatively, PSD is similar in LXe and LAr - strong at high energy and weak at low energy. However it is well mapped only in LAr where it is very high above $\sim$ 50 keV, achieving values above $\sim 10^8$. [151]

This extremely powerful PSD in LAr is sufficient to overcome the ER background from ^{39}Ar, which is roughly 10^7 times higher than the fundamental low energy ER background from p-p solar neutrinos. In a multi-ton detector the event rate from ^{39}Ar poses a significant pile-up challenge, and the DarkSide collaboration is pursuing ^{39}Ar reduction through two methods. One, for which a factor 1400 reduction in $\sim$ 50 kg Ar has been demonstrated, is extracting “aged” Ar from underground (cosmic ray shielded) gas deposits in which the 269 yr half-life ^{39}Ar has decayed. [152] The other method is removal by distillation. The need for ^{39}Ar depleted Ar negates the much lower raw material cost of Ar compared to Xe. Kr must also be removed from both Xe and Ar experiments (and Ar must be from Xe experiments), comparatively easy tasks compared to isotopic separation. This is done through distillation or a chromatographic technique. In current LXe experiments the remaining dominant ER backgrounds is the beta decay of a daughter of ^{222}Rn in the active LXe, where the Rn has emanated from detector materials or external plumbing. Rn will be even more important as experiments scale up in size, but can in principle be reduced by better materials screening and online Rn separation, again by either distillation or chromatography. Neutrons are in general some six orders of magnitude less abundant than gamma rays and betas in U and Th decay chains, but they naturally scatter in the WIMP energy range, and their single scatters cannot be discriminated against. Self shielding is less powerful for neutrons than gamma rays, so that they are an increasingly important background at the current ton scale and future larger experiments, both in Ar and Xe. Active outer shielding layers which tag and veto neutrons are being included in most next generation experiments.

The WIMP sensitivity is a combination of backgrounds, discrimination, and WIMP scattering rates. The scattering rates are model dependent, but are in general dominated by spin-independent coherent scattering on the full nucleus. This has an

A^2 dependence, favoring high mass targets. The energy spectrum is close to a falling exponential, so that the lowest possible energy threshold maximizes sensitivity. Experiments using LXe TPCs have had the leading sensitivity for standard WIMP dark matter for well over a decade, for all but the lowest WIMP masses. The ton-scale XENON1T [153] achieved a WIMP-nucleon sensitivity of $4.1 \times 10^{-47}\ cm^2$ at 30 GeV mass, closely followed by PANDAX-II [154] and LUX [155]. The next generation $\sim$ 7 tonne experiments LZ [156] and XENONnT [157], and $\sim$ 4 tonne PandaX-4T [158] are currently in late stages of construction. The DarkSide program is carrying out WIMP searches with LAr TPCs. The 50 kg DarkSide-50 achieved a sensitivity $\gtrsim$ 40 times poorer than XENON1T. A 50 ton scale-up, DarkSide-20 is being pursued which features SiPMs instead of PMTs. [159]. (The best current limit using LAr is not from a TPC, but instead the scintillation-only DEAP-3600 experiment. [151])

LZ and XENONnT project sensitivity to WIMPs about a decade above the"floor" of coherent scattering of astrophysical neutrinos, which, absent a directional measurement (see below), are essentially indistinguishable from WIMPs. DARWIN, a proposed a 50 ton LXe TPC would approach the practical limit set by this floor for WIMP masses above $\sim$ 5 GeV [160], while ARGO a $\sim$ 200 ton LAr detector would achieve similar sensitivity for WIMPs masses well above $\sim$ 50 GeV. [159]

There has been recent interest in models featuring low mass dark matter. These give rise to low energy recoils, and also strongly favor low mass target nuclei (despite the A^2 rate penalty). This has led to renewed focus on events below the scintillation threshold, where the charge signal alone achieves very low threshold due to the gain of the electroluminescence readout. This preserves $x - y$ spatial information, but only very weak depth information based on electron diffusion. Thus it is subject to the high backgrounds at the top and bottom of the active region, and decays of Rn daughters on grids. While the first such results came from XENON10, a recent result in LAr from DarkSide-50 extends to much lower dark matter mass because of the lower mass of Ar. To maximize the sensitivity of such searches in the future, studies have begun to understand and minimize the sources of electron backgrounds from both radioactivity and spurious sources such as field emission from grids. There is also an effort to develop a superfluid He TPC [161] read out with superconducting sensors (similar to the proposed HERON solar neutrino experiment). The rich set of signals in this case - scintillation, rotons, and ionization - potentially offer significant background rejection.

Measurement of NR recoil track direction would provide proof of the galactic origin of a dark matter signal since the prevailing WIMP direction varies on a daily basis as the earth spins. This cannot be achieved for the sub-micron tracks in any existing solid or liquid technology, but the mm-scale tracks in a low pressure gas (typically, P $\sim$ 50 Torr) could be imaged with sufficiently dense instrumentation. Directionality can be established with $O(10^2)$ events by measuring just the track direction, while, with finer resolution that distinguishes the diffuse (dense) tail and dense (diffuse) head of NR (ER) tracks, only $O(10)$ events are required. Such imaging requires a high energy threshold, decreasing WIMP sensitivity, but also powerfully rejecting less dense ER background tracks.

A variety of TPC configurations are being pursued to accomplish this, most with a CF_4 target. The longest established effort, DRIFT, avoids diffusion washing out tracks for electron drift distances greater than $\sim$ 20 cm by attaching electrons to CS_2, which drifts with vastly reduced diffusion. Other efforts drift electrons directly and use a variety of techniques for their measurement: DMTPC (electroluminescence + CCDs), MIMAC (MicroMegas), NEWAGE (GEMs), and D^3 (Si pixels). A related suggestion is that the amount of recombination in a high pressure Xe gas with an electron-cooling additive could be sensitive to the angle between the track and electric field [162], eliminating the need for track imaging. Directional measurements appear to be the only possibility to push beyond the floor of coherent neutrino scatters [163], though at the cost of enormous target mass and channel count.

36.4.2 $0\nu\beta\beta$ *Decay*

Another major class of rare event search is neutrinoless double beta decay ($0\nu\beta\beta$). A limited set of nuclei are unstable against simultaneous beta decay of two neutrons. Fortuitously, this includes the Xe isotope ^{136}Xe (Q-value 2458 keV), which can be used as the active material in a detector, and which, as an inert gas, can also be more readily enriched from its natural 8.9% abundance than any other $\beta\beta$ isotope. Observation of the lepton-number violating neutrinoless version of this decay would establish that neutrinos are Majorana particles and provide a direct measure of neutrino mass. For a recent review, see [137, 164]. The signal in $0\nu\beta\beta$ decay is distinctive: the full Q-value energy of the nuclear decay appears as equal energy back-to-back recoil electrons. A large TPC is advantageous for observing this low rate decay for all the reasons described above. The first detector to observe the standard model process two neutrino double beta decay was a gaseous TPC which imaged the two electrons tracks from ^{82}Se embedded in a foil. [165] Modern TPCs use Xe as the detector medium.

The dominant background is gamma rays originating outside the active volume. Most of these undergo multiple Compton-scatters which are efficiently recognized and rejected through sub-cm position resolution, though the few percent of gammas at this energy that photoabsorb are not. Self shielding of gamma rays in the double beta decay energy window is less powerful than in the low energy dark matter window, since in the former case there is some small probability of penetrating to some depth followed by the modestly small probability of photo-absorption. The latter case consists of three small probability processes: penetration to some depth, a very low-energy scatter, and the gamma exiting without a second interaction. Because of this and the fact that background and the signal are both electron recoils (i.e., NR/ER discrimination is of no value), the requirements on radioactivity in all the surrounding materials of a $\beta\beta$ TPC are much more stringent than an otherwise similar dark matter detector, unless other background rejection tools are available. However $\beta\beta$ searches are insensitive to low energy backgrounds (e.g., ^{85}Kr and ^{39}Ar) important for dark matter.

Very good energy resolution is crucial to avoid background from $2\nu\beta\beta$ decays and gammas including the prominent 2615 keV line from ^{208}Tl in the Th chain. Here a combined charge and light measurement largely eliminates the otherwise dominant fluctuations in recombination which lead to anti-correlated fluctuations in charge and light. Because of the high energy of the $\beta\beta$ signal, charge can be read out directly, and the scintillation measurement is easily tolerant of the dark rates of SiPMs. These goals have led $\beta\beta$ detectors to have somewhat different optimization than dark matter detectors, although the next generation large Xe dark matter experiments (LZ, XENONnT, DARWIN) have significant $\beta\beta$ reach.

The recently completed EXO-200 experiment used a single-phase LXe TPC with roughly 110 active kg of Xe enriched to 80.7 % ^{136}Xe to achieve one of the best $\beta\beta$ search limits [166]. The energy resolution obtained is (FWHM) of 2.71% (at 2458 keV), and lower values in LXe appear possible. A multi-ton successor experiment, nEXO, has been proposed which would fully cover the inverted neutrino mass hierarchy. [167] EXO-200 featured LAAPDs for light readout, and direct charge readout, while nEXO will use SiPMs.

A related but different approach is to use high pressure gaseous Xe TPC. [168] The lower density requires a large apparatus for given target mass, but has two significant advantages. The larger track size allows the two-electron topology of $0\nu\beta\beta$ events to be distinguished from single electrons from photoabsorption of background gammas. In addition, the low recombination fraction in the gas phase suppresses recombination fluctuations, allowing higher energy resolution. Recent progress with a 5 kg prototype by the NEXT collaboration has demonstrated the topology based discrimination, and, notably, 1% (FWHM) energy resolution. A $\sim$ 100 kg detector is now under construction, and ton-scale designs being studied. Finally, a long-standing idea that would provide definitive identification of a $0\nu\beta\beta$ signal is to extract and tag the ionized Ba daughter via atomic physics techniques [169], either

in gas or liquid and gas phases. Significant recent progress by both the EXO and NEXT collaborations has now achieved the key milestone of demonstrating single Ba ion sensitivity in test setups. [170–172]

36.5 Sub-kelvin detectors

Written October 2021 by O. Cremonesi (INFN, Milano-Bicocca), L. Hsu (FNAL) and G. Signorelli (INFN, Pisa).

36.5.1 *Motivation for Sub-kelvin Detectors*

Detectors operating below 1 K are referred to as low-temperature detectors (LTDs). The advantage of using LTDs over conventional detectors resides in their better energy resolutions, lower noise, and improved energy thresholds, which can all be achieved with a versatile choice in materials. In certain applications, these advantages outweigh the potential drawbacks of cooling and reading out a detector payload at sub-kelvin temperatures, and thus enable exploration of new frontiers in fundamental physics, astrophysics and cosmology. Among the endeavors enabled by LTDs are direct searches for dark matter over a wide mass range, precision experiments to measure the electron neutrino mass, searches for neutrinoless double-beta decay, and X-ray observation of the Universe. Large arrays of LTDs are also employed to measure the properties of the cosmic microwave background (CMB) spectrum whose parameters are determined by fundamental physics. These include dark matter and dark energy densities, the sum of neutrino masses and the number of light relativistic species, as well as probing the physics of inflation at energy scales of $\sim 10^{16}$ GeV. This article presents a brief overview of LTDs, their features, and several applications. More detailed treatment of this subject is available in the literature [173–176].

The advantages of LTDs are enabled by the detection of very low energy excitations (e.g. phonons and quasiparticles). In a typical interaction, energy from an incident particle is dissipated through excitation of secondary particles such as electrons, ions, holes, photons, phonons etc. These particles will in turn produce their own secondaries. Thus there is a cascade down in energy until the original energy deposit is converted entirely into heat and the detector reaches thermal equilibrium. Prior to the equilibrium phase, the energy at any given moment is partitioned among multiple excitation modes. Conventional particle detectors work by sensing the higher energy excitation modes, such as ionization and scintillation, which require an average minimum energy of few eV to 10's of eV to produce. For such detectors, a large fraction of the deposited energy remains undetected in the form of heat. Furthermore, the measurements are subject to the fluctuations inherent in the partition of energy across different excitation modes. Secondaries that don't eventually escape the detector, will de-excite or recombine to dissipate their energy in the form of phonons and quasiparticles, which are characterized by energies in the range of meV down to μeV. These can be detected by LTDs at various stages of their final degradation towards thermal equilibrium. Thus LTDs allow for energy resolutions and operational thresholds much lower than detectors that only sense scintillation and ionization. Furthermore, LTDs provide a precise energy measurement owing to the relatively large number of excitation quanta that can be detected. In fact, LTDs designed to measure thermal phonons achieve the highest possible energy resolutions with optimal noise performance.

At thermal equilibrium, energy E deposited in an LTD causes a temperature rise $\Delta T = E/C$ where C is the heat capacity. Thermal equilibrium is characterized by the condition where the average heat flowing to an LTD equals the average heat flowing from the LTD (into a proper heat sink or bath). In this state, the ideal intrinsic energy resolution is determined by the statistical fluctuations in the phonon system. Fluctuations in the total number of phonons in the LTD absorber have variance C/k_B, which yields a minimum resolution of $\Delta E^2 = k_B T^2 C$ to the device energy resolution, where k_B is Boltzmann's constant. Thus, the smaller the heat capacity, the more sensitive the response of the calorimeter and the better the energy resolution. The most relevant feature of this result is that the latter is independent of the energy deposition. The heat capacity itself is the product of the detector volume (V) and the specific heat (c_p). Optimization of LTD response can be achieved by using small detector volumes and materials with low specific heat. Noise contributions from additional sources will increase the variance and are generally parameterized as a multiplicative factor ($\xi \gtrsim 1$) to the variance expression above.

Similarly, the power P from incident particles or radiation can be measured through a temperature rise given by $\Delta T = P/G$, where G is the thermal conductance to a weakly linked bath held at constant temperature. Power fluctuations are limited by G and have a spectral density of $S_P = NEP^2 = 4k_{\rm B}T^2G$, where NEP is the noise equivalent power, defined as the power in a 1 Hz bandwidth that gives a response signal with an equal amplitude to the noise. Hence lower conductance yields better sensitivities. To minimize thermal conductance in precise power measurements, weak thermal links can be realized by using thin membranes or by decoupling the electron and phonon systems. However, a compromise must be made. While lower G yields better noise metrics, conversely, larger G is needed to dissipate all incident power (which can be large in the case of CMB detectors) or to have a faster detector response (the characteristic response time being $\tau = C/G$).

LTDs that measure power are sometimes referred to as *bolometers* in literature, as opposed to *calorimeters* that measure energy, generating some confusion. In principle, there is no clear distinction between a calorimeter and a bolometer. The operation mode is generally determined by the ratio of the characteristic time constant and the average time between the arrival of incident particles or quanta [177].Yet another convention is to refer to *non-equilibrium* LTDs as those detectors that measure incident energy or power by counting excitations that have energy $\gg k_B T$. In such detectors, energy resolution is determined by the statistical fluctuations of the energy partition, similar to conventional ionization detectors but with a much lower average excitation energy and hence a larger number of excitation quanta.

Table 36.4: Low temperature dependence on temperature (T) for specific heat, based on different material classes. In the table below Θ_D is the Debye temperature and T_C is the transition temperature of the superconductor.

Heat Capacity	Material
$\left(\frac{T}{\Theta_D}\right)^3$	Dielectric and diamagnetic
T	Conductor
$\exp\left(-\frac{2T_C}{T}\right)$	Superconductor
$\left(\frac{\mu_B B}{k_B T}\right)^2 \mathrm{sech}^2\left(\frac{\mu_B B}{k_B T}\right)$	Paramagnet (in magnetic field **B**)

A variety of possible detector materials and sensor technologies makes LTDs very versatile and highly customizable. Dielectric, superconducting and paramagnetic materials are often used owing to the fact that at very low temperatures, the specific heat decreases strongly as a function of T (see table 36.4). Superconductors offer additional advantages: the abrupt change in resistance when a material transitions from its normal to superconducting state enables highly sensitive measures of temperature changes. Additionally, the existence of a small (less than a meV) but distinct energy gap that is required to break a Cooper pair, provides a means to measure energy deposits by counting the resulting quasiparticles (QP). QP relaxation processes are typically faster than thermal processes making these detectors suitable for high-rate photo-counting. In summary, both the sensitivity and energy resolution of an LTD benefit greatly from low temperature operation.

36.5.2 *Detector Types*

A generalized LTD calorimeter consists of an absorber in thermal contact with a phonon or quasiparticle sensor, and a thermal link to a heat bath at a constant temperature (see figure

36.11). The absorber provides the mass necessary for the interaction of the particle and a fast and complete thermalization of the deposited energy. The sensor accomplishes the task of translating the particle interaction into measurable parameters. It is generally sensitive to equilibrium phonons (e.g. thermistors and MMCs) and thus provides a precise measurement of the temperature. However, non-equilibrium (e.g. STJ's) and mixed (e.g. TES) phonon sensors have been devised and implemented in many applications as well. The goal of the thermal link is to cool the absorber down to its equilibrium temperature after the absorption of a particle. In monolithic detectors the thermometer and absorber are identical, while in composite detectors the thermometer is attached to a separate absorber. This basic design applies to single-event particle detection as well as for continuous radiation measurement devices. In the case of the latter, a suitable absorber whose mass is irrelevant, *e.g.* an antenna at the end of a waveguide, collects the incident power and dissipates it onto a resistive (*e.g.* Au) film, which is put in contact with a sensor capable of detecting tiny temperature changes (e.g. semiconductor thermistors, transition-edge sensors, and kinetic inductance detectors, to name a few).

Superconducting Tunnel Junctions (STJs) and Kinetic Inductance Detectors (KIDs) are examples of non-equilibrium detectors. STJs exploit Josephson tunnelling of particles and QPs between two superconductors. The superconductors act as radiation absorbers, and are separated by a thin insulating layer. When such a junction is DC biased at a voltage just below the gap voltage, the excess quasiparticles generated by the incoming radiation are detected as a tunneling-current proportional to the incoming energy. Statistical fluctuations in the tunnelling process limit the energy resolution which is given by:

$$\sigma_E = \sqrt{\varepsilon(F+G)E_0}, \tag{36.5}$$

where $\varepsilon \sim \Delta$, the band-gap, while $F \sim 0.2$ and $G > 1$ are the Fano factor and tunnelling fluctuation respectively. STJs have been proven to be excellent single photon and UV-VIS spectroscopic detectors with near theoretical energy resolutions, high detection efficiencies and excellent time resolution. In astrophysics they are used as mixers to detect radiation in the 100 GHz to 1 THz range by exploiting the non-linear behaviour of its current versus voltage characteristic curve. STJs share similar design elements to charge qubits, which are being used for the development of quantum computers. Such qubits have also recently been used in dark matter searches as single photon detectors to evade the standard quantum limit in measurement noise [178]. Despite their extremely good energy resolutions, STJs cannot be scaled-up to produce sensors with large observing volumes due to readout complexity and the difficulty in uniformly suppressing the superconducting Josephson current, which is superimposed on the QP current.

KIDs exploit the variation of the kinetic energy T stored in a superconductor by Cooper pairs whose inertia acts as an effective inductance, given by:

$$T = \frac{1}{2}nm^*v^2 = \frac{1}{2}LI^2 \tag{36.6}$$

where n is the number density of Cooper pairs, $m^* = 2m_e$ is the Cooper pair mass and $I = 2nev$ is the Cooper pair current. $L = m_e/2ne$ is defined as Kinetic Inductance and is inversely proportional to the number of Cooper pairs [179]. When a KID is placed in series with a superconducting capacitor, the resonance frequency of the circuit will be temporarily shifted by incident radiation, which converts Cooper pairs to QPs, thus changing the effective inductance. The presence and amount of radiation is observed as a change in amplitude or phase of a tuned sinusoidal signal that is sent through the circuit. In practice the change in L is small, and very high Q microwave resonance circuits are needed to sense this variation (hence the name MKIDs, for Microwave-KIDs). Furthermore, only areas of the film where large currents are flowing will be sensitive to pair breaking, thus making the response of a distributed KID position dependent. To overcome this issue, QP trapping (by coupling two superconductors with different band-gaps) is used for absorbing optical photons and X-rays. To detect lower frequencies (*e.g.* in the 100-1000 GHz range for CMB) a lumped element resonator (LEKID), with little current variation across the device, is used. The device itself, based on a series LC circuit inductively coupled to a microstrip feed line, can act as the absorber as well as the sensing element in a detector system. Macroscopic devices (few mm^2) can be fabricated by shaping the inductor in the form of a meander coupled to an inter-digitated capacitor [180]. The theoretical noise limit of these devices is governed by generation-recombination noise and takes the form:

$$NEP_{QP} = 2\Delta\sqrt{\frac{n_{QP}}{\tau_{QP}}}, \tag{36.7}$$

where n_{QP} and τ_{QP} are the QP number and lifetime respectively. KIDs are easy to fabricate, very sensitive, broad band and easily multiplexable: they can be coupled with a single microstrip that simultaneously reads 1000s of detectors resonating at different frequencies. They provide therefore a promising solution for deploying large arrays of detectors with applications to high-energy physics, astronomy or CMB measurements, although there are still some challenges, especially at frequencies below 100 GHz, related to their worse noise performance when compared to other LTDs, and to the choice of materials with a sufficiently small energy-gap.

Semiconductor thermistors are resistive elements characterised by a strong dependence of the resistance on the temperature. Usually, they consist of small crystals of germanium or silicon with a dopant concentration slightly below the metal-to-insulator transition. However, they can also be realized in the form of amorphous films such as NbSi. At low temperatures, their resistivity (ρ) is governed by variable range hopping (VRH) conduction and is described by the expression $\rho(T) = \rho_0 \exp\left((T_0/T)^\gamma\right)$, where T_0 and ρ_0 are parameters controlled by the doping level, while γ depends on the compensation level K (ratio of acceptor to donor concentrations). For low values of K it is well approximated by 1/4 while it converges to 1/2 as K increases.

Semiconductor thermistors are high impedance devices (1–100 MΩ) whose performance is usually parameterized in terms of the logarithmic sensitivity $\alpha = \mathrm{d}\log R/\mathrm{d}\log T$, typically in the range of 1–10. Silicon thermistors are fabricated using a multiple ion implantation process in high purity silicon wafers to produce a thin and uniformly doped box-like volume. The best germanium thermistors are fabricated starting from bulk, high-purity germanium crystals doped by means of neutron irradiation in the core of a nuclear reactor, referred to as nuclear transmutation doping (NTD). Individual sensors are then produced by dicing the irradiated samples and finishing them by hand. The great advantage of NTDs is the highly uniform doping level over large volumes which results in a better signal to noise ratio with respect to other doping techniques. The doping level depends on the isotopic composition of the starting material and the irradiation time.

The weak coupling to the heat sink can be provided by the electrical leads used for the read-out. However, nowadays microelectronic planar technologies and silicon micromachining are more commonly preferred, and sensors are suspended on thin silicon nitride membranes or thin silicon beams. Thermistors are read-out in an approximately constant current biasing configuration obtained by inserting large load resistors in the bias circuit, which allows for direct conversion of the thermal signal (ΔT) into a voltage signal (ΔV).

Semiconductor thermistors are very practical to use with some drawbacks. One of these is related to their high impedance which requires a JFET front-end placed as close as possible to the device in order to minimize the signal integration on parasitic electrical capacitances. This can represent a technical challenge, because JFETs must be maintained at significantly higher temperatures ($\gtrapprox$100 K). Furthermore, deviations from the exponential behaviour of the conductivity have been observed at low temperatures. They are usually described in terms of a finite thermal coupling between electrons and phonons which results in an intrinsic limit to the signal rise times, which is of the order of hundreds of milliseconds at temperatures below 100 mK. Nevertheless, semiconductor thermistors are an established and robust technology, and arrays of detectors based on these devices have been widely

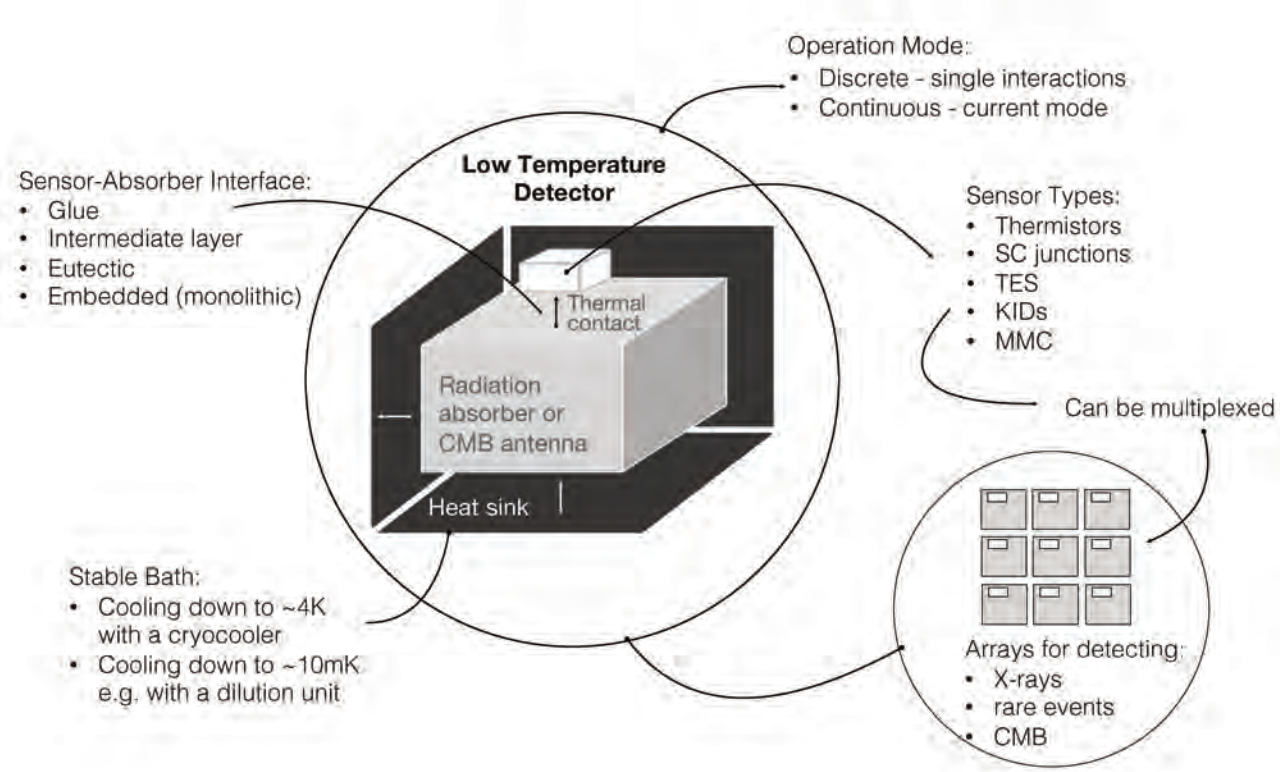

Figure 36.11: A generalized LTD consists of an absorber, a sensor and a thermal link to a stable-temperature bath. Biasing schemes and readout is described in detail in the text for individual sensor types.

used for neutrinoless double beta decay searches, neutrino mass measurements and X-ray spectroscopy. Energy resolutions lower than 5 eV have been achieved with Sn or HgTe absorbers.

Superconducting Transition Edge Sensors (TESs) exploit the sharp transition between superconducting and normal conducting phases, yielding a high sensitivity to temperature variations. Temperature perturbations, and hence resistance changes, are sensed as modulations in the current through the TES. TESs are operated in a constant voltage biasing configuration where Joule heating, arising from the current flowing in the TES, decreases with a rise in resistance, which then brings the TES back to its nominal operating temperature. This electrothermal feedback (EFT) is achieved by providing a TES with a voltage bias whose power, $P_J = V_{\rm bias}^2/R(T)$, heats the TES to its nominal operation point, the superconducting transition temperature. Operation in ETF mode improves linearity, speeds up response (to faster than $\tau = C/G$), and in some cases it provides tolerance for $T_{\rm C}$ (critical temperature) variation between multiple TESs in a large array. The low impedance in this configuration makes them well-suited for readout by SQUID (Superconducting QUantum Interference Device) based amplifiers. Logarithmic sensitivities $\alpha = {\rm d}\log R/{\rm d}\log T$ of the order of several hundreds can be achieved. By using different superconductors, or superconductor-metal pairs patterned in suitable shapes, a wide range of resistances, transition temperatures and time constants are obtainable to meet the requirements of the desired application [181].

Nano-TESs are fabricated by lithographic techniques in the form of long (few μm) and narrow (nm) wires that exhibit extremely small NEPs due to their reduced C and G, enabling single-photon sensing. Superconducting Nanonwire Single-Photon Detectors (SNSPDs) are similarly patterned superconductors or superconducting bilayers maintained at a temperature well below their $T_{\rm C}$. When a DC current just below the critical current is driven through the nanowire, the absorption of a single photon causes the formation of a hot spot that drives the superconductor to a normal conducting state, resulting in a very fast (tens of picoseconds) current pulse through a shunt resistor. For this reason, nano-TESs and SNSPDs are used as single photon detectors for light dark matter and axion searches in applications where large detecting mass is not critical [182].

Magnetic Metallic Calorimeters (MMC) exploit paramagnetic sensors exposed to a weak magnetic field with a weak thermal link to a heat bath. A temperature rise causes a change in the sensor magnetization, which is sensed by a SQUID magnetometer. A common material is an Au:Er mixture, with the addition of a few hundred ppm of enriched ^{166}Er, which is needed to reduce the unwanted contribution of nuclear magnetic moments of other Er isotopes. The read-out is non-dissipative and avoids the noise sources common to the dissipative devices. The use of a metallic host ensures relatively fast time response, since the typical spin-electron relaxation times are of the order of 0.1 microseconds at ~50 mK [183]. For an optimized MMC, the energy resolution is given by $\Delta_E = \sqrt{2k_B T^2 C}\,(\tau_0/\tau_1)^{1/4}$, where τ_0 (order of micro second) and τ_1 (order of milli second) denote the signal rising and decay times respectively [173]. In order to obtain a fast and efficient energy thermalization, MMC are typically fabricated from gold. The intrinsically large heat capacity of the paramagnet does not spoil the temperature sensitivity and allows the use of relatively large gold absorbers without degrading the device performance. Furthermore, thermal isolation from the heat sink is not generally an issue. Owing to the simple concept of these devices, MMC can be precisely customized and fabricated by employing standard microtechnology. Planar MMC arrays characterized by an excellent energy resolution, large dynamic range and good linearity have been successfully used for the detection of soft X-rays.

Performance and technological constraints limit the maximum size of LTDs. To improve overall experimental sensitivities, a large number of sensors must be deployed, typically at temperatures of a few tens of mK, where cooling power is limited to a few μW. To reduce the readout complexity and the heat load at the colder stages, multiplexing (MUX) techniques are often employed. Multiplexing consists of reading multiple detectors out

through a limited number of lines that traverse room temperature to cryogenic temperatures [184]. In frequency-domain multiplexing (FDM), a tuned superconducting LC circuit is placed in series with each sensor, and a frequency comb of AC biases (usually in the MHz range) is sent to a group of sensors in parallel. A synchronous demodulation of the amplified current signal allows the recovery of the resistance variation of each detector. Microwave-multiplexing (μMUX) represents a variation of this concept, based on the usage of rf-SQUIDs, where the frequency comb is in the GHz range. Alternatively, the signal from a single detector can be recovered by readout of one detector at a time (time-domain multiplexing, TDM). KIDs have been gaining popularity owing to the fact that they naturally form resonant circuits, hence multiplexing in the frequency domain is readily achieved by adjusting their capacitance.

36.5.3 *Experimental Applications*

LTDs are sensitive over a wide range of energy, from centimetre wavelength ($\sim$ meV) through the visible spectrum ($\sim$ eV) up to the X-ray domain ($\sim$ keV) and beyond. Several broad categories of LTD applications towards measurements of fundamental physics are described in more detail in the text below and summarized in tables 36.5 and 36.6.

Bolometric detectors are favored as microwave detectors owing to their nearly constant response over frequency, playing an important role in far-infrared astronomy and in the survey of the cosmic background radiation. The high-frequency instrument of the Planck satellite (HFI) used spiderweb bolometers read by NTD-Ge thermistors, but current experiments use mainly TESs or, more recently, KIDs. Depending on the objective of the experiment, antenna coupling or absorber coupling is used. In the former case, the bolometer detects one polarization and one (or a few) modes of the radiation, while absorber-coupled bolometers do not distinguish between polarizations. In order to avoid the absorption or emission from Earth's atmosphere, many (CMB) instruments are operated by observatories located at high altitude, dry places (such as the Atacama desert or Antarctica), balloon-borne platforms, or from space. In Table 36.5, we list a subset of the ongoing or planned CMB experiments (see Section 29 of this Review for the details on present challenges). In the Atacama desert in Chile, CLASS is taking data, POLARBEAR is being upgraded to Simons Array and ACTPol is being upgraded to AdvancedACT-Pol, the next big step being the deployment of the Simons Observatory. At the South Pole, SPTPol has been upgraded to SPT-3G, while BICEP3 and BICEP array will constitute the South Pole Observatory. The most powerful upgrade in terms of both size and sensitivity will be CMB-S4, a consortium of telescopes both at the Pole and in Chile. In the Canary islands, QUIJOTE and GroundBIRD are operating and LSPE/STRIP is in preparation. QUBIC will soon start operations in Argentina and AliCPT is in preparation in Tibet. Regarding balloon projects, SPIDER and EBEX were already launched while LSPE/SWIPE and PIPER will be in the near future. Finally from space, after the success of Planck, LiteBIRD has been selected by the Japan Aerospace Exploration Agency (JAXA) as the next strategic large mission to be launched in the 2020s.

The incoming radiation couples directly to the antenna probes (as in BICEP/Keck) or through micro-machined horn waveguides (AdvancedACT-Pol, CLASS) or lenslets (Simons Array, SPT-3G), depending on the frequency range. All of these experiments have focal planes with hundreds to hundreds of thousands of sensors. To optimize focal plane occupancy, multi-mode or multi-chroic, dual polarization sensitive detectors are used. In the former case, the sensitivity is enhanced by collecting power from a larger number of modes at the expense of angular resolution. In the latter, one single mode of the radiation is focused on a broad band antenna, and on-chip polarization separation and band-pass filters split the signal in different frequency bands directing the power to different absorbers and sensors.

Experimental design is driven by a trade-off between the sensitivity and the complexity of the production processes and readout. On the one front, single-sensor NEP at the level of 10^{-21} W/$\sqrt{\text{Hz}}$ has been achieved in laboratories and research centers. Meanwhile, efforts are in place for the industrialization of the fabrication processes, which is essential for scaling up production for the large number of detectors needed for future experiments.

Massive cryogenic calorimeters have been proposed since the 1980's as particle detectors for the search of rare processes (e.g. dark matter, neutrinoless double beta decay) [185]. Almost simultaneously, the use of arrays of small mass calorimeters was suggested for X-ray astrophysics [186] and precision measurements of the neutrino mass [187, 188]. Although essential to understanding the nature of neutrinos, neutrinoless double beta decay (NDBD) has eluded discovery (or definitive exclusion) for over 50 years. Calorimeteric techniques provide the best sensitivities to NDBD. However, before the advent of low temperature calorimeters (LTC), only a few isotopes (^{48}Ca, ^{136}Xe and ^{76}Ge) could be utilized for NDBD studies with the calorimetric approach. This limitation was removed by the advancement of LTC's, and in particular by CUORE, which takes advantage of the naturally high abundance of ^{130}Te in TeO_2 crystals. Additionally, the operation of CUORE at LNGS [189] has demonstrated that the technical challenges of operating ton-sized LTD detectors in a deep, underground location are surmountable. Currently, the most promising future approach is based on the hybrid approach of scintillating LTCs, which unfortunately cannot be used for ^{130}Te. Now, new projects are being proposed based on different scintillating compounds. In particular ^{100}Mo is the choice of CUPID [190] (NTD thermistors glued to $Li_2{}^{100}MoO_4$ crystals), which will use the same infrastracture of CUORE and follows from the successful operation of several demonstrators (CUPID-0 [191] and CUPID-Mo [192]), and AMORE (MMC sensors on $Ca^{100}MoO_4$ or $Li_2{}^{100}MoO_4$ crystals) [193]. With an energy resolution comparable to germanium diodes and a mass of the order of a ton, these experiments aim to probe the inverted hierarchy of neutrino masses. The slow response of these detectors is still a dominant limitation because pile-up may prove to be a serious background. Extremely pure materials, careful assembly procedures, and deep underground laboratories are therefore necessary.

In the 1980's, the calorimetric technique was recognized as a feasible approach to make a direct measurement of the neutrino mass from the end-point of a beta spectrum. Thus, LTCs were proposed as a possible alternative to the standard spectrometric measurements [194]. Calorimetric measurements offer a number of advantages: i) a weak dependence on the final excited states, ii) no source effects (e.g. self-absorption), and iii) lack of backscattering from the detector. Therefore LTCs provide a faithful reconstruction of the beta spectral shape over a broad energy range below the end-point. However, the difficulty in resolving a small fraction of the spectrum near the end-point is a serious limitation that strongly constrains the source strength and the statistics that need to be accumulated. Such an inconvenience can be mitigated by selecting beta emitters with a small Q value, owing to the fact that the fraction of counts in an interval, δ close to Q, scales as $(\delta/\text{Q})^3$. However, this is generally at the cost of choosing decays with more complex nuclear transitions. In addition, LTCs may be affected by specific systematics (e.g. solid state effects). Ultimately it is recognized that spectrometers and calorimeters have complicated but different systematic effects. It is therefore critical to develop complementary experiments exploiting both techniques.

LTCs were initially proposed as perfect calorimeters to measure the energy spectrum of a low Q beta emitter embedded in an absorber. However, the requirements of excellent energy resolution and a low rate (to avoid pileup) requires a very large number, $O(10^4 - 10^6)$, of small mass devices (micro-calorimeters). Early experiments used ^{187}Re, which is a long-lived beta emitter that is naturally abundant in rhenium samples and is characterised by a very low Q value (2.4709 keV [199]). A large number of ^{187}Re based experiments have been developed over the years (MANU [200], MIBETA [201], MARE [202]). Nowadays a different approach is preferred and is based on the measurement of the atomic radiation following electron capture, typically in ^{163}Ho which is also characterized by a very low Q (2.837 keV [203]). Different experiments have been proposed to face the challenge: ECHo in Germany [195] (using MMC sensors), HOLMES in Italy [196] and NUMECS [197] in the US (using TESs). The very large number

Table 36.5: Some selected experiments using LTDs to measure the CMB. These experiments constrain the physics of inflation and the absolute mass, hierarchy, and number of neutrino species. The experiment location determines the part of the sky that is observed. The size of the aperture determines the angular resolution. The table also indicates the type of sensor used, the number of sensors, the frequency range, and the number of frequency bands. Data for planned upgrades or future experiments are provided in parentheses.

Sub-K CMB Experiment	Location	Aperture	Sensor type	# Sensors (planned)	Frequency (planned)	Bands (planned)
Ground-based

of microcalorimeters needed to obtain sensitivities comparable to spectrometric measurements is a serious challenge, both for the readout and the thermal heat load. An alternative readout based on the use of KIDs, for their multiplexing capability, has been proposed and is presently under development.

Traditional searches for WIMP-like dark matter aim to measure the scatter of a massive dark matter particle off of a target nucleus. Similar to detectors employed for neutrinoless double beta decay, these searches benefit from large-mass absorbers for the target because the dark matter interaction rate scales directly with the number of nuclei in the target and hence its mass. Among the most successful experiments to date, are those that combine the detection of phonons with another channel such as ionization energy (EDELWEISS and SuperCDMS) or scintilation light (CRESST). This simultaneous, dual measurement takes advantage of the fact that the energy deposited in the absorber is partitioned into these channels differently depending on whether the initial particle interaction produces electron or nuclear recoils (or

both). This particle identification allows for the rejection of background from natural sources of radiation, which most commonly manifest themselves as electron recoils in the detector.

In recent years, multi-ton liquid noble detectors have outclassed LTD-based technologies in searches for heavy (>10 GeV/c^2) dark matter owing to their ability to more easily and cheaply scale to large target masses. However, the lower thresholds achieved by LTDs continue to make them the technology of choice for low-mass dark matter searches. New advances have enabled these detectors to reach much lower energy thresholds than previously obtained, albeit sometimes at the cost of being able to detect energy in more than one channel as described above. For example, the use of an electric field to generate Neganov-Trofimov-Luke [204, 205] phonons in proportion to the applied voltage, has enabled the detection of single electron hole pairs in Si detectors with thresholds as low as a few eV (SuperCDMS HVeV). This and similar advances in Ge LTDs (EDELWEISS_SubGeV) have enabled sensitive searches for dark photons and dark matter that scatters off electrons [206, 207]. Next generation experiments such as SPICE/HERALD aim to further optimize the intrinsic energy resolution of TES detectors, coupled with a strategic choice of target materials (superfluid He and polar crystals) to enable sensitivites to dark matter with masses below an MeV/c^2 [208]. Current state-of-the-art axion searches use SQUID based quantum amplifies such as Josephson Parametric Amplifiers along with resonant cavities operating below 100 mK to look for a signal above fluctuations in the thermal noise [209]. Future axion experiments are also working to close the sensitivity gap between particle and wave-like dark matter with the help of LTDs. Broad-band axion searches in the THz range are being proposed, which will make use of TES, SNSPDs or KIDs for single photon detection [210]. Finally, LTD-based dark matter detectors are also actively employed to study coherent neutrino scattering, owing to the fact that the hypothesized signal from dark matter-nucleus scattering is nearly identical to that from neutrino-nucleus scattering, with both inducing nuclear recoils in a similar energy range [211, 212].

36.6 Low-radioactivity background techniques

Revised October 2021 by Al. Ianni (INFN, LNGS) and S. Schönert (Munich Tech. U.).

36.6.1 *Introduction*

The study of rare phenomena in fundamental physics, such as proton decay, neutrinoless double beta decay, dark matter, and MeV-scale neutrino interactions, requires extremely low levels of background radiation. Experiments searching for these rare events record electron recoils or nuclear recoils in the energy scale from a few eV to several MeV. The detector technologies used are multiple from organic and cryogenic liquid scintillators, to bolometers, solide state calorimeters, gaseous detectors, and crystal scintillators. As far as the background contamination is concerned at some extent the application defines the requirements, although the common denominator is that an extreme reduction of all background sources is essential. Leading experiments in rare events search have achieved trace contaminations that generate background events in the region of interest (ROI) as low as order of 50 pBq/kg. As a first and crucial step, a dedicated radiopurity assay of the detector set-up components has to be carried out. Over the last fifty years, special screening and cleaning techniques have been developed to measure and mitigate ultra-low levels of background. In order to characterize the background sources we refer to Heusser [213] and identify the following five main categories:

- environmental radioactivity in the location where the detector is installed;
- radioimpurities in the detector and shielding;
- radon and its progenies;
- cosmic rays and induced radioactivity;
- neutrons from natural fission, (α,n) reactions, and from cosmic-ray muons interactions.

The energy range affected by these background sources is mainly <10 MeV. All materials contain traces of long-lived primordial radioimpurities, such as ^{238}U, ^{232}Th, ^{235}U (^{238}U/^{235}U $\sim$ 138), and ^{40}K (^{40}K/K^{nat} $\sim 1.17\times10^{-4}$). We recall that 1 *ppt* of ^{238}U and ^{232}Th corresponds to 12.36 and 4.06 μBq/kg, respectively; 1 *ppb* of K^{nat} corresponds to 30.25 μBq/kg. In the Earth's crust the abundance of uranium and thorium is of the order of $1-10$ ppm which corresponds to about $10-100$ Bq/kg. Taking into account these contamination levels and the low background requirements, a fundamental background reduction and mitigation is essential to carry out rare phenomena research.

Besides primordial radionuclides other radioactive elements are produced through interactions with matter of secondary cosmic ray particles. Among these so-called cosmogenic radionuclides we recall, in particular, ^{3}H, ^{14}C, ^{7}Be, ^{39}Ar, ^{42}Ar , and, in copper, steel and iron often used as shielding materials, ^{57,60}Co.

A third category of background source in our environment consists of anthropogenic radionuclides. These are artificially produced mainly through nuclear reactions in nuclear power plants, nuclear fuel reprocessing plants, and nuclear weapons testing. Anthropogenic background elements of concern for rare phenomena are ^{85}Kr, ^{137}Cs, ^{241}Am, ^{60}Co, and ^{90}Sr. The concentration of ^{85}Kr ($T_{1/2}$=10.76 y, Q_β=687 keV) in air has been slowly increasing since World War Two with a present activity of order 1 Bq/m^3. As a consequence ^{85}Kr is a crucial background in experiments making use of nitrogen, xenon, and argon from air.

Once detectors components radioactive backgrounds have been assayed and reduced by a careful selection campaign, which can last several years, a further step to push the background level beyond the screening possibilities is needed to reach the required sensitivity. For this purpose special active vetos, purification methods, and offline analyses have been developed. A meticulous background understanding and mitigation is crucial to explain any possible signal excess which may be detected. Background mitigation techniques are based on:

- use of radio-pure materials that absorb ionizing radiation;
- identify radio-pure material for detector construction;
- perform advanced surface and sub-surface cleaning treatment;
- reduce muon flux with underground detector deployment and using active vetos;
- exploit advanced detection and tagging techniques to discriminate signal from background.

In the following we describe radio-assay and background mitigation techniques developed and exploited in the framework of rare phenomena searches in deep underground laboratories.

36.6.2 *Radio-purity assay*

The radio-purity assay of detector components is a basic prerequisite to be carried out in low counting experiments. Several techniques are exploited for radio-purity assay. They are complementary to characterise the radio-purity of materials for shielding or core detector components. Next generation experiments radioassay campaign requires a considerable effort and organization for several years [214–216].

Gamma spectroscopy (GS) via high purity germanium (HPGe) detectors is a powerful and crucial technique [213]. It is nondestructive and thanks to the energy resolution allows to distinguish various radionuclides elements. Radiation from ^{238}U and ^{232}Th comes with all decay products in the radioactive chains. However, if secular equilibrium is broken, this crucial information can be addressed by separating different gamma-ray lines characterizing elements in the decay chains. In the ^{238}U chain one can have three sub-chains out of equilibrium. The first sub-chain can be assessed through ^{234}Th direct progeny of ^{238}U. The second sub-chain, which originates from ^{226}Ra, can be probed by ^{214}Pb and ^{214}Bi. A third sub-chain, which starts from ^{210}Pb, cannot be efficiently probed by GS, yet is of crucial importance and alternative methods must be used. In the ^{232}Th chain again one can probe two sub-chains which can be out of secular equilibrium: the first one through ^{228}Ac from ^{228}Ra; the second from ^{228}Th can be measured through ^{212}Pb, ^{212}Bi and ^{208}Tl. The technology for HPGe operated in deep underground counting facilities [217, 218] or in shallow laboratories with an efficient active

veto shielding [219] has been boosted to sensitivities of the order of 10-100 μBq/kg by carefully selecting detector components, electronics and sample handling systems. The HPGe screening method requires order of ≥ 100 g of material, and weeks of acquisition to produce a reliable measurement.

A second crucial technique is based on inductively coupled plasma mass spectrometry (ICP-MS) [220]. This technique can probe primordial parents activity at the level of 1 μBq/kg. It is a destructive method and often needs special sample preparation on a small quantity of material. The ICP-MS does not measure the radioactive decay of isotopes but determines their concentration. At present, it is the most sensitive and rapid screening technique which allows to select materials at sub-ppt level of impurities. The drawback is that ICP-MS cannot assess whether the uranium and thorium chains are out of equilibrium and to reach ultra-high sensitivities one needs to carefully prepare and handle the samples in a cleanroom environment. ICP-MS screening must be coupled with other methods to properly assess the radio-purity of materials in the context of rare events searches. The Glow Discharge Mass Spectroscopy (GDMS) is a trace element analysis technique somehow alternative to ICP-MS. An advantage of GDMS is the possibility to determine the bulk composition of the sample, assuming homogeneity. Sensitivities of the order of 10 ppt can be achieved.

A third screening technique is based on neutron activation analysis (NAA) [221]. A sample exposed to a neutrons flux can be activated to form radioactive isotopes which can be detected using HPGe detectors or ICP-MS. Considering the difficulties to irradiate samples, this method is not often used. NAA can probe sensitivities at the level of 0.01 μBq/kg. This method is not destructive and the irradiated sample can be used if the activated products are not long-lived.

In case out of secular equilibrium conditions are measured for uranium and thorium from GS screening, a rigorous assessment cannot avoid radon emanation measurements. This matter is discussed in Section 36.6.3.

Complementarity between radio-purity assay techniques is a crucial parameter to design detectors for rare phenomena searches. As it has been pointed out above, requirements can be more stringent than the best sensitivity which can be obtained with the current radioassay techniques. In these cases, a number of prototype detectors have been built and operated to prove the feasibility to reach ultra-low backgrounds.

36.6.3 *Radon and its progeny*

Radon is considered to be rare in nature because most of its isotopes are short-lived. However, ^{222}Rn ($T_{1/2}$=3.82 d) is of particular concern in our context. ^{222}Rn is produced by ^{226}Ra and is a radioactive noble gas which can move within active detector components. ^{222}Rn daughters are heavy metals which can deposit on surfaces. If diffusive ^{222}Rn is supported by ^{226}Ra this can deposit on surfaces the long-lived ^{210}Pb, which is a major concern for low counting experiments. In addition, due to $\sim$100 keV nuclear recoil energies from alpha decays in the ^{226}Ra sub-chain, eventually ^{210}Pb can be implanted into a sub-surface layer of a material exposed to radon. This sub-surface contamination can remain even after surface cleaning. Surface contamination of ^{210}Pb is a serious background for direct dark matter experiments through alpha decay of ^{210}Po, which can generate neutrons by (α,n) reactions. Low energy beta/gamma emissions from ^{210}Pb are also a concern. Therefore, radon-free cleanrooms are essential for the assembly of the detector components. Effective radon abatement systems are available for this purpose.

In assembling and commissioning rare events experiments, special care must be dedicated to the estimate of radon emanation of the materials and continuous radon monitoring. For this purpose different methods for radon assay have been developed and exploited since the beginning of solar neutrino observations. ^{222}Rn atoms are collected inside an exhalation chamber for several half-lives before adsorption and counting. Detection limits of the order of 100 μBq (about 50 ^{222}Rn atoms) can be obtained with $\sim$50 l stainless steel electro-polished chambers [222]. This limit can be pushed down to 30 μBq for 1-liter scale chamber. Emanation of large vessels (cryostats, storage tanks, purification columns) can be determined by collecting exhaled radon into transportable charcoal traps [223]. The same method can be used for liquid samples. In this case instead of evacuating the exhalation chamber into a charcoal trap, He is flushed through a sparger tube for about 10 times the volume of the liquid used. Sensitivities of the order of 10 μBq/kg have been reached.

Nitrogen or synthetic air is often used in rare events experiments for purging, stripping, and assembling the experimental apparatus. These gases might contain radon. In gases ^{222}Rn can also be detected using electrostatic collection of ^{218}Po and ^{214}Po [224, 225]. Sensitivities of the order of mBq/m^3 can be obtained. In Borexino three grades of nitrogen purity were used: regular purity, high purity, and low argon and krypton purity. The regular purity is obtained from boil-off gas and has radon, measured with the method reported above, at the level of $< 100 \mu$Bq/m^3. For stripping the purified liquid scintillator a higher purity is needed. To remove radon from regular purity nitrogen a dedicated absorber plant has been built. This system can reduce radon by a factor of 100. Finally, we mention that not only radon is found in nitrogen. For specific applications the long-lived ^{39}Ar and ^{85}Kr in nitrogen are an important source of background.

36.6.4 *Surface backgrounds*

Surface contamination of long-lived ^{222}Rn daughters can be challenging in low-counting experiments. Considering required sensitivities of the next generation experiments, this source of background has to be properly quantified and mitigated. Therefore, exposure to ^{222}Rn should be monitored and limited to reduce build-up of ^{210}Pb on surfaces. In addition, ^{222}Rn exposure could also produce sub-surface contamination as discussed in Section 36.6.3. For one cannot avoid radon contamination in many circumstances during production of detectors components, it is crucial to quantify the effectiveness of cleaning aiming at removing surface contamination of ^{210}Pb, ^{210}Bi, and ^{210}Po. A simple cleaning procedure, which implies degreasing, wiping, and rinsing the material surfaces is not effective in removing these surface contaminants. Studies of cleaning procedures have been carried out exposing stainless steel, copper and other materials to a strong radon source. Etching and electropolishing with subsequential passivation and rinsing have been investigated in great details. Several recipes for etching and electropolishing have been proposed [226]. Electropolishing has been shown to be very effective in reducing ^{210}Pb, ^{210}Bi, and ^{210}Po from both copper and stainless steel by a factor greater than 100. Etching, which is easier to perform than electropolishing, followed by passivation and rinsing with deionized water is effective in reducing ^{210}Pb and ^{210}Bi by a factor between 50 and 100. However, it is less effective for ^{210}Po, which in copper is very poorly reduced. Removing ^{210}Po from surfaces is crucial, therefore, naturally ^{210}Po contaminated copper and stainless steel surfaces have been deeply investigated with a high sensitivity (1 mBq/m^2) alpha spectrometer [227]. After multi-etching steps (≥ 3), followed by a passivation, a reduction of order 100 has been obtained. On the contrary, static etching (single step) is poorly effective. Electropolishing, or multi-etching are recommended in case copper is in direct contact with the active core of the detector and ultra-high radio-purity is essential or when copper electroforming cannot be used. Electroplating of a thin layer of high radio-pure copper onto the surface of less radio-pure copper has also been investigate to mitigate surface background [227]. This technique is shown to be near-perfect in reducing surface activity of ^{210}Po when electroformed copper is used [227].

Besides copper and steel other materials often used, such as polyethylene and teflon, have been investigated to understand how to reduce radon plate-out contaminations [228].

As far as surface contamination is concerned particulate fallout in cleanrooms environment could be of concern. In general, chemical composition of dust reflects local composition of soil and dust. This is not necessarily true in cleanroom spaces, where the composition of dust depends on ongoing activities and handled materials [229]. The rate of fallout is an important information in the framework of rare events experiments, where assembling is performed in cleanrooms. The ^{210}Pb contamination, inferred from stable lead measured by ICP-MS, due to dust fallout has been

investigated [229]. This contamination has a different origin with respect to ^{210}Pb from radon progeny implantation. Ultimately, one can conclude that radon exposure is more crucial than dust fallout. Therefore, the best practice for rare events experiments to face surface background contamination is to perform cleaning and assembling in a radon-free cleanroom environment.

36.6.5 *Mitigation of backgrounds and active background discrimination*

In this Section we discuss a selection of different background mitigation techniques used in experiments to search for rare events in deep underground laboratories. This includes both the avoidance or reduction of specific radioactive contamination, as well as active background suppression techniques based on specific event features and topologies.

- *Mitigation of ^{222}Rn daughters deposition.* In dark matter direct search radiogenic (α,n) reactions due to radioactive decays are of great concern. The emitted neutron can mimic a nuclear recoil induced by a dark matter particle interaction. In the DarkSide-50 and LUX-ZEPLIN (LZ) experiments to mitigate this background, cleaning of parts and assembling of the dual-phase Time Projection Chamber have been carried out in a radon-free cleanroom with ^{222}Rn activity of the order of $\lesssim 50\,\mathrm{mBq/m^3}$.
- *Underground argon.* Liquid argon is an excellent scintillator to search for dark matter interactions due to the high electron-recoils rejection power through pulse shape discrimination. Events from $\beta-\gamma$ background can be rejected at the level of 10^7 or better with respect to nuclear-recoils. Moreover, liquid argon is used as an active shield in GERDA and the upcoming LEGEND experiment searching for neutrinoless double beta decay. However, a major drawback for dark matter search is due to the fact that atmospheric argon contains about 1 Bq/kg of cosmogenic ^{39}Ar ($T_{1/2}$=269 y, Q_β=565 keV) [230]. For neutrinoless double beta decay search with GERDA and LEGEND, ^{42}Ar ($T_{1/2}$=32.9 y, Q_β=599 keV) with its short lived progeny ^{42}K ($T_{1/2}$=12 h, Q_β=3525 keV) is a major source of background. This limits significantly the dark matter and neutrinoless double beta decay sensitivity search. Therefore, a source of argon with reduced ^{39}Ar and ^{42}Ar is crucial. Centrifugation or differential thermal diffusion are established methods to separate $^{39/42}$Ar and ^{40}Ar. However, this is an expensive method for a large fiducial mass. Argon from underground natural gas reservoirs is shown to contain low ^{39}Ar [231], and it is expected that ^{42}Ar is similar or even better reduced. Therefore, the use of underground argon mitigates the $^{39/42}$Ar backgrounds. DarkSide-50, with a mass of 150 kg of underground argon, has shown that this source of argon contains ^{39}Ar at a level reduced by a factor of $(1.4 \pm 0.3) \times 10^3$ with respect to atmospheric argon.
- *Electro-formed copper.* High radio-purity copper is often used as shielding and as core detectors components. The radioimpurities in the copper can be a dominant source of external background. Copper electro-forming is a technique used to reduce this background component in rare events experiments. Copper electro-forming is a well known process to obtain ultra-high radio-purity copper. This technique has been used in the framework of the Majorana Demonstrator experiment to search for neutrinoless double beta decay and in ANAIS to search for dark matter annual modulation. Subppt levels in uranium and thorium have been achieved with electro-formed copper.
- *Background suppression using topological event information.* In addition to rigorous selection of high-purity target and shielding materials from external radiation, additional active suppression techniques must usually be employed in low background experiments to achieve the appropriate experimental sensitivities. While signal and background events may be indistinguishable if only their energy deposition is measured, their event features may differ significantly in time and space. Liquid scintillators use the characteristic photon emission time distributions to distinguish between electron- and alpha-like signals [232] and nuclear recoils [233], respectively. High-purity germanium detectors use the time evolution of the induced charges to separate point-like signal candidates for neutrinoless double-beta decay events from background signals induced, for example, by gamma interactions with multiple interactions within a crystal, or from β or α events on the n+ or p+ electrodes [234]. The operation of bare high-purity germanium detectors in an instrumented liquid argon shield enabled the GERDA experiment to identify backgrounds with signal-like event topology within the HPGe detectors, but with random energy deposition in the surrounding liquid argon. These synergistic background suppression techniques enabled for a first time ever a quasi background-free search for neutrinoless double beta decays with GERDA.

  The NEXT experiment for neutrinoless double beta decay in ^{136}Xe exploits differences in the spatial ionization patterns of double beta decay and single electron events to reject the background [235]. The former is characterized by two Bragg peaks at opposite ends of the tracks, the latter on the contrary displays only one peak. The combination of topology information and good energy resolution offer a powerful tool for background rejection.

  In addition, the 3D location of detected events in a multivariate fit, which accounts for spacial surface and bulk distributions of signal and background together with other properties, such as pulse shape and topological features, is a powerful tool for background mitigation.
- *Signal detection in rare events searches.* In direct dark matter experiments electron recoil events have to be mitigated with respect to nuclear recoil events. In semiconductor bolometers, operating at a few tens of mK under a bias electric field and used as calorimeters, drifting charges produce a large phonon signal proportional to the ionization, which allows to discriminate electron recoils by the combination of charge and phonon signals [236]. In scintillating bolometers the phonon and light signals are used for the same purpose [237]. Cryogenic scintillators, such as xenon and argon, in time projection chambers offer a strong electron recoils background mitigation through the detection of a primary scintillation signal in liquid and a secondary signal in gas from the drift and extraction of ionization electrons. This background mitigation technique is also being used for neutrinoless double beta decay with ^{136}Xe. The accurate fiducialization and good rejection of multiple-scattering events allow dark matter optimized experiments to attempt a search for this very rare phenomenon.
- *Neutron tagging in dark matter searches.* Present and next generation experiments need large neutron tagging detectors. In DarkSide-50 a dedicated active veto has been developed to both suppress and measure *in situ* the rate of neutron-induced background events [238]. The detector consists of a boron-loaded liquid scintillator, which serves both as shielding against γ-rays and as a tag for neutrons. Neutrons are thermalised and captured on ^{10}B. Experimental data has shown a neutron rejection power greater than 99.1% with 5% concentration of TMB in 30 tonnes pseudocumene-based liquid scintillator. The LZ direct dark matter detector with a central TPC of 7 tonnes of liquid xenon makes use of an outer Gd-loaded liquid scintillator neutron tagging veto, which works similarly to the DarkSide-50 veto, replacing boron with gadolinium. The 22 tonnes liquid scintillator is based on linear alkyl benzene (LAB) as solvent. This detector has been designed to operate with a neutron tagging efficiency greater than 95%. The nuclear-recoil background is reduced by a factor of 10. The XENONnT detector makes use of a cylindrical stainless steel tank filled with Gd-loaded water, which surrounds the cryostat with a TPC of 5.9 tonnes of active liquid xenon. The Gd concentration in water is 0.2% in mass. Neutrons leaving the TPC volume will be moderated and captured by the Gd with a probability of 91%. The gamma-rays emitted after the capture are detected from

Cherenkov photons, providing a neutron tagging.

- *Mitigation of cosmogenic background.* In recent years the required sensitivity to search for dark matter and neutrinoless double beta decay asks for a strong reduction of cosmogenic background. We have emphasized that muons can produce neutrons that can enter the active volume of the detector from the surrounding rock or from external detector components. The yield of these so-called *cosmogenic neutrons* depend on the muon energies and the material properties of the medium the muon passes through. In addition, muons can produce by spallation radioisotopes inside the detector active volume. Cosmogenic backgrounds are a function of depth and experimental design, and can limit the sensitivity to search for rare events. Most of these radioisotopes are short-lived and their effect can be easily removed by an active veto based on the time correlation with a crossing muon. However, a number of cosmogenic radioisotopes are long-lived and they require an important consideration. Mitigation of these cosmogenic backgrounds produced in-situ deep underground are a major challenge for upcoming and future experiments. Optimizing the detector design and analysis strategies at a given depth equals an effective muon flux reduction. In particular, we mention two discrimination techniques for muon-induced isotopes: 1) ^{11}C tagging by a three-fold coincidence between the crossing muon, the capture of the ejected neutron from ^{12}C, and the ^{11}C decay [239]; 2) similar delayed coincidence tagging can be exploited to mitigate the background due to ^{77}Ge and its metastable state ^{77m}Ge, which have been identified as dominant cosmogenic background in the search for neutrinoless double beta decay of ^{76}Ge.
- *Purification.* A number of high efficiency specific purification methods have been developed for different detectors in order to remove long-lived radio-isotopes, ^{39}Ar, ^{85}Kr, and ^{210}Pb progeny. For organic liquid scintillators, distillation and water extraction have been shown to be very effective to reach radiopurity levels of the order of $10^{-5}\mu$Bq/kg or better in uranium and thorium, and $10^{-3}\mu$Bq/kg in ^{210}Pb [240]. Distillation has been used to reduce ^{85}Kr in xenon by a factor of 10^3 [241]. Cryogenic distillation will be used to reduce the isotopic abundance of ^{39}Ar in argon extracted from underground with a 350 m column in the ARIA project [242]. For semiconductors [243] and scintillating crystals [244] zone-refining has been exploited to remove impurities at the cost of a small fraction of material kept after the purification.
- *Direct isotope tagging.* In neutrinoless double beta decay in order to explore half-lives greater than 10^{28} y one needs an almost background-free detector. A robust method to reject backgrounds from radioactive decays would be the identification of the daughter atom of the double beta decaying nucleus: for example, for ^{136}Xe, the $^{136}Ba^{2+}$. Important step forwards to establish a valid and promising method for this tagging have been recently made [245, 246].

37. Radioactivity and Radiation Protection

Revised August 2021 by S. Roesler (CERN) and M. Silari (CERN).

37.1 Definitions [1–3]

It would be desirable if legal protection limits could be expressed in directly measurable *physical quantities*. However, this does not allow quantifying biological effects of the exposure of the human body and its detriment to ionizing radiation.

For this reason, dose limits are expressed in terms of so-called *protection quantities* which, although calculable, are not measurable. Protection quantities are used to quantify the extent of exposure of the human body to ionizing radiation from both whole and partial body external irradiation and from intakes of radionuclides.

In order to demonstrate compliance with dose limits, so-called *operational quantities* are typically used, which aim at providing conservative estimates of protection quantities. Often radiation protection detectors used for individual and area monitoring are calibrated in terms of operational quantities and, thus, these quantities become "measurable".

37.1.1 *Physical quantities*

• **Fluence,** Φ (unit: $1/m^2$): The fluence is the quotient of the sum of the particle track lengths dl in the volume dV

$$\Phi = dl/dV \ .$$

It can also be expressed in terms of number of particles dN incident upon a small sphere of cross-sectional area da

$$\Phi = dN/da \ .$$

• **Absorbed dose,** D (unit: gray, 1 Gy=1 J/kg=100 rad): The absorbed dose is the energy imparted by ionizing radiation in a volume element of a specified material divided by the mass of this volume element.

• **Kerma,** K (unit: gray): Kerma is the sum of the initial kinetic energies of all charged particles set in motion by indirectly ionizing radiation in a volume element of the specified material divided by the mass of this volume element.

• **Linear energy transfer,** L **or** LET (unit: J/m, often given in keV/μm, 1 keV/μm $\approx 1.602 \times 10^{-10}$ J/m): The linear energy transfer is the mean energy, dE, lost by a charged particle owing to collisions with electrons in traversing a distance dl in matter. *Low-LET radiation:* X rays and gamma rays (accompanied by charged particles due to interactions with the surrounding medium) or light charged particles such as electrons that produce sparse ionizing events far apart at a molecular scale ($L < 10$ keV/μm). *High-LET radiation:* neutrons and heavy charged particles that produce ionizing events densely spaced at a molecular scale ($L > 10$ keV/μm). While the above LET definition refers to electronic stopping power only, at low energy nuclear stopping power could be a significant fraction of the total stopping power.

• **Activity,** A (unit: Becquerel, 1 Bq=1/s=27 pCi): Activity is the expectation value of the number of nuclear decays occurring in a given quantity of material per unit time.

37.1.2 *Protection quantities*

• **Organ absorbed dose,** D_T (unit: gray): The mean absorbed dose in an organ or tissue T of mass m_T is defined as

$$D_T = \frac{1}{m_T} \int_{m_T} D dm \ .$$

• **Equivalent dose,** H_T (unit: sievert, 1 Sv=1 J/kg=100 rem):

The equivalent dose H_T in an organ or tissue T is equal to the sum of the absorbed doses $D_{T,R}$ in the organ or tissue caused by different radiation types R weighted with so-called radiation weighting factors w_R:

$$H_T = \sum_R w_R \times D_{T,R} \ .$$

It expresses long-term risks (primarily cancer and leukemia) from low-level chronic exposure. The values for w_R recommended by ICRP [2] are given in Table 37.1.

Table 37.1: Radiation weighting factors, w_R.

Radiation type	w_R
Photons, electrons and muons	1
Neutrons, $E_n < 1$ MeV	$2.5 + 18.2 \times \exp[-(\ln E_n)^2/6]$
1 MeV $\leq E_n \leq$ 50 MeV	$5.0 + 17.0 \times \exp[-(\ln(2E_n))^2/6]$
$E_n >$ 50 MeV	$2.5 + 3.25 \times \exp[-(\ln(0.04E_n))^2/6]$
Protons and charged pions	2
Alpha particles, fission fragments, heavy ions	20

• **Effective dose,** E (unit: sievert): The sum of the equivalent doses, weighted by the tissue weighting factors w_T ($\sum_T w_T = 1$) of several organs and tissues T of the body that are considered to be most sensitive [2], is called "effective dose":

$$E = \sum_T w_T \times H_T \ . \tag{37.1}$$

37.1.3 *Operational quantities*

• **Dose equivalent,** H (unit: sievert): The dose equivalent at a point in tissue is given by:

$$H = D \times Q \tag{37.2}$$

where D is the absorbed dose and Q is the quality factor at that point. The quality factor at a point in tissue, is given by:

$$Q = \frac{1}{D} \int_{L=0}^{\infty} Q(L) D_L dL$$

where D_L is the distribution of D in unrestricted linear energy transfer L at the point of interest, and $Q(L)$ is the quality factor as a function of L. The integration is to be performed over D_L, due to all charged particles, excluding their secondary electrons.

• **Ambient dose equivalent,** $H^*(10)$ (unit: sievert): The dose equivalent at a point in a radiation field that would be produced by the corresponding expanded and aligned field in a 30 cm diameter sphere of unit density tissue (so-called ICRU sphere/tissue with a mass composition of 76.2% oxygen, 11.1% carbon, 10.1% hydrogen and 2.6% nitrogen) at a depth of 10 mm on the radius vector opposing the direction of the aligned field. Ambient dose equivalent is the operational quantity for *area monitoring*.

• **Personal dose equivalent,** $H_p(d)$ (unit: sievert): The dose equivalent in ICRU tissue at an appropriate depth, d, below a specified point on the human body. The specified point is normally taken to be where the individual dosimeter is worn. For the assessment of effective dose, $H_p(10)$ with a depth $d = 10$ mm is chosen, and for the assessment of the dose to the skin and to the hands and feet the personal dose equivalent, $H_p(0.07)$, with a depth $d = 0.07$ mm, is used. Personal dose equivalent is the operational quantity for *individual monitoring*.

37.1.4 *Dose conversion coefficients*

Dose conversion coefficients allow direct calculation of protection or operational quantities from particle fluence and are functions of particle type, energy and irradiation configuration. The most common coefficients are those for effective dose and ambient dose equivalent. The former are based on simulations in which the dose to organs of anthropomorphic phantoms is calculated for approximate actual conditions of exposure, such as irradiation of the front of the body (antero-posterior irradiation) or isotropic irradiation.

Conversion coefficients from fluence to effective dose are given for anterior-posterior irradiation and various particle types in Fig. 37.1 [4]. For example, the effective dose from an anterior-posterior irradiation in a field of 1-MeV neutrons with a fluence of 1 neutron per cm^2 is about 290 pSv. In Monte Carlo simulations such coefficients allow multiplication with fluence at scoring

time such that effective dose to a human body at the considered location is directly obtained.

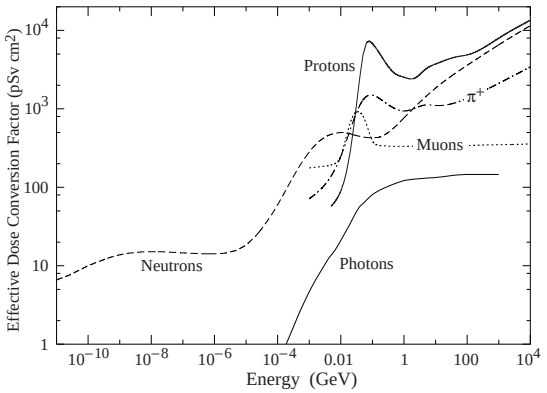

Figure 37.1: Fluence to effective dose conversion coefficients for anterior-posterior irradiation and various particle types [4].

37.2 Radiation levels [5]

• **Natural background radiation**:

On a worldwide average, the annual whole-body dose equivalent due to all sources of natural background radiation ranges from 1.0 to 13 mSv (0.1–1.3 rem) with an annual average of 2.4 mSv [6]. In certain areas values up to 50 mSv (5 rem) have been measured. A large fraction (typically more than 50%) originates from inhaled natural radioactivity, mostly radon and radon daughters [7]. The latter can vary by more than one order of magnitude: it is 0.1–0.2 mSv in open areas, 2 mSv on average in a house and more than 20 mSv in poorly ventilated mines.

• **Cosmic ray background radiation**: At sea level, the whole-body dose equivalent due to cosmic ray background radiation is dominated by muons; at higher altitudes also nucleons contribute. Dose equivalent rates range from less than 0.1 μSv/h at sea level to a few μSv/h at aircraft altitudes. Details on cosmic ray fluence levels are given in the Cosmic Rays section (Sec. 30 of this *Review*).

37.3 Health effects of ionizing radiation

Radiation can cause two types of health effects, deterministic and stochastic:

• **Deterministic effects** are tissue reactions which cause injury to a population of cells if a given threshold of absorbed dose is exceeded. The severity of the reaction increases with dose. The quantity in use for tissue reactions is the absorbed dose, D. When particles other than photons and electrons (low-LET radiation) are involved, a Relative Biological Effectiveness (RBE)-weighted dose may be used. The RBE of a given radiation is the reciprocal of the ratio of the absorbed dose of that radiation to the absorbed dose of a reference radiation (usually X rays) required to produce the same degree of biological effect. It is a complex quantity that depends on many factors such as cell type, dose rate, fractionation, etc.

• **Stochastic effects** are malignant diseases and heritable effects for which the probability of an effect occurring, but not its severity, is a function of dose without threshold.

• **Lethal dose**: The whole-body dose from penetrating ionizing radiation resulting in 50% mortality in 30 days (assuming no medical treatment) is 2.5–4.5 Gy (250–450 rad)[1], as measured internally on the body longitudinal center line. The surface dose varies due to variable body attenuation and may be a strong function of energy.

• **Cancer induction**:

The cancer induction probability is about 5% per Sv on average for the entire population [3].

• **Recommended effective dose limits**: The International Commission on Radiological Protection (ICRP) recommends a limit for radiation workers of 20 mSv effective dose per year averaged over 5 years, with the provision that the dose should not exceed 50 mSv in any single year [3]. The limit in the EU-countries and Switzerland is 20 mSv per year, in the U.S. it is 50 mSv per year (5 rem per year). Many physics laboratories in the U.S. and elsewhere set lower limits. The effective dose limit for the general public is typically 1 mSv per year.

[1] RBE-weighted when necessary

37.4 Prompt neutrons at accelerators

Neutrons dominate the radiation environment outside thick shielding (*e.g.*, > 1 m of concrete) for high energy (> a few hundred MeV) electron and hadron accelerators. In addition, for accelerators with energies above about 10 GeV, muons contribute significantly at small angles with regard to the beam, even behind several meters of shielding. Another special case are synchrotron light sources where particular care has to be taken to shield the very intense low-energy photons extracted from the electron synchrotron into the experimental areas. Due to its importance at high energy accelerators this section focuses on prompt neutrons.

37.4.1 *Electron accelerators*

At electron accelerators, neutrons are generated via photonuclear reactions from bremsstrahlung photons. Neutron production takes place above a threshold value which varies from 10 to 19 MeV for light nuclei (with important exceptions, such as 2.23 MeV for deuterium and 1.67 MeV for beryllium) and from 4 to 6 MeV for heavy nuclei. It is commonly described by different mechanisms depending on the photon energy: the giant dipole resonance interactions (from threshold up to about 30 MeV, often the dominant process), the quasi-deuteron effect (between 30 MeV and a few hundred MeV), the delta resonance mechanism (between 200 MeV and a few GeV) and the vector meson dominance model at higher energies.

The giant dipole resonance reaction consists in a collective excitation of the nucleus, in which neutrons and protons oscillate in the direction of the photon electric field. The oscillation is damped by friction in a few cycles, with the photon energy being transferred to the nucleus in a process similar to evaporation. Nucleons emitted in the dipolar interaction have an anisotropic angular distribution, with a maximum at 90°, while those leaving the nucleus as a result of evaporation are emitted isotropically with a Maxwellian energy distribution described as [8]:

$$\frac{dN}{dE_n} = \frac{E_n}{T^2} e^{-E_n/T} \ , \tag{37.3}$$

where T is a nuclear 'temperature' (in units of MeV) characteristic of the particular target nucleus and its excitation energy. For heavy nuclei the 'temperature' generally lies in the range of $T =$ 0.5–1.0 MeV. Neutron yields from semi-infinite targets per kW of electron beam power are plotted in Fig. 37.2 as a function of the electron beam energy [8].

While for thick targets neutron production is mainly due to photonuclear interactions, for thin targets (thickness of fractions of the radiation length) electronuclear interactions are the dominating process.

Typical neutron energy spectra outside of concrete (80 cm thick, 2.35 g/cm^3) and iron (40 cm thick) shields are shown in Fig. 37.3. In order to compare these spectra to those caused by proton beams (see below) the spectra are scaled by a factor of 100, which roughly corresponds to the difference in the high energy hadronic cross sections for photons and hadrons (*e.g.*, the fine structure constant). The shape of these spectra are generally characterized by a low-energy peak at around 1 MeV (evaporation neutrons) and a high-energy shoulder at around 70–80 MeV. In case of concrete shielding, the spectrum also shows a pronounced peak at thermal neutron energies.

37.4.2 *Proton accelerators*

At proton accelerators, neutron yields emitted per incident proton by different target materials are roughly independent of proton energy between 20 MeV and 1 GeV, and are given by the ratio C : Al : Cu-Fe : Sn : Ta-Pb = 0.3 : 0.6 : 1.0 : 1.5 : 1.7 [12]. Above about 1 GeV, the neutron yield is proportional to E^m, where $0.80 \leq m \leq 0.85$ [13].

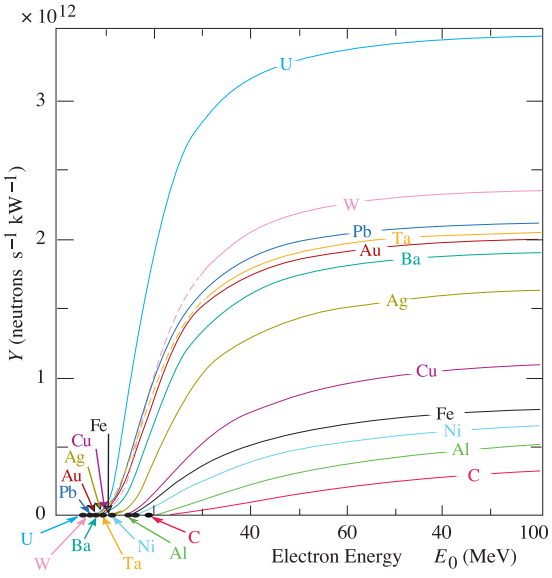

Figure 37.2: Neutron yields from semi-infinite targets per kW of electron beam power, as a function of the electron beam energy, disregarding target self-shielding [8].

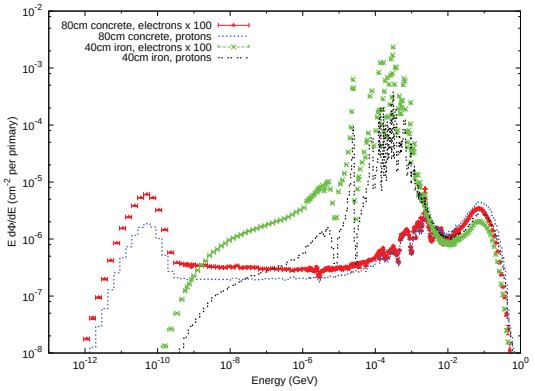

Figure 37.3: Neutron energy spectra calculated with the FLUKA code [9–11] from 25 GeV proton and electron beams on a thick copper target. Spectra are evaluated at 90° to the beam direction behind 80 cm of concrete or 40 cm of iron. All spectra are normalized per beam particle. For better visualization, spectra for electron beam are multiplied by a factor of 100.

Typical neutron energy spectra outside of concrete and iron shielding are shown in Fig. 37.3. Here, the radiation fields are caused by a 25 GeV proton beam interacting with a thick copper target. The comparison of these spectra with those for an electron beam of the same energy reflects the difference in the hadronic cross sections between photons and hadrons above a few 100 MeV. Differences are increasing towards lower energies because of different interaction mechanisms. Furthermore, the slight shift in energy above about 100 MeV follows from the fact that the energies of the interacting photons are lower than 25 GeV. Apart from this the shapes of the two spectra are similar.

The neutron-attenuation length is shown in Fig. 37.4 for concrete and mono-energetic broad-beam conditions. It reaches an asymptotic value of about 117 g/cm^2 above 200 MeV. As the cascade through thick shielding is carried by particles with energies between about 100 MeV and 300 MeV (in this energy range non-elastic cross sections are at minimum and are dominated by quasi-elastic processes leading to low attenuation) this value is equal to the equilibrium attenuation length for particles emitted at 90° in concrete.

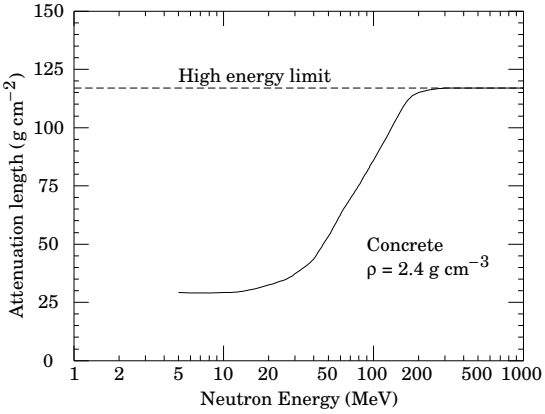

Figure 37.4: The variation of the attenuation length for mono-energetic neutrons in concrete as a function of neutron energy [12].

37.5 Photon sources

The dose equivalent rate in tissue (in mSv/h) from a gamma point source emitting one photon of energy E (in MeV) per second at a distance of 1 m is $4.6\times10^{-9}\,\mu_{en}/\rho\,E$, where μ_{en}/ρ is the mass energy absorption coefficient. The latter has a value of 0.029 ± 0.004 cm^2/g for photons in tissue over an energy range between 60 keV and 2 MeV (see Ref. [14] for tabulated values).

Similarly, the dose equivalent rate in tissue (in mSv/h) at the surface of a semi-infinite slab of uniformly activated material containing 1 Bq/g of a gamma emitter of energy E (in MeV) is $2.9\times10^{-4}\,R_\mu\,E$, where R_μ is the ratio of the mass energy absorption coefficients of the photons in tissue and in the material.

37.6 Accelerator-induced radioactivity

Typical medium- and long-lived activation products in metallic components of accelerators are ^{22}Na, ^{46}Sc, ^{48}V, ^{51}Cr, ^{54}Mn, ^{55}Fe, ^{59}Fe, ^{56}Co, ^{57}Co, ^{58}Co, ^{60}Co, ^{63}Ni and ^{65}Zn. Gamma-emitting nuclides dominate doses from external irradiation at longer decay times (more than one day) while at short decay times β^+ emitters are also important (through photons produced by β^+ annihilation). Due to their short range, β^- emitters are relevant, for example, only for dose to the skin and eyes or for doses due to inhalation or ingestion. Fig. 37.5 and Fig. 37.6 illustrate the contributions of gamma and β^+ emitters to the total dose rate at 12.4 cm distance to a copper sample [15]. The sample was activated by the stray radiation field created by a 120 GeV mixed hadron beam dumped in a copper target during about 8 hours at intensities between $10^7 - 10^8$ hadrons per second. Here, the contributions by individual nuclides were calculated analytically assuming exponential decay of the nuclide inventory present at 20 minute cooling time. The total dose rate, however, also includes decay chains and as such also contributions from daughter nuclides.

Typically, dose rates at a certain decay time are mainly determined by radionuclides having a half-life of the order of the decay time. Extended irradiation periods might be an exception to this general rule as in this case the activity of long-lived nuclides can build up sufficiently so that it dominates that one of short-lived even at short cooling times.

Activation in concrete is dominated by ^{24}Na (short decay time) and ^{22}Na (long decay time). Both nuclides can be produced either by low-energy neutron reactions on the sodium-component in the concrete or by spallation reactions on silicon, calcium and other constituents such as aluminum. At long decay times nuclides of radiological interest in activated concrete can also be ^{60}Co, ^{152}Eu, ^{154}Eu and ^{134}Cs, all of which produced by (n,γ)-reactions with traces of natural cobalt, europium and cesium, Thus, such trace elements might be important even if their content in concrete is only a few parts per million or less by weight.

The explicit simulation of radionuclide production with general-purpose Monte Carlo codes has become the most commonly applied method to calculate induced radioactivity and its radiologi-

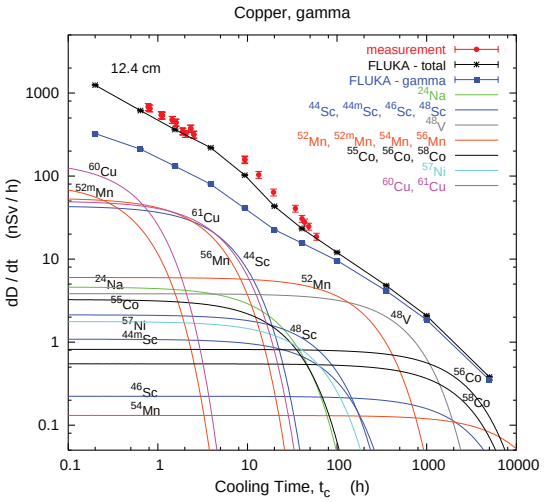

Figure 37.5: Contribution of individual gamma-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [15].

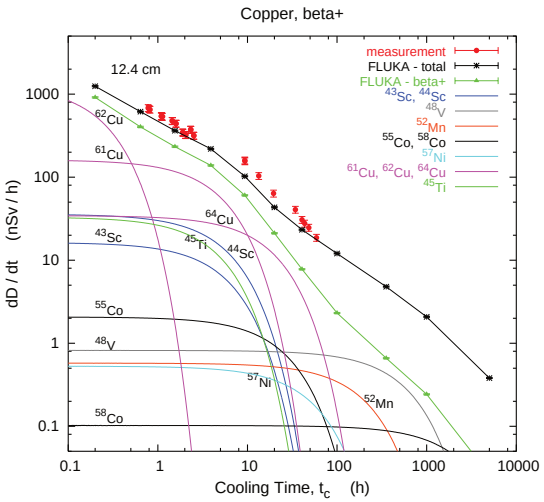

Figure 37.6: Contribution of individual positron-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [15].

cal consequences [15] (see also Sec. 37.8). They are complemented by analytical codes based on folding particle fluence spectra with nuclide production cross sections. ActiWiz [16, 17] is an example of such a code targeting the domain of radiological characterization and material optimization. It allows for calculating nuclide inventories by convolution of fluence spectra with nuclide production data for 85 chemical elements and arbitrary compounds from threshold to an energy of 100 TeV.

37.7 Radiation protection instrumentation

The capacity to distinguish and measure the high-LET (mostly neutrons) and the low-LET components (photons, electrons, muons) of the radiation field at workplaces is of primary importance to evaluate the exposure of personnel. At proton accelerators the prompt dose equivalent outside a shield is mainly due to neutrons, with some contribution from photons and, to a minor extent, charged particles. At high-energy electron accelerators the dominant stray radiation during operation consists also of neutrons, because the shielding is normally thick enough to absorb most of the bremsstrahlung photons. Most of the personnel exposure at accelerator facilities is often received during maintenance interventions, and is due to gamma/beta radiation coming from residual radioactivity in accelerator components.

Radiation detectors used both for radiation surveys and area monitoring are normally calibrated in ambient dose equivalent $H^*(10)$.

37.7.1 *Neutron detectors*

• **Rem counters:** A rem counter [18] is a portable detector consisting of a thermal neutron counter embedded in a polyethylene moderator, with a response function that approximately follows the curve of the conversion coefficients from neutron fluence to $H^*(10)$ over a wide energy range. Conventional rem counters provide a response to neutrons up to approximately 10-15 MeV, extended-range units are heavier as they include a converter consisting of a material with high mass number to correctly measure $H^*(10)$ up to several hundred MeV [19].

• **Bonner Sphere Spectrometer (BSS):** A BSS [20] consists of a thermal neutron detector at the centre of moderating spheres of different diameters made of polyethylene (PE) or a combination of PE and a high-A material to enhance its response to high energy neutrons (similar to rem counters). Each sphere has a different response function versus neutron energy, and the neutron energy, at which the sensitivity peaks, increases with sphere diameter. The energy resolution of the system is rather low but satisfactory for radiation protection purposes. The neutron spectrum is obtained by unfolding the experimental counts of the BSS with its response matrix by a computer code that is often based on an iterative algorithm such as GRAVEL [21] and MAXED [22]. BSS exist in active (using ^{3}He or BF_3 proportional counters or ^{6}LiI scintillators) and passive versions (using CR-39 track detectors or LiF), for use *e.g.* in strongly pulsed fields. With ^{3}He counters the discrimination with respect to gamma rays and noise is excellent.

• **Bubble detectors:** A bubble detector [23] is a dosimeter based on a super-heated emulsion (super-heated droplets suspended in a gel) contained in a vial and acting as a continuously sensitive, miniature bubble chamber. The total number of bubbles evolved from the radiation-induced nucleation of drops gives an integrated measure of the total neutron exposure. Various techniques exist to record and count the bubbles, *e.g.*, visual inspection, automated reading with video cameras or acoustic counting. Bubble detectors are insensitive to low-LET radiation. Super-heated emulsions are used as personal, area and environmental dosimeters, as well as neutron spectrometers.

• **Track etched detectors:** Track etched detectors (TEDs) [24] are based on the preferential dissolution of suitable, mostly insulator, materials along the damage trails of charged particles of sufficiently high-energy deposition density. The detectors are effectively not sensitive to radiation which deposits the energy through the interactions of particles with low LET. These dosimeters are generally able to determine neutron ambient dose equivalent down to around 100 μSv. They are used both as personal dosimeters and for area monitoring, *e.g.*, in BSS.

37.7.2 *Photon detectors* [25]

• **Geiger Müller (GM) counters:** GM counters are low cost devices simple to operate. They work in pulse mode and since they only count radiation-induced events, any spectrometric information is lost. In general they are calibrated in terms of air kerma, for instance in a ^{60}Co field. The response of GM counters to photons is constant within 15% for energies up to 2 MeV and shows considerable energy dependence above.

• **Ionization chambers:** Ionization chambers are gas-filled detectors used both as hand-held instruments (*e.g.*, for radiation surveys) and environmental monitors. They are normally operated in current mode although pulse-mode operation is also possible. They possess a relatively flat response to a wide range of X- and gamma ray energies (typically from 10 keV to several MeV), can measure radiation over a wide intensity range and are capable of discriminating between the beta and gamma components of a radiation field (by use of, *e.g.*, a beta window). Pressurized ion chambers (filled, *e.g.*, with Ar or H gas to several tens of bars) are used for environmental and stray radiation monitoring applications. They have good sensitivity to neutrons and charged hadrons in addition to low LET radiation (gammas and muons),

with the response function to the former being strongly non-linear with energy.

• **Proportional counters:** Proportional counters are another type of gas-filled detector, operated in pulse mode. They are normally of cylindrical geometry, with a thin central wire (the anode) on the axis of a hollow tube (the cathode). The initial electron charge created by the interaction of the radiation with the gas is amplified by the multiplication process (Townsend avalanche) produced by the strong electric field in a narrow volume around the anode. The generated pulses are still proportional to the original number of ion pairs but are much larger than in an ionization chamber, yielding a much improved signal-to-noise ratio. Proportional counters are also used for neutron detection: the rem counter and BSS discussed in the previous sections typically employ ^{3}He or BF_3 filled tubes with a large sensitivity to thermal neutrons.

• **Scintillators:** Scintillation-based detectors are used in radiation protection as hand-held probes and in fixed installations, *e.g.*, portal monitors. A scintillation detector or counter is obtained coupling a scintillator to an electronic light sensor such as a photomultiplier tube (PMT), a photodiode or a silicon photomultiplier (SiPM). There is a wide range of scintillating materials, inorganic (such as CsI and BGO), organic or plastic; they find application in both photon dosimetry and spectrometry.

37.7.3 *Operation in pulsed radiation fields*

There are many practical situations with particle accelerators used for scientific, industrial and medical applications where the time structure of the stray radiation limits the use of active monitors or requires specifically designed electronics. Pulsed neutron and gamma fields may be present because of beam losses at, *e.g.*, targets, collimators and beam dumps. The time duration of a single burst can range from a few ns to about 1 ms with a typical repetition rate in the range 0.1–100 Hz. Conventional detectors generally suffer from dead time effects and have strong limitations in the measurements of pulsed fields. Severe under response has been observed, *e.g.*, in commercial rem counters, with tremendous underestimation of the ambient dose equivalent, $H^*(10)$, up to three orders of magnitude [26]. The common techniques used to correct the response of radiation detectors which include dead-time corrections operate properly in a steady-state radiation field, whereas it is much more difficult to cope with dead time losses in a pulsed radiation field of unknown time structure and burst dose. Generally speaking the monitoring instrumentation must be chosen on the basis of the knowledge of the radiation field. Detectors with specifically designed electronics must be employed in pulsed field conditions in place of conventional rem counters for neutrons, such as the LUPIN detector [27]. If real-time monitoring is not required, passive detectors or dosimeters such as TEDs mentioned in Sec. 37.7.1 or LiF mentioned in Sec. 37.7.5 can be employed, as they are insensitive to the time structure of the radiation.

37.7.4 *Operation in presence of magnetic fields*

There may be circumstances in which a radiation survey needs to be performed in the presence of a magnetic field. This may be the case for example for measurements on activated detector components in the underground experimental areas of CERN LHC experiments without switching off the intense magnetic field ofthe detectors; or measurements of the residual radioactivity of permanent magnets sometimes used in particle accelerators. In hospitals, one of most advanced diagnostic modalities is PET-MRI, in which PET imaging uses radioactive substances (radiopharmaceuticals) in proximity of the strong magnetic field of the MRI scanner. Most of the commercial survey meters do not operate correctly or do not function at all in the presence of even comparatively weak magnetic fields below 0.3 T, and often already at 0.1 T. This is either because of the presence of components in their electronics sensitive to magnetic field (e.g. inductive elements), ferromagnetic materials in general (such as shells, screws and frames), battery drain/heating or LCD screen failure. An instrument called B-RAD has recently been developed [28] that overcomes the above limitations and is now commercially available. It is a hand-held instrument for gamma dose rate and gamma spectrometry measurements, consisting of a central unit (housing a microcontroller, magnetic field insensitive electronic circuitry, the battery and two displays) and a probe connected through a cable, certified to operate up to 3 T fields. The probe uses a $LaBr_3$(Ce) crystal coupled to an array of silicon photomultipliers. The excellent scintillation properties and the high photon resolution of the scintillator (3.3% FWHM at 662 keV) make the device capable of operating in the energy range from 30 keV to 2 MeV photons with a very fast response.

37.7.5 *Personal dosimeters*

Personal dosimeters, calibrated in $H_p(10)$, are worn by persons exposed to ionizing radiation for professional reasons to record the dose received. They are typically passive detectors, either film, track etched detectors, ^{6}Li/^{7}Li-based dosimeters (*e.g.* LiF), optically stimulated luminescence (OSL) or radiophotoluminescence detectors (RPL) but semi-active dosimeters using miniaturized ion-chambers also exist, like the Direct Ion Storage (DIS) dosimeters in use at CERN.

Electronic personal dosimeters are small active units for on-line monitoring of individual exposure, designed to be worn on the body. They can give an alarm on both the integral dose received or dose rate once a pre-set threshold is exceeded.

37.8 Monte Carlo codes for radiation protection studies

The use of general-purpose particle interaction and transport Monte Carlo codes is often the most accurate and efficient choice for assessing radiation protection quantities at accelerators. Due to the vast spread of such codes to all areas of particle physics and the associated extensive benchmarking with experimental data, the modeling has reached an unprecedented accuracy. Furthermore, most codes allow the user to simulate all aspects of a high energy particle cascade in one and the same run: from the first interaction of a TeV nucleus over the transport and re-interactions (hadronic and electromagnetic) of the produced secondaries, to detailed nuclear fragmentation, the calculation of radioactive decays and even of the electromagnetic shower caused by the radiation from such decays. A brief account of the codes most widely used for radiation protection studies at high energy accelerators is given in the following.

• **FLUKA [9–11]:** FLUKA is a general-purpose particle interaction and transport code. It comprises all features needed for radiation protection, such as detailed hadronic and nuclear interaction models up to 10 PeV, full coupling between hadronic and electromagnetic processes and numerous variance reduction options. The latter include weight windows, region importance biasing, and leading particle, interaction, and decay length biasing (among others). The capabilities of FLUKA are unique for studies of induced radioactivity, especially with regard to nuclide production, decay, and transport of residual radiation. In particular, particle cascades by prompt and residual radiation are simulated in parallel based on the microscopic models for nuclide production and a solution of the Bateman equations for activity build-up and decay.

• **GEANT4 [29–31]:** GEANT4 is an object-oriented toolkit consisting of a kernel that provides the framework for particle transport, including tracking, geometry description, material specifications, management of events and interfaces to external graphics systems. The kernel also provides interfaces to physics processes. It allows the user to freely select the physics models that best serve the particular application needs. Implementations of interaction models exist over an extended range of energies, from optical photons and thermal neutrons to high-energy interactions required for the simulation of accelerator and cosmic ray experiments. To facilitate the use of variance reduction techniques, general-purpose biasing methods such as importance biasing, weight windows, and a weight cut-off method have been introduced directly into the toolkit. Other variance reduction methods, such as leading particle biasing for hadronic processes, come with the respective physics packages.

• **MARS15 [32,33]:** The MARS15 code system is a set of Monte Carlo programs for the simulation of hadronic and electromagnetic cascades. It covers a wide energy range: 1 keV to 100 TeV for muons, charged hadrons, heavy ions and electromagnetic showers;

and 0.00215 eV to 100 TeV for neutrons. Hadron-nucleus interactions as well as practically all other strong, weak and electromagnetic interactions in the entire energy range can be simulated either inclusively or exclusively. MARS15 uses ENDFB-VII nuclear data to handle interactions of neutrons with energies below 14 MeV. Several variance reduction techniques, such as weight windows, particle splitting, and Russian roulette, are available. A tagging module allows tagging the origin of a given signal for source term or sensitivity analyses. The geometry module allows either a basic solid body representation option or a ROOT-based powerful engine. Further features of MARS15 include a MAD-MARS merge for a convenient creation of accelerator models and multi-turn tracking and cascade simulation in accelerator and beamline lattices.

• **MCNP6 [34, 35]:** MCNP6 is the latest version of the Monte Carlo N-Particle transport (MCNP) family of neutron interaction and transport codes and, therefore, features one of the most comprehensive and detailed descriptions of the related physical processes. It transports 37 different particle types, including ions and electromagnetic particles. The neutron interaction and transport modules use standard evaluated data libraries mixed with physics models where such libraries are not available. The transport is continuous in energy. MCNP6 contains one of the most powerful implementations of variance reduction techniques. Spherical mesh weight windows can be created by a generator in order to focus the simulation time on certain spatial regions of interest. In addition, a more generalized phase space biasing is also possible through energy- and time-dependent weight windows. Other biasing options include pulse-height tallies with variance reduction and criticality source convergence acceleration.

• **PHITS [36, 37]:** The Particle and Heavy-Ion Transport code System PHITS was among the first general-purpose codes to simulate the transport and interactions of heavy ions in a wide energy range, from 10 MeV/nucleon to 100 GeV/nucleon. It is based on the high-energy hadron transport code NMTC/JAM that was extended to heavy ions. The transport of low-energy neutrons employs cross sections from evaluated nuclear data libraries such as ENDF and JENDL below 20 MeV. Electromagnetic interactions are simulated based on the ITS code in the energy range between 1 keV and 100 MeV for electrons and positrons and between 1 keV and 100 GeV for photons. Several variance reduction techniques, including weight windows and region importance biasing, are available.

$^{228}_{90}$Th	1.912 y	6α:	5.341 – 8.785		0.239	44%
		3β^-:	0.334 – 2.246		0.583	31%
					2.614	36%
$\left(\rightarrow {}^{224}_{88}$Ra 361 d $\rightarrow {}^{220}_{86}$Rn 55.8 s $\rightarrow {}^{216}_{84}$Po 0.148 s $\rightarrow {}^{212}_{82}$Pb 10.64 h $\rightarrow {}^{212}_{83}$Bi 60.54 m $\rightarrow {}^{212}_{84}$Po 300 ns$\right)$						
$^{241}_{95}$Am	432.6 y	α	5.443	13%	0.060	36%
			5.486	84%	Np L x rays	38%
$^{241}_{95}$Am/Be	432.6 y	neutrons ($\langle E\rangle = 4$ MeV) and γ's (4.43 MeV from $^{9}_{4}\mathrm{Be}(\alpha, n)$)				
$^{244}_{96}$Cm	18.11 y	α	5.763	24%	Pu L x rays	$\sim 9\%$
			5.805	76%		
$^{252}_{98}$Cf	2.645 y	α	6.076	15%		
		(97%)	6.118	82%		
Fission (3.1%): Average 7.8 γ's/fission; $\langle E_\gamma\rangle = 0.88$ MeV ≈ 4 neutrons/fission; $\langle E_n\rangle = 2.14$ MeV						

"Emission probability" is the probability per decay of a given emission; because of cascades these may total more than 100%. Only principal emissions are listed. EC means electron capture, and e^- means monoenergetic internal conversion (Auger) electron. The intensity of 0.511 MeV e^+e^- annihilation photons depends upon the number of stopped positrons. Endpoint $\beta^\pm$ energies are listed. In some cases when energies are closely spaced, the γ-ray values are approximate weighted averages. Radiation from short-lived daughter isotopes is included where relevant.

Isotopic data may be found at `https://physics.nist.gov/cgi-bin/Compositions/stand_alone.pl`.

Neutron sources: See *e.g.* J. Liu *et al.*, "Neutron Calibration Sources in the Daya Bay Experiment" [1]. $^{51}_{24}$Cr calibration of neutrino detectors is discussed in *e.g.* J.N. Abdurashitov *et al.*, "Measurement of the response of a gallium metal solar neutrino experiment to neutrinos from a ^{51}Cr source" [2]. The use of $^{75}_{34}$Se and other isotopes has also been proposed.

39. Probability

Revised August 2021 by G. Cowan (RHUL).

39.1 General

Further discussion of probability can be found, *e.g.*, in Refs. [1–8].

An abstract definition of probability can be given by considering a set S, called the sample space, and possible subsets $A, B, \ldots$, the interpretation of which is left open. The probability P is a real-valued function defined by the following axioms due to Kolmogorov [9]:

1. For every subset A in S, $P(A) \geq 0$;
2. For disjoint subsets (*i.e.*, $A \cap B = \emptyset$), $P(A \cup B) = P(A) + P(B)$;
3. $P(S) = 1$.

In addition, one defines the conditional probability $P(A|B)$ (read as P of A given B) as

$$P(A|B) = \frac{P(A \cap B)}{P(B)} \ . \tag{39.1}$$

From this definition and using the fact that $A \cap B$ and $B \cap A$ are the same, one obtains *Bayes' theorem*,

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)} \ . \tag{39.2}$$

From the three axioms of probability and the definition of conditional probability, one obtains the *law of total probability*,

$$P(B) = \sum_i P(B|A_i)P(A_i) \ , \tag{39.3}$$

for any subset B and for disjoint A_i with $\cup_i A_i = S$. This can be combined with Bayes' theorem (Eq. (39.2)) to give

$$P(A|B) = \frac{P(B|A)P(A)}{\sum_i P(B|A_i)P(A_i)} \ , \tag{39.4}$$

where the subset A could, for example, be one of the A_i.

The most commonly used interpretation of the elements of the sample space are outcomes of a repeatable experiment. The probability $P(A)$ is assigned a value equal to the limiting frequency of occurrence of A. This interpretation forms the basis of *frequentist statistics*.

The elements of the sample space might also be interpreted as *hypotheses*, *i.e.*, statements that are either true or false, such as 'The mass of the W boson lies between 80.3 and 80.5 GeV.' Upon repetition of a measurement, however, such statements are either always true or always false, *i.e.*, the corresponding probabilities in the frequentist interpretation are either 0 or 1. Using *subjective probability*, however, $P(A)$ is interpreted as the degree of belief that the hypothesis A is true. Subjective probability is used in *Bayesian* (as opposed to frequentist) statistics. Bayes' theorem can be written

$$P(\text{theory}|\text{data}) \propto P(\text{data}|\text{theory})P(\text{theory}) \ , \tag{39.5}$$

where 'theory' represents some hypothesis and 'data' is the outcome of the experiment. Here $P(\text{theory})$ is the *prior* probability for the theory, which reflects the experimenter's degree of belief before carrying out the measurement, and $P(\text{data}|\text{theory})$ is the probability to have gotten the data actually obtained, given the theory, which is also called the *likelihood*.

Bayesian statistics provides no fundamental rule for obtaining the prior probability, which may depend on previous measurements, theoretical prejudices, *etc.* Once this has been specified, however, Eq. (39.5) tells how the probability for the theory must be modified in the light of the new data to give the *posterior* probability, $P(\text{theory}|\text{data})$. As Eq. (39.5) is stated as a proportionality, the probability must be normalized by summing (or integrating) over all possible hypotheses.

39.2 Random variables

A *random variable* is a numerical characteristic assigned to an element of the sample space. In the frequency interpretation of probability, it corresponds to an outcome of a repeatable experiment. Let x be a possible outcome of an observation. If x can take on any value from a continuous range, we write $f(x;\theta)dx$ as the probability that the measurement's outcome lies between x and $x + dx$. The function $f(x;\theta)$ is called the *probability density function* (p.d.f.), which may depend on one or more parameters θ. If x can take on only discrete values (*e.g.*, the non-negative integers), then we use $f(x;\theta)$ to denote the probability to find the value x. In the following the term p.d.f. is often taken to cover both the continuous and discrete cases, although technically the term density should only be used in the continuous case.

The p.d.f. is always normalized to unity. Both x and θ may have multiple components and are then often written as vectors. If θ is unknown, we may wish to estimate its value from a given set of measurements of x; this is a central topic of *statistics* (see Sec. 40).

The *cumulative distribution function* $F(a)$ is the probability that $x \leq a$:

$$F(a) = \int_{-\infty}^{a} f(x)\,dx \ . \tag{39.6}$$

Here and below, if x is discrete-valued, the integral is replaced by a sum. The endpoint a is expressly included in the integral or sum. Then $0 \leq F(x) \leq 1$, $F(x)$ is nondecreasing, and $P(a < x \leq b) = F(b) - F(a)$. If x is discrete, $F(x)$ is flat except at allowed values of x, where it has discontinuous jumps equal to $f(x)$.

Any function of random variables is itself a random variable, with (in general) a different p.d.f. The *expectation value* of any function $u(x)$ is

$$E[u(x)] = \int_{-\infty}^{\infty} u(x)\,f(x)\,dx \ , \tag{39.7}$$

assuming the integral is finite. The expectation value is linear, *i.e.*, for any two functions u and v of x and constants c_1 and c_2, $E[c_1u + c_2v] = c_1E[u] + c_2E[v]$.

The n^{th} moment of a random variable x is

$$\alpha_n \equiv E[x^n] = \int_{-\infty}^{\infty} x^n f(x)\,dx \ , \tag{39.8a}$$

and the n^{th} central moment of x (or moment about the mean, α_1) is

$$m_n \equiv E[(x-\alpha_1)^n] = \int_{-\infty}^{\infty} (x-\alpha_1)^n f(x)\,dx \ . \tag{39.8b}$$

The most commonly used moments are the mean μ and variance σ^2:

$$\mu \equiv \alpha_1 \ , \tag{39.9a}$$

$$\sigma^2 \equiv V[x] \equiv m_2 = \alpha_2 - \mu^2 \ . \tag{39.9b}$$

The mean is the location of the "center of mass" of the p.d.f., and the variance is a measure of the square of its width. Note that $V[cx + k] = c^2V[x]$. It is often convenient to use the *standard deviation* of x, σ, defined as the square root of the variance.

Any odd moment about the mean is a measure of the skewness of the p.d.f. The simplest of these is the dimensionless coefficient of skewness $\gamma_1 = m_3/\sigma^3$.

The fourth central moment m_4 provides a convenient measure of the tails of a distribution. For the Gaussian distribution (see Sec. 39.4), one has $m_4 = 3\sigma^4$. The *kurtosis* is defined as $\gamma_2 = m_4/\sigma^4 - 3$, *i.e.*, it is zero for a Gaussian, positive for a *leptokurtic* distribution with longer tails, and negative for a *platykurtic* distribution with tails that die off more quickly than those of a Gaussian.

The *quantile* x_α is the value of the random variable x at which the cumulative distribution is equal to α. That is, the quantile

is the inverse of the cumulative distribution function, *i.e.*, $x_\alpha = F^{-1}(\alpha)$. An important special case is the *median*, $x_{\rm med}$, defined by $F(x_{\rm med}) = 1/2$, *i.e.*, half the probability lies above and half lies below $x_{\rm med}$. (More rigorously, $x_{\rm med}$ is a median if $P(x \geq x_{\rm med}) \geq 1/2$ and $P(x \leq x_{\rm med}) \geq 1/2$. If only one value exists, it is called '*the* median.')

Under a monotonic change of variable $x \to y(x)$, the quantiles of a distribution (and hence also the median) obey $y_\alpha = y(x_\alpha)$. In general the expectation value and *mode* (most probable value) of a distribution do not, however, transform in this way.

Let x and y be two random variables with a *joint* p.d.f. $f(x,y)$. The *marginal* p.d.f. of x (the distribution of x with y unobserved) is

$$f_1(x) = \int_{-\infty}^{\infty} f(x,y)\,dy \ , \tag{39.10}$$

and similarly for the marginal p.d.f. $f_2(y)$. The *conditional* p.d.f. of y given fixed x (with $f_1(x) \neq 0$) is defined by $f_3(y|x) = f(x,y)/f_1(x)$, and similarly $f_4(x|y) = f(x,y)/f_2(y)$. From these, we immediately obtain Bayes' theorem (see Eqs. (39.2) and (39.4)),

$$f_4(x|y) = \frac{f_3(y|x)f_1(x)}{f_2(y)} = \frac{f_3(y|x)f_1(x)}{\int f_3(y|x')f_1(x')\,dx'} \ . \tag{39.11}$$

The mean of x is

$$\mu_x = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} x\,f(x,y)\,dx\,dy = \int_{-\infty}^{\infty} x\,f_1(x)\,dx \ , \tag{39.12}$$

and similarly for y. The *covariance* of x and y is

$$\mathrm{cov}[x,y] = E[(x-\mu_x)(y-\mu_y)] = E[xy] - \mu_x\mu_y \ . \tag{39.13}$$

A dimensionless measure of the covariance of x and y is given by the *correlation coefficient*,

$$\rho_{xy} = \mathrm{cov}[x,y]/\sigma_x\sigma_y \ , \tag{39.14}$$

where σ_x and σ_y are the standard deviations of x and y. It can be shown that $-1 \leq \rho_{xy} \leq 1$.

Two random variables x and y are *independent* if and only if

$$f(x,y) = f_1(x)f_2(y) \ . \tag{39.15}$$

If x and y are independent, then $\rho_{xy} = 0$; the converse is not necessarily true. If x and y are independent, $E[u(x)v(y)] = E[u(x)]E[v(y)]$, and $V[x+y] = V[x]+V[y]$; otherwise, $V[x+y] = V[x]+V[y]+2\mathrm{cov}[x,y]$, and $E[uv]$ does not necessarily factorize.

Consider a set of n continuous random variables $\boldsymbol{x} = (x_1,\ldots,x_n)$ with joint p.d.f. $f(\boldsymbol{x})$, and a set of n new variables $\boldsymbol{y} = (y_1,\ldots,y_n)$, related to $\boldsymbol{x}$ by means of a function $\boldsymbol{y}(\boldsymbol{x})$ that is one-to-one, *i.e.*, the inverse $\boldsymbol{x}(\boldsymbol{y})$ exists. The joint p.d.f. for $\boldsymbol{y}$ is given by

$$g(\boldsymbol{y}) = f(\boldsymbol{x}(\boldsymbol{y}))|J| \ \ , \tag{39.16}$$

where $|J|$ is the absolute value of the determinant of the square matrix $J_{ij} = \partial x_i/\partial y_j$ (the Jacobian determinant). If the transformation from $\boldsymbol{x}$ to $\boldsymbol{y}$ is not one-to-one, the $\boldsymbol{x}$-space must be broken into regions where the function $\boldsymbol{y}(\boldsymbol{x})$ can be inverted, and the contributions to $g(\boldsymbol{y})$ from each region summed.

Given a set of functions $\boldsymbol{y} = (y_1,\ldots,y_m)$ with $m < n$, one can construct $n-m$ additional independent functions, apply the procedure above, then integrate the resulting $g(\boldsymbol{y})$ over the unwanted y_i to find the marginal distribution of those of interest.

For a one-to-one transformation of discrete random variables, the probability is obtained by simple substitution; no Jacobian is necessary because in this case f is a probability rather than a probability density. If the transformation is not one-to-one, then one must sum the probabilities for all values of the original variable that contribute to a given value of the transformed variable. If f depends on a set of parameters $\boldsymbol{\theta}$, a change to a different parameter set $\boldsymbol{\eta}(\boldsymbol{\theta})$ is made by simple substitution; no Jacobian is used.

39.2.1 *Propagation of errors*

Consider n random variables $\boldsymbol{x} = (x_1,\ldots,x_n)$ and m functions $\boldsymbol{y}(\boldsymbol{x}) = (y_1(\boldsymbol{x}),\ldots,y_m(\boldsymbol{x}))$. Suppose here that the mean values $\boldsymbol{\mu} = (\mu_1,\ldots,\mu_n) = E[\boldsymbol{x}]$ are known, although in practice they will only be estimated, and suppose we also know or have estimated the covariance matrix $V_{ij} = \mathrm{cov}[x_i,x_j]$. The goal of *error propagation* is to determine the covariance matrix for the functions, $U_{ij} = \mathrm{cov}[y_i,y_j]$. In particular, the diagonal elements $U_{ii} = V[y_i]$ give the variances. The new covariance matrix can be found by expanding the functions $\boldsymbol{y}(\boldsymbol{x})$ about the means $\boldsymbol{\mu}$ to first order in a Taylor series. Using this one finds

$$U_{ij} \approx \sum_{k,l} \left.\frac{\partial y_i}{\partial x_k}\frac{\partial y_j}{\partial x_l}\right|_{\boldsymbol{\mu}} V_{kl} \ . \tag{39.17}$$

This can be written in matrix notation as $U \approx AVA^T$ where the matrix of derivatives A is

$$A_{ij} = \left.\frac{\partial y_i}{\partial x_j}\right|_{\boldsymbol{\mu}} \ \ , \tag{39.18}$$

and A^T is its transpose. The approximation is exact if $\boldsymbol{y}(\boldsymbol{x})$ is linear. If this is not the case, the approximation can break down if, for example, $\boldsymbol{y}(\boldsymbol{x})$ is significantly nonlinear close to $\boldsymbol{\mu}$ in a region of a size comparable to the standard deviations of $\boldsymbol{x}$.

39.3 Characteristic functions

The characteristic function $\phi(u)$ associated with the p.d.f. $f(x)$ is essentially its Fourier transform, or the expectation value of e^{iux}:

$$\phi(u) = E\left[e^{iux}\right] = \int_{-\infty}^{\infty} e^{iux} f(x)\,dx \ . \tag{39.19}$$

Once $\phi(u)$ is specified, the p.d.f. $f(x)$ is uniquely determined and vice versa; knowing one is equivalent to the other. Characteristic functions are useful in deriving a number of important results about moments and sums of random variables.

It follows from Eqs. (39.8) and (39.19) that the n^{th} moment of a random variable x that follows $f(x)$ is given by

$$i^{-n}\ \left.\frac{d^n\phi}{du^n}\right|_{u=0} = \int_{-\infty}^{\infty} x^n f(x)\,dx = \alpha_n \ . \tag{39.20}$$

Thus it is often easy to calculate all the moments of a distribution defined by $\phi(u)$, even when $f(x)$ cannot be written down explicitly.

If the p.d.f.s $f_1(x)$ and $f_2(y)$ for independent random variables x and y have characteristic functions $\phi_1(u)$ and $\phi_2(u)$, then the characteristic function of the weighted sum $ax+by$ is $\phi_1(au)\phi_2(bu)$. The rules of addition for several important distributions (*e.g.*, that the sum of two Gaussian distributed variables also follows a Gaussian distribution) easily follow from this observation.

Let the (partial) characteristic function corresponding to the conditional p.d.f. $f_2(x|z)$ be $\phi_2(u|z)$, and the p.d.f. of z be $f_1(z)$. The characteristic function after integration over the conditional value is

$$\phi(u) = \int \phi_2(u|z)f_1(z)\,dz \ . \tag{39.21}$$

Suppose we can write ϕ_2 in the form

$$\phi_2(u|z) = A(u)e^{ig(u)z} \ . \tag{39.22}$$

Then

$$\phi(u) = A(u)\phi_1(g(u)) \ . \tag{39.23}$$

The cumulants (semi-invariants) κ_n of a distribution with characteristic function $\phi(u)$ are defined by the relation

$$\phi(u) = \exp\left[\sum_{n=1}^{\infty}\frac{\kappa_n}{n!}(iu)^n\right] = \exp\left(i\kappa_1 u - \frac{1}{2}\kappa_2 u^2 + \ldots\right) \ . \tag{39.24}$$

The values κ_n are related to the moments α_n and m_n. The first few relations are

$$\begin{aligned}\kappa_1 &= \alpha_1 \ (= \mu, \text{ the mean})\\ \kappa_2 &= m_2 \ = \alpha_2 - \alpha_1^2 \ (= \sigma^2, \text{ the variance})\\ \kappa_3 &= m_3 = \alpha_3 - 3\alpha_1\alpha_2 + 2\alpha_1^3.\end{aligned} \tag{39.25}$$

39.4 Commonly used probability distributions

Table 39.1 gives a number of common probability density functions and corresponding characteristic functions, means, and variances. Further information may be found in Refs. [1–8] [10], and [11], which has particularly detailed tables. Monte Carlo techniques for generating each of them may be found in our Sec. 42.4 and in Ref. [10]. We comment below on all except the trivial uniform distribution.

39.4.1 *Binomial and multinomial distributions*

A random process with exactly two possible outcomes which occur with fixed probabilities is called a *Bernoulli* process. If the probability of obtaining a certain outcome (a "success") in an individual trial is p, then the probability of obtaining exactly r successes ($r = 0, 1, 2, \ldots, N$) in N independent trials, without regard to the order of the successes and failures, is given by the binomial distribution $f(r; N, p)$ in Table 39.1. If r and s are binomially distributed with parameters (N_r, p) and (N_s, p), then $t = r + s$ follows a binomial distribution with parameters $(N_r + N_s, p)$. If there are are m possible outcomes for each trial having probabilities $p_1, p_2, \ldots, p_m$, then the joint probability to find $r_1, r_2, \ldots, r_m$ of each outcome after a total of N independent trials is given by the multinomial distribution as shown in Table 39.1. We can regard outcome i as "success" and all the rest as "failure", so individually, any of the r_i follow a binomial distribution for N trials and a success probability p_i.

39.4.2 *Poisson distribution*

The Poisson distribution $f(n; \nu)$ gives the probability of finding exactly n events in a given interval of x (*e.g.*, space or time) when the events occur independently of one another and of x at an average rate of ν per the given interval. The variance σ^2 equals ν. It is the limiting case $p \to 0$, $N \to \infty$, $Np = \nu$ of the binomial distribution. The Poisson distribution approaches the Gaussian distribution for large ν.

For example, a large number of radioactive nuclei of a given type will result in a certain number of decays in a fixed time interval. If this interval is small compared to the mean lifetime, then the probability for a given nucleus to decay is small, and thus the number of decays in the time interval is well modeled as a Poisson variable.

39.4.3 *Normal or Gaussian distribution*

The normal (or Gaussian) probability density function $f(x; \mu, \sigma^2)$ given in Table 39.1 has mean $E[x] = \mu$ and variance $V[x] = \sigma^2$. Comparison of the characteristic function $\phi(u)$ given in Table 39.1 with Eq. (39.24) shows that all cumulants κ_n beyond κ_2 vanish; this is a unique property of the Gaussian distribution. Some other properties are:

$$\begin{aligned}&P(x \text{ in range } \mu \pm \sigma) = 0.6827,\\ &P(x \text{ in range } \mu \pm 0.6745\sigma) = 0.5,\\ &E[|x - \mu|] = \sqrt{2/\pi}\sigma = 0.7979\sigma,\\ &\text{half-width at half maximum} = \sqrt{2\ln 2}\,\sigma = 1.177\sigma.\end{aligned}$$

For a Gaussian with $\mu = 0$ and $\sigma^2 = 1$ (the *standard normal*) the cumulative distribution, often written $\Phi(x)$, is related to the error function erf by

$$F(x; 0, 1) \equiv \Phi(x) = \frac{1}{2}\left[1 + \mathrm{erf}(x/\sqrt{2})\right] \ . \tag{39.26}$$

The error function and standard Gaussian are tabulated in many references (*e.g.*, Ref. [11, 12]) and are available in software packages such as ROOT [13]. For a mean μ and variance σ^2, replace x by $(x - \mu)/\sigma$. The probability of x in a given range can be calculated with Eq. (40.71).

For x and y independent and normally distributed, $z = ax + by$ follows a normal p.d.f. $f(z; a\mu_x + b\mu_y, a^2\sigma_x^2 + b^2\sigma_y^2)$; that is, the weighted means and variances add.

The Gaussian derives its importance in large part from the *central limit theorem*:

If independent random variables $x_1, \ldots, x_n$ are distributed according to *any* p.d.f. with finite mean and variance, then the sum $y = \sum_{i=1}^{n} x_i$ will have a p.d.f. that approaches a Gaussian for large n. If the p.d.f.s of the x_i are not identical, the theorem still holds under somewhat more restrictive conditions. The mean and variance are given by the sums of corresponding terms from the individual x_i. Therefore, the sum of a large number of fluctuations x_i will be distributed as a Gaussian, even if the x_i themselves are not.

For a set of n Gaussian random variables $\boldsymbol{x}$ with means $\boldsymbol{\mu}$ and covariances $V_{ij} = \mathrm{cov}[x_i, x_j]$, the p.d.f. for the one-dimensional Gaussian is generalized to

$$f(\boldsymbol{x}; \boldsymbol{\mu}, V) = \frac{1}{(2\pi)^{n/2}\sqrt{|V|}} \exp\left[-\frac{1}{2}(\boldsymbol{x} - \boldsymbol{\mu})^T V^{-1} (\boldsymbol{x} - \boldsymbol{\mu})\right] \ , \tag{39.27}$$

where the determinant $|V|$ must be greater than 0. For diagonal V (independent variables), $f(\boldsymbol{x}; \boldsymbol{\mu}, V)$ is the product of the p.d.f.s of n Gaussian distributions.

For $n = 2$, $f(\boldsymbol{x}; \boldsymbol{\mu}, V)$ is

$$\begin{aligned}f(x_1, x_2;\ \mu_1, \mu_2, \sigma_1, \sigma_2, \rho) &= \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}}\\ \times\ \exp&\left\{\frac{-1}{2(1-\rho^2)}\left[\frac{(x_1-\mu_1)^2}{\sigma_1^2} - \frac{2\rho(x_1-\mu_1)(x_2-\mu_2)}{\sigma_1\sigma_2} + \frac{(x_2-\mu_2)^2}{\sigma_2^2}\right]\right\}.\end{aligned} \tag{39.28}$$

The characteristic function for the multivariate Gaussian is

$$\phi(\boldsymbol{u}; \boldsymbol{\mu}, V) = \exp\left[i\boldsymbol{\mu}\cdot\boldsymbol{u} - \frac{1}{2}\boldsymbol{u}^T V \boldsymbol{u}\right] \ . \tag{39.29}$$

If the components of $\boldsymbol{x}$ are independent, then Eq. (39.29) is the product of the characteristic functions of n Gaussians.

For an n-dimensional Gaussian distribution for $\boldsymbol{x}$ with mean $\boldsymbol{\mu}$ and covariance matrix V, the marginal distribution for any single x_i is is a one-dimensional Gaussian with mean μ_i and variance V_{ii}. The equation $(\boldsymbol{x} - \boldsymbol{a})^T V^{-1} (\boldsymbol{x} - \boldsymbol{a}) = C$, where C is any positive number, defines an n-dimensional ellipse centered about $\boldsymbol{a}$. If $\boldsymbol{a}$ is equal to the mean $\boldsymbol{\mu}$, then C is a random variable obeying the χ^2 distribution for n degrees of freedom, which is discussed in the following section. The probability that $\boldsymbol{x}$ lies outside the ellipsoid for a given value of C is given by $1 - F_{\chi^2}(C; n)$, where F_{χ^2} is the cumulative χ^2 distribution. This may be read from Fig. 40.1. For example, the "s-standard-deviation ellipsoid" occurs at $C = s^2$. For the two-variable case ($n = 2$), the point $\boldsymbol{x}$ lies outside the one-standard-deviation ellipsoid with 61% probability. The use of these ellipsoids as indicators of probable error is described in Sec. 40.4.2.2; the validity of those indicators assumes that $\boldsymbol{\mu}$ and V are correct.

39.4.4 *Log-normal distribution*

If a random variable y follows a Gaussian distribution with mean μ and variance σ^2, then $x = e^y$ follows a log-normal distribution, as given in Table 39.1. As a consequence of the central limit theorem described in Sec. 39.4.3, the distribution of the product of a large number of positive random variables approaches a log-normal. It is bounded below by zero and is thus well suited for modeling quantities that are intrinsically non-negative such as an efficiency. One can implement a log-normal model for a random variable x by defining $y = \ln x$ so that y follows a Gaussian distribution.

39.4.5 χ^2 *distribution*

If $x_1, \ldots, x_n$ are independent Gaussian random variables, the sum $z = \sum_{i=1}^{n} (x_i - \mu_i)^2/\sigma_i^2$ follows the χ^2 p.d.f. with n *degrees*

Table 39.1: Some common probability density functions, with corresponding characteristic functions and means and variances. In the Table, $\Gamma(k)$ is the gamma function, equal to $(k-1)!$ when k is an integer; ${}_1F_1$ is the confluent hypergeometric function of the 1st kind [11].

Distribution	Probability density function f (variable; parameters)	Characteristic function $\phi(u)$	Mean	Variance
Uniform	$f(x;a,b) = \begin{cases} 1/(b-a) & a \le x \le b \\ 0 & \text{otherwise} \end{cases}$	$\frac{e^{ibu}-e^{iau}}{(b-a)iu}$	$\frac{a+b}{2}$	$\frac{(b-a)^2}{12}$
Binomial	$f(r;N,p) = \frac{N!}{r!(N-r)!}\, p^r q^{N-r}$ $r = 0,1,2,\ldots,N; \quad 0 \le p \le 1; \quad q = 1-p$	$(q+pe^{iu})^N$	Np	Npq
Multinomial	$f(r_1,\ldots,r_m;N,p_1,\ldots,p_m) = \frac{N!}{r_1!\cdots r_m!} p_1^{r_1}\cdots p_m^{r_m}$	$\left(\sum_{k=1}^m p_k e^{iu_k}\right)^N$	$E[r_i] = Np_i$	$\mathrm{cov}[r_i,r_j] = Np_i(\delta_{ij}-p_j)$
Poisson	$f(n;\nu) = \frac{\nu^n e^{-\nu}}{n!}$; $n = 0,1,2,\ldots$; $\nu > 0$	$\exp[\nu(e^{iu}-1)]$	ν	ν
Normal (Gaussian)	$f(x;\mu,\sigma^2) = \frac{1}{\sigma\sqrt{2\pi}}\, \exp(-(x-\mu)^2/2\sigma^2)$	$\exp(i\mu u - \frac{1}{2}\sigma^2 u^2)$	μ	σ^2
Multivariate Gaussian	$f(\boldsymbol{x};\boldsymbol{\mu},V) = \frac{1}{(2\pi)^{n/2}\sqrt{\lvert V\rvert}} \times \exp\left[-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^T V^{-1}(\boldsymbol{x}-\boldsymbol{\mu})\right]$ $-\infty < x_j < \infty; \quad -\infty < \mu_j < \infty; \quad \lvert V\rvert > 0$	$\exp\left[i\boldsymbol{\mu}\cdot\boldsymbol{u} - \frac{1}{2}\boldsymbol{u}^T V \boldsymbol{u}\right]$	$\boldsymbol{u}$	V_{jk}
Log-normal	$f(x;\mu,\sigma^2) = \frac{1}{\sigma\sqrt{2\pi}}\frac{1}{x}\, \exp(-(\ln x-\mu)^2/2\sigma^2)$ $0 < x < \infty; \quad -\infty < \mu < \infty; \quad \sigma > 0$	—	$\exp(\mu+\sigma^2/2)$	$\exp(2\mu+\sigma^2) \times[\exp(\sigma^2)-1]$
χ^2	$f(z;n) = \frac{z^{n/2-1}e^{-z/2}}{2^{n/2}\Gamma(n/2)}$; $z \ge 0$	$(1-2iu)^{-n/2}$	n	$2n$
Student's t	$f(t;n) = \frac{1}{\sqrt{n\pi}}\, \frac{\Gamma[(n+1)/2]}{\Gamma(n/2)} \left(1+\frac{t^2}{n}\right)^{-(n+1)/2}$ $-\infty < t < \infty$; n not required to be integer	—	0 for $n > 1$	$n/(n-2)$ for $n > 2$
Gamma	$f(x;\lambda,k) = \frac{x^{k-1}\lambda^k e^{-\lambda x}}{\Gamma(k)}$; $0 \le x < \infty$; k not required to be integer	$(1-iu/\lambda)^{-k}$	k/λ	k/λ^2
Beta	$f(x;\alpha,\beta) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1}(1-x)^{\beta-1}$ $0 \le x \le 1$	${}_1F_1(\alpha;\alpha+\beta;iu)$	$\frac{\alpha}{\alpha+\beta}$	$\frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$

of freedom, which we denote by $\chi^2(n)$. More generally, for n correlated Gaussian variables as components of a vector $\boldsymbol{X}$ with covariance matrix V, $z = \boldsymbol{X}^T V^{-1} \boldsymbol{X}$ follows $\chi^2(n)$ as in the previous section. For a set of z_i, each of which follows $\chi^2(n_i)$, $\sum z_i$ follows $\chi^2(\sum n_i)$. For large n, the χ^2 p.d.f. approaches a Gaussian with a mean and variance given by $\mu = n$ and $\sigma^2 = 2n$, respectively (here the formulae for μ and σ^2 are valid for all n).

The χ^2 p.d.f. is often used in evaluating the level of compatibility between observed data and a hypothesis for the p.d.f. that the data might follow. This is discussed further in Sec. 40.3.2 on significance tests.

39.4.6 *Student's t distribution*

Suppose that y and $x_1,\ldots,x_n$ are independent and Gaussian distributed with mean 0 and variance 1. We then define

$$z = \sum_{i=1}^{n} x_i^2 \quad \text{and} \quad t = \frac{y}{\sqrt{z/n}}\,. \tag{39.30}$$

The variable z thus follows a $\chi^2(n)$ distribution. Then t is distributed according to Student's t distribution with n degrees of freedom, $f(t;n)$, given in Table 39.1.

If defined through gamma functions as in Table 39.1, the parameter n is not required to be an integer. As $n \to \infty$, the distribution approaches a Gaussian, and for $n = 1$ it is a *Cauchy* or *Breit–Wigner* distribution.

As an example, consider the *sample mean* $\overline{x} = \sum x_i/n$ and the *sample variance* $s^2 = \sum(x_i-\overline{x})^2/(n-1)$ for normally distributed x_i with unknown mean μ and variance σ^2. The sample mean has a Gaussian distribution with a variance σ^2/n, so the variable $(\overline{x}-\mu)/\sqrt{\sigma^2/n}$ is normal with mean 0 and variance 1. The quantity $(n-1)s^2/\sigma^2$ is independent of this and follows $\chi^2(n-1)$. The ratio

$$t = \frac{(\overline{x}-\mu)/\sqrt{\sigma^2/n}}{\sqrt{(n-1)s^2/\sigma^2(n-1)}} = \frac{\overline{x}-\mu}{\sqrt{s^2/n}} \tag{39.31}$$

is distributed as $f(t;n-1)$. The unknown variance σ^2 cancels, and t can be used to test the hypothesis that the true mean is some particular value μ.

39.4.7 *Gamma distribution*

For a process that generates events as a function of x (*e.g.*, space or time) according to a Poisson distribution, the distance in x from an arbitrary starting point (which may be some particular event) to the k^{th} event follows a *gamma* distribution, $f(x;\lambda,k)$. The Poisson parameter μ is λ per unit x. The special case $k = 1$ (*i.e.*, $f(x;\lambda,1) = \lambda e^{-\lambda x}$) is called the *exponential* distribution. A sum of k' exponential random variables x_i is distributed as $f(\sum x_i;\lambda,k')$.

The parameter k is not required to be an integer. For $\lambda = 1/2$ and $k = n/2$, the gamma distribution reduces to the $\chi^2(n)$ distribution.

39.4.8 *Beta distribution*

The beta distribution describes a continuous random variable x in the interval $[0,1]$. By scaling and translation one can easily generalize it to have arbitrary endpoints. In Bayesian inference about the parameter p of a binomial process, if the prior p.d.f. is a beta distribution $f(p;\alpha,\beta)$ then the observation of r successes out of N trials gives a posterior beta distribution $f(p;r+\alpha,N-r+\beta)$ (Bayesian methods are discussed further in Sec. 40). The uniform distribution is a beta distribution with $\alpha = \beta = 1$.

40. Statistics

Revised August 2021 by G. Cowan (RHUL).

This chapter gives an overview of statistical methods used in high-energy physics. In statistics, we are interested in using a given sample of data to make inferences about a probabilistic model, *e.g.*, to assess the model's validity or to determine the values of its parameters. There are two main approaches to statistical inference, which we may call frequentist and Bayesian.

In frequentist statistics, probability is interpreted as the limiting frequency of the outcome of a repeatable experiment. The most important tools in this framework are parameter estimation, covered in Section 40.2, statistical tests, discussed in Section 40.3, and confidence intervals, which are constructed so as to cover the true value of a parameter with a specified probability, as described in Section 40.4.2. Note that in frequentist statistics one does not define a probability for a hypothesis or for the value of a parameter.

In Bayesian statistics, the subjective interpretation of probability is used to quantify one's *degree of belief* in a hypothesis. This allows one to define a probability density function (p.d.f.) for a parameter, which reflects one's knowledge about where its true value lies.

Bayesian methods provide a natural means to include additional information, which in general may be subjective; in fact they *require* prior probabilities for the hypotheses (or parameters) in question, *i.e.*, the degree of belief about the parameters' values, before carrying out the measurement. Using Bayes' theorem (Eq. (39.4)), the prior degree of belief is updated by the data from the experiment. Bayesian methods for interval estimation are discussed in Sections 40.4.1 and 40.4.2.4.

For many inference problems, the frequentist and Bayesian approaches give similar numerical values, even though they answer different questions and are based on fundamentally different interpretations of probability. In some important cases, however, the two approaches may yield very different results. For a discussion of Bayesian vs. non-Bayesian methods, see references written by a statistician [1], by a physicist [2], or the detailed comparison in Ref. [3].

40.1 Fundamental concepts

Consider an experiment whose outcome is characterized by one or more data values, which we can write as a vector $\boldsymbol{x}$. A *hypothesis* H is a statement about the probability for the data, often written $P(\boldsymbol{x}|H)$. (We will usually use a capital letter for a probability and lower case for a probability density. Often the term p.d.f. is used loosely to refer to either a probability or a probability density.) This could, for example, define completely the p.d.f. for the data (a *simple* hypothesis), or it could specify only the functional form of the p.d.f., with the values of one or more parameters not determined (a *composite* hypothesis).

If the probability $P(\boldsymbol{x}|H)$ for data $\boldsymbol{x}$ is regarded as a function of the hypothesis H, then it is called the *likelihood* of H, usually written $L(H)$. Often the hypothesis is characterized by one or more parameters $\boldsymbol{\theta}$, in which case $L(\boldsymbol{\theta}) = P(\boldsymbol{x}|\boldsymbol{\theta})$ is called the likelihood function.

In some cases one can obtain at least approximate frequentist results using the likelihood evaluated only with the data obtained, for example, when determining confidence regions with Eq. (40.74). In general, however, the frequentist approach requires a full specification of the probability model $P(\boldsymbol{x}|H)$ both as a function of the data $\boldsymbol{x}$ and hypothesis H.

In the Bayesian approach, inference is based on the posterior probability for H given the data $\boldsymbol{x}$, which represents one's degree of belief that H is true given the data. This is obtained from Bayes' theorem (39.4), which can be written

$$P(H|\boldsymbol{x}) = \frac{P(\boldsymbol{x}|H)\pi(H)}{\int P(\boldsymbol{x}|H')\pi(H')\,dH'} \,. \tag{40.1}$$

Here $P(\boldsymbol{x}|H)$ is the likelihood for H, which depends only on the data actually obtained. The quantity $\pi(H)$ is the prior probability for H, which represents one's degree of belief for H before carrying out the measurement. The integral in the denominator (or sum, for discrete hypotheses) serves as a normalization factor. If H is characterized by a continuous parameter θ then the posterior probability is a p.d.f. $p(\theta|\boldsymbol{x})$. Note that the likelihood function itself is not a p.d.f. for θ.

40.2 Parameter estimation

Here we review *point estimation* of parameters, first with an overview of the frequentist approach and its two most important methods, maximum likelihood and least squares, treated in Sections 40.2.2 and 40.2.3. The Bayesian approach is outlined in Sec. 40.2.6.

An *estimator* $\widehat{\theta}$ (written with a hat) is a function of the data used to estimate the value of the parameter θ. Sometimes the word 'estimate' is used to denote the value of the estimator when evaluated with given data. There is no fundamental rule dictating how an estimator must be constructed. One tries, therefore, to choose that estimator which has the best properties. The most important of these are (a) *consistency*, (b) *bias*, (c) *efficiency*, and (d) *robustness*.

(a) An estimator is said to be *consistent* if the estimate $\widehat{\theta}$ converges in probability (see Ref. [3]) to the true value θ as the amount of data increases. This property is so important that it is possessed by all commonly used estimators.

(b) The *bias*, $b = E[\widehat{\theta}] - \theta$, is the difference between the expectation value of the estimator and the true value of the parameter. The expectation value is taken over a hypothetical set of similar experiments in which $\widehat{\theta}$ is constructed in the same way. When $b = 0$, the estimator is said to be unbiased. The bias depends on the chosen metric, *i.e.*, if $\widehat{\theta}$ is an unbiased estimator of θ, then $\widehat{\theta}^{\,2}$ is not in general an unbiased estimator for θ^2.

(c) *Efficiency* is the ratio of the minimum possible variance for any estimator of θ to the variance $V[\widehat{\theta}]$ of the estimator $\widehat{\theta}$. For the case of a single parameter, under rather general conditions the minimum variance is given by the Rao-Cramér-Fréchet bound,

$$\sigma^2_{\rm min} = \left(1 + \frac{\partial b}{\partial \theta}\right)^2 / I(\theta) \,, \tag{40.2}$$

where

$$I(\theta) = E\left[\left(\frac{\partial \ln L}{\partial \theta}\right)^2\right] = -E\left[\frac{\partial^2 \ln L}{\partial \theta^2}\right] \tag{40.3}$$

is the *Fisher information*, L is the likelihood, and the operator $E[]$ in (40.3) is the expectation value with respect to the data. For the final equality to hold, the range of allowed data values must not depend on θ.

The *mean-squared error*,

$$\text{MSE} = E[(\widehat{\theta} - \theta)^2] = V[\widehat{\theta}] + b^2 \,, \tag{40.4}$$

is a measure of an estimator's quality which combines bias and variance.

(d) *Robustness* is the property of being insensitive to departures from assumptions about the p.d.f., *e.g.*, owing to uncertainties in the distribution's tails.

It is not in general possible to optimize simultaneously for all the measures of estimator quality described above. For some common estimators, the properties above are known exactly. More generally, it is possible to evaluate them by Monte Carlo simulation. Note that they will in general depend on the unknown θ.

40.2.1 *Estimators for mean, variance, and median*

Suppose we have a set of n independent measurements, $x_1, \ldots, x_n$, each assumed to follow a p.d.f. with unknown mean μ and unknown variance σ^2 (the measurements do not necessarily have to follow a Gaussian distribution). Then

$$\widehat{\mu} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{40.5}$$

$$\widehat{\sigma^2} = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \widehat{\mu})^2 \tag{40.6}$$

are unbiased estimators of μ and σ^2. The variance of $\widehat{\mu}$ is σ^2/n and the variance of $\widehat{\sigma^2}$ is

$$V\left[\widehat{\sigma^2}\right] = \frac{1}{n}\left(m_4 - \frac{n-3}{n-1}\sigma^4\right) , \tag{40.7}$$

where m_4 is the 4^{th} central moment of x (see Eq. (39.8)). For Gaussian distributed x_i, this becomes $2\sigma^4/(n-1)$ for any $n \geq 2$, and for large n the standard deviation of $\widehat{\sigma}$ is $\sigma/\sqrt{2n}$. For any n and Gaussian x_i, $\widehat{\mu}$ is an efficient estimator for μ, and the estimators $\widehat{\mu}$ and $\widehat{\sigma^2}$ are uncorrelated. Otherwise the arithmetic mean (40.5) is not necessarily the most efficient estimator; this is discussed further in Sec. 8.7 of Ref. [4].

If σ^2 is known, it does not improve the estimate $\widehat{\mu}$, as can be seen from Eq. (40.5); however, if μ is known, one can substitute it for $\widehat{\mu}$ in Eq. (40.6) and replace $n-1$ by n to obtain an estimator of σ^2 still with zero bias but smaller variance. If the x_i have different, known variances σ_i^2, then the weighted average

$$\widehat{\mu} = \frac{1}{w}\sum_{i=1}^{n} w_i x_i , \tag{40.8}$$

where $w_i = 1/\sigma_i^2$ and $w = \sum_i w_i$, is an unbiased estimator for μ with a smaller variance than an unweighted average. The standard deviation of $\widehat{\mu}$ is $1/\sqrt{w}$.

As an estimator for the median x_{med}, one can use the value $\widehat{x}_{\text{med}}$ such that half the x_i are below and half above (the sample median). If there are an even number of observations and the sample median lies between two observed values, the estimator is set by convention to their arithmetic average. If the p.d.f. of x has the form $f(x-\mu)$ and μ is both mean and median, then for large n the variance of the sample median approaches $1/[4nf^2(0)]$, provided $f(0) > 0$. Although estimating the median can often be more difficult computationally than the mean, the resulting estimator is generally more robust, as it is insensitive to the exact shape of the tails of a distribution.

40.2.2 *The method of maximum likelihood*

Suppose we have a set of measured quantities $\boldsymbol{x}$ and the likelihood $L(\boldsymbol{\theta}) = P(\boldsymbol{x}|\boldsymbol{\theta})$ for a set of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$. The *maximum likelihood* (ML) estimators for $\boldsymbol{\theta}$ are defined as the values that give the maximum of L. Because of the properties of the logarithm, it is usually easier to work with $\ln L$, and since both are maximized for the same parameter values $\boldsymbol{\theta}$, the ML estimators can be found by solving the *likelihood equations*,

$$\frac{\partial \ln L}{\partial \theta_i} = 0 , \qquad i = 1, \ldots, M . \tag{40.9}$$

Often the solution must be found numerically. Maximum likelihood estimators are important because they are asymptotically (*i.e.*, for large data samples) unbiased, efficient and have a Gaussian sampling distribution under quite general conditions, and the method has a wide range of applicability.

In general the likelihood function is obtained from the probability of the data under assumption of the parameters. An important special case is when the data consist of *i.i.d.* (independent and identically distributed) values. Here one has a set of n statistically independent quantities $\boldsymbol{x} = (x_1, \ldots, x_n)$, where each component follows the same p.d.f. $f(x;\boldsymbol{\theta})$. In this case the joint p.d.f. of the data sample factorizes and the likelihood function is

$$L(\boldsymbol{\theta}) = \prod_{i=1}^{n} f(x_i;\boldsymbol{\theta}) . \tag{40.10}$$

In this case the number n of observations (usually individual "events" in particle physics) is regarded as fixed. If, however, the probability to observe n events itself depends on the parameters $\boldsymbol{\theta}$, then this dependence should be included in the likelihood. For example, if n follows a Poisson distribution with mean μ and the independent x values all follow $f(x;\boldsymbol{\theta})$, then the likelihood becomes

$$L(\boldsymbol{\theta}) = \frac{\mu^n}{n!}e^{-\mu}\prod_{i=1}^{n} f(x_i;\boldsymbol{\theta}) . \tag{40.11}$$

Equation (40.11) is often called the *extended likelihood* (see, *e.g.*, Refs. [5–7]). If μ is given as a function of $\boldsymbol{\theta}$, then including the probability for n given $\boldsymbol{\theta}$ in the likelihood provides additional information about the parameters. This therefore leads to a reduction in their statistical uncertainties and in general changes their estimated values.

In evaluating the likelihood function, it is important that any normalization factors in the p.d.f. that involve $\boldsymbol{\theta}$ be included. However, we will only be interested in the maximum of L and in ratios of L at different values of the parameters; hence any multiplicative factors that do not involve the parameters that we want to estimate may be dropped, including factors that depend on the data but not on $\boldsymbol{\theta}$.

Under a one-to-one change of parameters from $\boldsymbol{\theta}$ to $\boldsymbol{\eta}$, the ML estimators $\widehat{\boldsymbol{\theta}}$ transform to $\boldsymbol{\eta}(\widehat{\boldsymbol{\theta}})$. That is, the ML solution is invariant under change of parameter. However, other properties of ML estimators, in particular the bias, are not invariant under change of parameter.

The inverse V^{-1} of the covariance matrix $V_{ij} = \text{cov}[\widehat{\theta}_i, \widehat{\theta}_j]$ for a set of ML estimators can be estimated by using

$$(\widehat{V}^{-1})_{ij} = -\left.\frac{\partial^2 \ln L}{\partial\theta_i \partial\theta_j}\right|_{\widehat{\boldsymbol{\theta}}} . \tag{40.12}$$

Equation (40.12) holds for a sufficiently large data sample (or for a small sample only in special cases, e.g., where the means of Gaussian distributed data are linear functions of the parameters); otherwise it can result in a misestimation of the variances. Under the conditions where the equation is valid, L has a Gaussian form and $\ln L$ is (hyper)parabolic. In this case, s times the standard deviations σ_i of the estimators for the parameters can be obtained from the hypersurface defined by the $\boldsymbol{\theta}$ such that

$$\ln L(\boldsymbol{\theta}) = \ln L_{\max} - s^2/2 , \tag{40.13}$$

where $\ln L_{\max}$ is the value of $\ln L$ at the solution point (compare with Eq. (40.74)). The minimum and maximum values of θ_i on the hypersurface then give an approximate s-standard deviation confidence interval for θ_i (see Section 40.4.2.2).

40.2.2.1 *ML with binned data*

If the total number of data values x_i, $(i = 1, \ldots, n_{\text{tot}})$, is small, the unbinned maximum likelihood method, *i.e.*, use of Equation (40.10) (or (40.11) for extended ML), is preferred since binning can only result in a loss of information, and hence larger statistical errors for the parameter estimates. If the sample is large, it can be convenient to bin the values in a histogram with N bins, so that one obtains a vector of data $\boldsymbol{n} = (n_1, \ldots, n_N)$ with expectation values $\boldsymbol{\mu} = E[\boldsymbol{n}]$ and probabilities $f(\boldsymbol{n};\boldsymbol{\mu})$. Suppose the mean values $\boldsymbol{\mu}$ can be determined as a function of a set of parameters $\boldsymbol{\theta}$. Then one may maximize the likelihood function based on the contents of the bins.

As mentioned in Sec. 40.2.2, the total number of events $n_{\text{tot}} = \sum_i n_i$ can be regarded either as fixed or as a random variable. If it is fixed, the histogram follows a multinomial distribution,

$$f_{\text{M}}(\boldsymbol{n};\boldsymbol{\theta}) = \frac{n_{\text{tot}}!}{n_1!\cdots n_N!}p_1^{n_1}\cdots p_N^{n_N} , \tag{40.14}$$

where we assume the probabilities p_i are given functions of the parameters $\boldsymbol{\theta}$. The distribution can be written equivalently in terms of the expected number of events in each bin, $\mu_i = n_{\text{tot}}p_i$. If the n_i are regarded as independent and Poisson distributed, then the data are instead described by a product of Poisson probabilities,

$$f_{\text{P}}(\boldsymbol{n};\boldsymbol{\theta}) = \prod_{i=1}^{N}\frac{\mu_i^{n_i}}{n_i!}e^{-\mu_i} , \tag{40.15}$$

where the mean values μ_i are given functions of $\boldsymbol{\theta}$. The total number of events n_{tot} thus follows a Poisson distribution with mean $\mu_{\text{tot}} = \sum_i \mu_i$.

When using maximum likelihood with binned data, one can find the ML estimators and at the same time obtain a statistic

usable for a test of goodness-of-fit (see Sec. 40.3.2). Maximizing the likelihood $L(\boldsymbol{\theta}) = f_{\mathrm{M/P}}(\boldsymbol{n};\boldsymbol{\theta})$ is equivalent to maximizing the likelihood ratio $\lambda(\boldsymbol{\theta}) = f_{\mathrm{M/P}}(\boldsymbol{n};\boldsymbol{\theta})/f(\boldsymbol{n};\hat{\boldsymbol{\mu}})$, where in the denominator $f(\boldsymbol{n};\boldsymbol{\mu})$ is a model with an adjustable parameter for each bin, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_N)$, and the corresponding estimators are $\hat{\boldsymbol{\mu}} = (n_1, \ldots, n_N)$ (called the "saturated model"). Equivalently one often minimizes the quantity $-2\ln\lambda(\boldsymbol{\theta})$. For independent Poisson distributed n_i this is [8]

$$-2\ln\lambda(\boldsymbol{\theta}) = 2\sum_{i=1}^{N}\left[\mu_i(\boldsymbol{\theta}) - n_i + n_i\ln\frac{n_i}{\mu_i(\boldsymbol{\theta})}\right] , \qquad (40.16)$$

where for bins with $n_i = 0$, the last term in (40.16) is zero. The expression (40.16) without the terms $\mu_i - n_i$ also gives $-2\ln\lambda(\boldsymbol{\theta})$ for multinomially distributed n_i, *i.e.*, when the total number of entries is regarded as fixed. In the limit of zero bin width, minimizing (40.16) is equivalent to maximizing the unbinned extended likelihood function (40.11); in the corresponding multinomial case without the $\mu_i - n_i$ terms one obtains Eq. (40.10).

A smaller value of $-2\ln\lambda(\widehat{\boldsymbol{\theta}})$ corresponds to better agreement between the data and the hypothesized form of $\boldsymbol{\mu}(\boldsymbol{\theta})$. The value of $-2\ln\lambda(\widehat{\boldsymbol{\theta}})$ can thus be translated into a p-value as a measure of goodness-of-fit, as described in Sec. 40.3.2. Assuming the model is correct, then according to Wilks' theorem [9], for sufficiently large μ_i and provided certain regularity conditions are met, the minimum of $-2\ln\lambda$ as defined by Eq. (40.16) follows a χ^2 distribution (see, *e.g.*, Ref. [8]). If there are N bins and M fitted parameters, then the number of degrees of freedom for the χ^2 distribution is $N - M$ if the data are treated as Poisson-distributed, and $N - M - 1$ if the n_i are multinomially distributed.

Suppose the n_i are Poisson-distributed and the overall normalization $\mu_{\mathrm{tot}} = \sum_i \mu_i$ is taken as an adjustable parameter, so that $\mu_i = \mu_{\mathrm{tot}} p_i(\boldsymbol{\theta})$, where the probability to be in the ith bin, $p_i(\boldsymbol{\theta})$, does not depend on μ_{tot}. Then by minimizing Eq. (40.16), one obtains that the area under the fitted function is equal to the sum of the histogram contents, *i.e.*, $\sum_i \hat{\mu}_i = \sum_i n_i$. This is a property not possessed by the estimators from the method of least squares (see, *e.g.*, Sec. 40.2.3 and Ref. [7]).

40.2.2.2 *Frequentist treatment of nuisance parameters*

Suppose we want to determine the values of parameters $\boldsymbol{\theta}$ using a set of measurements $\boldsymbol{x}$ described by a probability model $P(\boldsymbol{x}|\boldsymbol{\theta})$. In general the model is not perfect, which is to say it cannot provide an accurate description of the data even at the most optimal point of its parameter space. As a result, the estimated parameters can have a systematic bias.

One can improve the model by including in it additional parameters. That is, $P(\boldsymbol{x}|\boldsymbol{\theta})$ is replaced by a more general model $P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})$, which depends on parameters of interest $\boldsymbol{\theta}$ and *nuisance parameters* $\boldsymbol{\nu}$. The additional parameters are not of intrinsic interest but must be included for the model to be sufficiently accurate for some point in the enlarged parameter space.

Although including additional parameters may eliminate or at least reduce the effect of systematic uncertainties, their presence will result in increased statistical uncertainties for the parameters of interest. This occurs because the estimators for the nuisance parameters and those of interest will in general be correlated, which results in an enlargement of the contour defined by Eq. (40.13).

To reduce the impact of the nuisance parameters one often tries to constrain their values by means of control or calibration measurements, say, having data $\boldsymbol{y}$. For example, some components of $\boldsymbol{y}$ could represent estimates of the nuisance parameters, often from separate experiments. Suppose the measurements $\boldsymbol{y}$ are statistically independent from $\boldsymbol{x}$ and are described by a model $P(\boldsymbol{y}|\boldsymbol{\nu})$. The joint model for both $\boldsymbol{x}$ and $\boldsymbol{y}$ is in this case therefore the product of the probabilities for $\boldsymbol{x}$ and $\boldsymbol{y}$, and thus the likelihood function for the full set of parameters is

$$L(\boldsymbol{\theta},\boldsymbol{\nu}) = P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})P(\boldsymbol{y}|\boldsymbol{\nu}) . \qquad (40.17)$$

Note that in this case if one wants to simulate the experiment by means of Monte Carlo, both the primary and control measurements, $\boldsymbol{x}$ and $\boldsymbol{y}$, must be generated for each repetition under assumption of fixed values for the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$.

Using all of the parameters $(\boldsymbol{\theta},\boldsymbol{\nu})$ in Eq. (40.13) to find the statistical errors in the parameters of interest $\boldsymbol{\theta}$ is equivalent to using the *profile likelihood*, which depends only on $\boldsymbol{\theta}$. It is defined as

$$L_{\mathrm{p}}(\boldsymbol{\theta}) = L(\boldsymbol{\theta},\widehat{\widehat{\boldsymbol{\nu}}}(\boldsymbol{\theta})), \qquad (40.18)$$

where the double-hat notation indicates the profiled values of the parameters $\boldsymbol{\nu}$, defined as the values that maximize L for the specified $\boldsymbol{\theta}$. The profile likelihood is discussed further in Section 40.3.2.1 in connection with hypothesis tests.

40.2.3 *The method of least squares*

The *method of least squares* (LS) coincides with the method of maximum likelihood in the following special case. Consider a set of N independent measurements y_i at known points x_i. The measurement y_i is assumed to be Gaussian distributed with mean $\mu(x_i;\boldsymbol{\theta})$ and known variance σ_i^2. The goal is to construct estimators for the unknown parameters $\boldsymbol{\theta}$. The log-likelihood function contains the sum of squares

$$\chi^2(\boldsymbol{\theta}) = -2\ln L(\boldsymbol{\theta}) + \text{ constant } = \sum_{i=1}^{N}\frac{(y_i - \mu(x_i;\boldsymbol{\theta}))^2}{\sigma_i^2} . \qquad (40.19)$$

The parameter values that maximize L are the same as those which minimize χ^2.

The minimum of the chi-square function in Equation (40.19) defines the least-squares estimators $\widehat{\boldsymbol{\theta}}$ for the more general case where the y_i are not Gaussian distributed as long as they are independent. If they are not independent but rather have a covariance matrix $V_{ij} = \mathrm{cov}[y_i, y_j]$, then the LS estimators are determined by the minimum of

$$\chi^2(\boldsymbol{\theta}) = (\boldsymbol{y} - \boldsymbol{\mu}(\boldsymbol{\theta}))^T V^{-1}(\boldsymbol{y} - \boldsymbol{\mu}(\boldsymbol{\theta})) , \qquad (40.20)$$

where $\boldsymbol{y} = (y_1, \ldots, y_N)$ is the (column) vector of measurements, $\boldsymbol{\mu}(\boldsymbol{\theta})$ is the corresponding vector of predicted values, and the superscript T denotes the transpose. If the y_i are not Gaussian distributed, then the LS and ML estimators will not in general coincide.

Often one further restricts the problem to the case where $\mu(x_i;\boldsymbol{\theta})$ is a linear function of the parameters, *i.e.*,

$$\mu(x_i;\boldsymbol{\theta}) = \sum_{j=1}^{m}\theta_j h_j(x_i) . \qquad (40.21)$$

Here the $h_j(x)$ are m linearly independent functions, *e.g.*, $1, x, x^2, \ldots, x^{m-1}$ or Legendre polynomials. We require $m < N$ and at least m of the x_i must be distinct.

Minimizing χ^2 in this case with m parameters reduces to solving a system of m linear equations. Defining $H_{ij} = h_j(x_i)$ and minimizing χ^2 by setting its derivatives with respect to the θ_i equal to zero gives the LS estimators,

$$\widehat{\boldsymbol{\theta}} = (H^T V^{-1} H)^{-1} H^T V^{-1}\boldsymbol{y} \equiv D\boldsymbol{y} . \qquad (40.22)$$

The covariance matrix for the estimators $U_{ij} = \mathrm{cov}[\widehat{\theta}_i, \widehat{\theta}_j]$ is given by

$$U = DVD^T = (H^T V^{-1} H)^{-1} , \qquad (40.23)$$

or equivalently, its inverse U^{-1} can be found from

$$(U^{-1})_{ij} = \frac{1}{2}\frac{\partial^2\chi^2}{\partial\theta_i\partial\theta_j}\bigg|_{\boldsymbol{\theta}=\widehat{\boldsymbol{\theta}}} = \sum_{k,l=1}^{N} h_i(x_k)(V^{-1})_{kl}h_j(x_l) . \qquad (40.24)$$

The LS estimators can also be found from the expression

$$\widehat{\boldsymbol{\theta}} = U\boldsymbol{g} , \qquad (40.25)$$

where the vector $\boldsymbol{g}$ is defined by

$$g_i = \sum_{j,k=1}^{N} y_j h_i(x_k)(V^{-1})_{jk} . \qquad (40.26)$$

For the case of uncorrelated y_i, for example, one can use (40.25) with

$$(U^{-1})_{ij} = \sum_{k=1}^{N} \frac{h_i(x_k)h_j(x_k)}{\sigma_k^2} \ , \tag{40.27}$$

$$g_i = \sum_{k=1}^{N} \frac{y_k h_i(x_k)}{\sigma_k^2} \ . \tag{40.28}$$

Expanding $\chi^2(\boldsymbol{\theta})$ about $\widehat{\boldsymbol{\theta}}$, one finds that the contour in parameter space defined by

$$\chi^2(\boldsymbol{\theta}) = \chi^2(\widehat{\boldsymbol{\theta}}) + 1 = \chi^2_{\rm min} + 1 \tag{40.29}$$

has tangent planes located at plus-or-minus-one standard deviation $\sigma_{\widehat{\theta}}$ from the LS estimates $\widehat{\boldsymbol{\theta}}$ (the relation is approximate if the fit function $\mu(x;\boldsymbol{\theta})$ is nonlinear in the parameters).

In constructing the quantity $\chi^2(\boldsymbol{\theta})$ one requires the variances or, in the case of correlated measurements, the covariance matrix. Often these quantities are not known *a priori* and must be estimated from the data. In this case the least-squares and maximum-likelihood methods are no longer exactly equivalent even for Gaussian distributed measurements. An important example is where the measured value y_i represents the event count in a histogram bin. If, for example, y_i represents a Poisson variable, for which the variance is equal to the mean, then one can either estimate the variance from the predicted value, $\mu(x_i;\boldsymbol{\theta})$, or from the observed number itself, y_i. In the first option, the variances become functions of the parameters, and as a result the estimators may need to be found numerically. The second option can be undefined if y_i is zero, and for small y_i, the variance will be poorly estimated. In either case, one should constrain the normalization of the fitted curve to the correct value, *i.e.*, one should determine the area under the fitted curve directly from the number of entries in the histogram (see Ref. [7], Section 7.4). As noted in Sec. 40.2.2.1, this issue is avoided when using the method of extended maximum likelihood with binned data by minimizing Eq. (40.16). In that case if the expected number of events $\mu_{\rm tot}$ does not depend on the other fitted parameters $\boldsymbol{\theta}$, then its extended ML estimator is equal to the observed total number of events.

As the minimum value of the χ^2 represents the level of agreement between the measurements and the fitted function, it can be used for assessing the goodness-of-fit; this is discussed further in Section 40.3.2.

40.2.4 *Parameter estimation with constraints*

In some applications one is interested in using a set of measured quantities $\boldsymbol{y} = (y_1, \ldots, y_N)$ to estimate a set of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$ subject to a number of constraints. For example, one may have measured coordinates from two tracks, and one wishes to estimate their momentum vectors subject to the constraint that the tracks have a common vertex. The parameters can also include momenta of undetected particles such as neutrinos, as long as the constraints from conservation of energy and momentum and from known masses of particles involved in the reaction chain provide enough information for these quantities to be inferred.

A set of K constraints can be given in the form of equations

$$c_k(\boldsymbol{\theta}) = 0 \ , \quad k = 1, \ldots, K \ . \tag{40.30}$$

In some problems it may be possible to define a new set of parameters $\boldsymbol{\eta} = (\eta_1, \ldots, \eta_L)$ with $L = M - K$ such that every point in $\boldsymbol{\eta}$-space automatically satisfies the constraints. If this is possible then the problem reduces to one of estimating $\boldsymbol{\eta}$ with, *e.g.*, maximum likelihood or least squares and then transforming the estimators back into $\boldsymbol{\theta}$-space.

In many cases it may be difficult or impossible to find an appropriate transformation $\boldsymbol{\eta}(\boldsymbol{\theta})$. Suppose that the parameters are determined through minimizing an objective function such as $\chi^2(\boldsymbol{\theta})$ in the method of least squares. Here one may enforce the constraints by finding the stationary points of the *Lagrange function*

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\lambda}, \boldsymbol{y}) = \chi^2(\boldsymbol{\theta}, \boldsymbol{y}) + \sum_{k=1}^{K} \lambda_k c_k(\boldsymbol{\theta}) \tag{40.31}$$

with respect to both the parameters $\boldsymbol{\theta}$ and a set of *Lagrange multipliers* $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_K)$. Combining the parameters and Lagrange multipliers into an $(M + K)$-component vector $\boldsymbol{\gamma} = (\theta_1, \ldots, \theta_M, \lambda_1, \ldots, \lambda_K)$, the solutions for $\boldsymbol{\gamma}$, *i.e.*, the estimators $\hat{\boldsymbol{\gamma}}$, are found (*e.g.*, numerically) from the system of equations

$$F_i(\boldsymbol{\gamma}, \boldsymbol{y}) \equiv \frac{\partial \mathcal{L}}{\partial \gamma_i} = 0 \ , \quad i = 1, \ldots, M + K \ . \tag{40.32}$$

To obtain the covariance matrix of the estimated parameters one can find solutions $\tilde{\boldsymbol{\gamma}}$ corresponding to the expectation values of the data $\langle \boldsymbol{y} \rangle$ and expand $F_i(\hat{\boldsymbol{\gamma}}, \boldsymbol{y})$ to first order about these values. This gives (see, e.g., Sec. 11.6 of Ref. [7]) linearized approximations for the estimators, $\hat{\boldsymbol{\gamma}}(\boldsymbol{y}) \approx \tilde{\boldsymbol{\gamma}} + C(\boldsymbol{y} - \langle \boldsymbol{y} \rangle)$, where the matrix $C = -A^{-1}B$, and A and B are given by

$$A_{ij} = \left[\frac{\partial F_i}{\partial \gamma_j} \right]_{\tilde{\boldsymbol{\gamma}}, \langle \boldsymbol{y} \rangle} \quad \text{and} \quad B_{ij} = \left[\frac{\partial F_i}{\partial y_j} \right]_{\tilde{\boldsymbol{\gamma}}, \langle \boldsymbol{y} \rangle} \ . \tag{40.33}$$

In practice the values $\langle \boldsymbol{y} \rangle$ and corresponding solutions $\tilde{\boldsymbol{\gamma}}$ are estimated using the data from the actual measurement. Using this approximation for $\hat{\boldsymbol{\gamma}}(\boldsymbol{y})$, one can find the covariance matrix $U_{ij} = \mathrm{cov}[\hat{\gamma}_i, \hat{\gamma}_j]$ of the estimators for the γ_i in terms of that of the data $V_{ij} = \mathrm{cov}[y_i, y_j]$ using error propagation (cf. Eqs. (39.17) and (39.18)),

$$U = CVC^T \ . \tag{40.34}$$

The upper-left $M \times M$ block of the matrix U gives the covariance matrix for the estimated parameters $\mathrm{cov}[\hat{\theta}_i, \hat{\theta}_j]$. One can show for linear constraints that $\mathrm{cov}[\hat{\theta}_i, \hat{\theta}_j]$ is also given by the upper-left $M \times M$ block of $2A^{-1}$. If the parameters are estimated using the method of least squares, then the number of degrees of freedom for the distribution of the minimized χ^2 is increased by the number of constraints, *i.e.*, it becomes $N - M + K$. Further details can be found in, *e.g.*, Ch. 8 of Ref. [4] and Ch. 7 of Ref. [10].

40.2.5 *Unfolding*

An important class of parameter estimation problem involves measurement of the differential distribution of a kinematic variable in the form of a histogram with N bins. The data thus consist of the vector of measured data values $\boldsymbol{n} = (n_1, \ldots n_N)$, with expectation values $\nu_i = E[n_i]$. The n_i are usually independent and often modeled as Poisson distributed, from which it follows that the maximum-likelihood estimators are $\hat{\nu}_i = n_i$ for all i.

Because of the limited acceptance and resolution of the experiment, however, the measured values of the kinematic variable in question differ in general from their true values, and as a consequence the form of the data histogram is distorted relative to what would be obtained with perfect resolution. The desired parameters are not, therefore, the ν_i but rather one wants to estimate the expected number of entries in a given bin that would be found with a perfect detector. We call this the "true histogram" and denote it with $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_M)$, where the number of bins M is not required to equal that of the observed histogram. The μ_i are related to the expected numbers of events in the observed histogram by

$$\nu_i = \sum_{j=1}^{M} R_{ij}\mu_j + \beta_i \ , \tag{40.35}$$

where β_i here represents the expected number of events in bin i due to background processes and the $N \times M$ *response matrix* R_{ij} gives the probability for an event to be observed in bin i of $\boldsymbol{\nu}$ given that the true value of the variable was in bin j of $\boldsymbol{\mu}$. For purposes of this discussion let us suppose that the response matrix and expected background values are known. There are two main approaches to this type of problem, which we can call *unfolding* and *folding*.

In unfolding, one treats the true histogram $\boldsymbol{\mu}$ as the parameters of interest. The result is thus given by estimators $\hat{\boldsymbol{\mu}}$ and the corresponding covariance matrix $U_{ij} = \mathrm{cov}[\hat{\mu}_i, \hat{\mu}_j]$. Provided the response matrix can be inverted, the maximum-likelihood solution is easily found as $\hat{\boldsymbol{\mu}} = R^{-1}(\boldsymbol{n} - \boldsymbol{\beta})$. If the response matrix allows for significant migration of events between bins, then the variances of these estimators can be very large, sometimes to the point where the $\hat{\boldsymbol{\mu}}$ bear essentially no resemblance to the true $\boldsymbol{\mu}$. In such cases the estimators can be found by maximizing a linear combination of the log-likelihood and a regularization function that imposes some degree of smoothness on the unfolded distribution. In achieving a reduction in variance one inevitably introduces some bias into the estimators.

In the approach of folding, by contrast, to test a given model prediction for the true histogram $\boldsymbol{\mu}$ it is first "folded" with the response matrix and corrected for expected background to give the corresponding $\boldsymbol{\nu}$ according to Eq. (40.35), and these are compared to the corresponding $\boldsymbol{n}$ using, e.g., a likelihood ratio as shown in Sec. 40.2.2.1. In this way, one avoids any bias due to regularization.

To account for systematic uncertainties, the response matrix and background values may not be expressed as constants but rather as functions of nuisance parameters $\boldsymbol{\theta}$. These may be constrained by auxiliary measurements $\boldsymbol{u}$ with pdf $p(\boldsymbol{u}|\boldsymbol{\theta})$ so that the full likelihood becomes (as in Eq. (40.17) but with different notation)

$$L(\boldsymbol{\mu}, \boldsymbol{\theta}) = P(\boldsymbol{n}|\boldsymbol{\nu}(\boldsymbol{\mu}, \boldsymbol{\theta}))p(\boldsymbol{u}|\boldsymbol{\theta}) \; . \tag{40.36}$$

Here the mean values $\boldsymbol{\nu} = R(\boldsymbol{\theta})\boldsymbol{\mu} + \boldsymbol{\beta}(\boldsymbol{\theta})$ now depend on both the true histogram parameters $\boldsymbol{\mu}$ as well as the nuisance parameters $\boldsymbol{\theta}$. Thus to record enough information for a future analysis using folding one must provide all of the ingredients used above: the primary data $\boldsymbol{n}$, the auxiliary measurements $\boldsymbol{u}$, and also the response matrix $R(\boldsymbol{\theta})$ and expected backgrounds $\boldsymbol{\beta}(\boldsymbol{\theta})$ as functions of the nuisance parameters. If unfolding is used, then future model tests or comparisons with other experiments can be carried out directly using the estimators $\hat{\boldsymbol{\mu}}$ and their covariance matrix.

If several distributions are unfolded, then to combine these in a test of a given model one should know how estimators for bins of different distributions are correlated, as can arise, e.g., through common systematic effects. If only the unfolded distributions and their separate covariance matrices are reported, however, then information on such correlations is not retained. In folding, one can include information on correlated systematic effects if the ingredients (R and $\boldsymbol{\beta}$) are known in terms of nuisance parameters that are common to different distributions.

In unfolding, the estimators for $\boldsymbol{\mu}$ can be constructed either by maximizing the log-likelihood using Eq. (40.36) or in the case where regularization is required one can maximize $\varphi(\boldsymbol{\mu}, \boldsymbol{\theta}) = \ln L(\boldsymbol{\mu}, \boldsymbol{\theta}) + \tau S(\boldsymbol{\mu})$, where the *regularization function* $S(\boldsymbol{\mu})$ reflects the smoothness of the true histogram and serves to reduce the variances of the estimators. Possible functions are based on the mean squared second derivative (a commonly used type of Tikhonov regularization) or the entropy of the true histogram. The parameter τ fixes the relative weighting of the log-likelihood and the regularization function and thus determines the balance between the bias and variance of the resulting estimators. Further discussion of the unfolding problem including methods for choosing the regularization function and parameter, as well as techniques that employ other types of regularization such as the iterative Bayes (Richardson-Lucy) method, can be found in Refs. [7, 10–12] and references therein.

40.2.6 *The Bayesian approach*

In the frequentist methods discussed above, probability is associated only with data, not with the value of a parameter. This is no longer the case in Bayesian statistics, however, which we introduce in this section. For general introductions to Bayesian statistics see, *e.g.*, Refs. [13–16].

Suppose the outcome of an experiment is characterized by a vector of data $\boldsymbol{x}$, whose probability distribution depends on an unknown parameter (or parameters) $\boldsymbol{\theta}$ that we wish to determine. In Bayesian statistics, all knowledge about $\boldsymbol{\theta}$ is summarized by the posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, whose integral over any given region gives the degree of belief for $\boldsymbol{\theta}$ to take on values in that region, given the data $\boldsymbol{x}$. It is obtained by using Bayes' theorem,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \frac{P(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})}{\int P(\boldsymbol{x}|\boldsymbol{\theta}')\pi(\boldsymbol{\theta}')\, d\boldsymbol{\theta}'} \; , \tag{40.37}$$

where $P(\boldsymbol{x}|\boldsymbol{\theta})$ is the likelihood function, *i.e.*, the joint p.d.f. for the data viewed as a function of $\boldsymbol{\theta}$, evaluated with the data actually obtained in the experiment, and $\pi(\boldsymbol{\theta})$ is the prior p.d.f. for $\boldsymbol{\theta}$. Note that the denominator in Eq. (40.37) serves to normalize the posterior p.d.f. to unity.

As it can be difficult to report the full posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, one would usually summarize it with statistics such as the mean (or median) value, and covariance matrix. In addition one may construct intervals with a given probability content, as is discussed in Sec. 40.4.1 on Bayesian interval estimation.

40.2.6.1 *Priors*

Bayesian statistics supplies no unique rule for determining the prior $\pi(\boldsymbol{\theta})$; this reflects the analyst's subjective degree of belief (or state of knowledge) about $\boldsymbol{\theta}$ before the measurement was carried out. For the result to be of value to the broader community, whose members may not share these beliefs, it is important to carry out a *sensitivity analysis*, that is, to show how the result changes under a reasonable variation of the prior probabilities.

One might like to construct $\pi(\boldsymbol{\theta})$ to represent complete ignorance about the parameters by setting it equal to a constant. A problem here is that if the prior p.d.f. is flat in $\boldsymbol{\theta}$, then it is not flat for a nonlinear function of $\boldsymbol{\theta}$, and so a different parametrization of the problem would lead in general to a non-equivalent posterior p.d.f.

For the special case of a constant prior, one can see from Bayes' theorem (40.37) that the posterior is proportional to the likelihood, and therefore the mode (peak position) of the posterior is equal to the ML estimator. The posterior mode, however, will change in general upon a transformation of parameter. One may use as the Bayesian estimator a summary statistic other than the mode, such as the median, which is invariant under parameter transformation. But this will not in general coincide with the ML estimator.

The difficult and subjective nature of encoding personal knowledge into priors has led to what is called *objective Bayesian statistics*, where prior probabilities are based not on an actual degree of belief but rather derived from formal rules. These give, for example, priors which are invariant under a transformation of parameters, or ones which result in a maximum gain in information for a given set of measurements. For an extensive review see, *e.g.*, Ref. [17].

Objective priors do not in general reflect degree of belief, but they could in some cases be taken as possible, although perhaps extreme, subjective priors. The posterior probabilities as well therefore do not necessarily reflect a degree of belief. However one may regard investigating a variety of objective priors to be an important part of the sensitivity analysis. Furthermore, use of objective priors with Bayes' theorem can be viewed as a recipe for producing estimators or intervals which have desirable frequentist properties.

An important procedure for deriving objective priors is due to Jeffreys. According to *Jeffreys' rule* one takes the prior as

$$\pi(\boldsymbol{\theta}) \propto \sqrt{\det(I(\boldsymbol{\theta}))} \; , \tag{40.38}$$

where

$$I_{ij}(\boldsymbol{\theta}) = -E\left[\frac{\partial^2 \ln P(\boldsymbol{x}|\boldsymbol{\theta})}{\partial\theta_i \partial\theta_j}\right] \tag{40.39}$$

is the *Fisher information matrix*. One can show that the Jeffreys prior leads to inference that is invariant under a transformation of parameters. One should note that the Jeffreys prior does not in general correspond to one's degree of belief about the value of a parameter. As examples, the Jeffreys prior for the mean μ of a Gaussian distribution is a constant, and for the mean of a Poisson distribution one finds $\pi(\mu) \propto 1/\sqrt{\mu}$.

Neither the constant nor $1/\sqrt{\mu}$ priors can be normalized to unit area and are therefore said to be *improper*. This can be allowed because the prior always appears multiplied by the likelihood function, and if the likelihood falls to zero sufficiently quickly then one may have a normalizable posterior density.

An important type of objective prior is the reference prior due to Bernardo and Berger [18]. To find the reference prior for a given problem one considers the Kullback-Leibler divergence $D_n[\pi, p]$ of the posterior $p(\boldsymbol{\theta}|\boldsymbol{x})$ relative to a prior $\pi(\boldsymbol{\theta})$, obtained from a set of i.i.d. data $\boldsymbol{x} = (x_1, \ldots, x_n)$:

$$D_n[\pi, p] = \int p(\boldsymbol{\theta}|\boldsymbol{x}) \ln \frac{p(\boldsymbol{\theta}|\boldsymbol{x})}{\pi(\boldsymbol{\theta})} \, d\boldsymbol{\theta} \; . \tag{40.40}$$

This is effectively a measure of the gain in information provided by the data. The reference prior is chosen so that the expectation value of this information gain is maximized for the limiting case of $n \to \infty$, where the expectation is computed with respect to the marginal distribution of the data,

$$p(\boldsymbol{x}) = \int p(\boldsymbol{x}|\boldsymbol{\theta}) \pi(\boldsymbol{\theta}) \, d\boldsymbol{\theta} \; . \tag{40.41}$$

For a single, continuous parameter the reference prior is usually identical to the Jeffreys prior. In the multiparameter case an iterative algorithm exists, which requires sorting the parameters by order of inferential importance. Often the result does not depend on this order, but when it does, this can be part of a sensitivity analysis. Further discussion and applications to particle physics problems can be found in Ref. [19].

40.2.6.2 *Bayesian treatment of nuisance parameters*

As discussed in Sec. 40.2.2, a model may depend on parameters of interest $\boldsymbol{\theta}$ as well as on nuisance parameters $\boldsymbol{\nu}$, which must be included for an accurate description of the data. Knowledge about the values of $\boldsymbol{\nu}$ may be supplied by control measurements, theoretical insights, physical constraints, etc. Suppose, for example, one has data $\boldsymbol{y}$ from a control measurement which is characterized by a probability $P(\boldsymbol{y}|\boldsymbol{\nu})$. Suppose further that before carrying out the control measurement one's state of knowledge about $\boldsymbol{\nu}$ is described by an initial prior $\pi_0(\boldsymbol{\nu})$, which in practice is often taken to be a constant or in any case very broad. By using Bayes' theorem (40.1) one obtains the updated prior $\pi(\boldsymbol{\nu})$ (*i.e.*, now $\pi(\boldsymbol{\nu}) = \pi(\boldsymbol{\nu}|\boldsymbol{y})$, the probability for $\boldsymbol{\nu}$ given $\boldsymbol{y}$),

$$\pi(\boldsymbol{\nu}|\boldsymbol{y}) \propto P(\boldsymbol{y}|\boldsymbol{\nu}) \pi_0(\boldsymbol{\nu}) \; . \tag{40.42}$$

In the absence of a model for $P(\boldsymbol{y}|\boldsymbol{\nu})$ one may make some reasonable but *ad hoc* choices in order to approximate $\pi(\boldsymbol{\nu})$. For a single nuisance parameter ν, for example, one might characterize the uncertainty by a p.d.f. $\pi(\nu)$ centered about its nominal value with a certain standard deviation σ_ν. Often a Gaussian p.d.f. provides a reasonable model for one's degree of belief about a nuisance parameter; in other cases, more complicated shapes may be appropriate. If, for example, the parameter represents a non-negative quantity then a log-normal or gamma p.d.f. can be a more natural choice than a Gaussian truncated at zero. Note also that truncation of the prior of a nuisance parameter ν at zero will in general make $\pi(\nu)$ nonzero at $\nu = 0$, which can lead to an unnormalizable posterior for a parameter of interest that appears multiplied by ν.

The likelihood function, prior, and posterior p.d.f.s all depend on both $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$, and are related by Bayes' theorem, as usual. Note that the likelihood here only refers to the primary measurement $\boldsymbol{x}$. Once any control measurements $\boldsymbol{y}$ are used to find the updated prior $\pi(\boldsymbol{\nu})$ for the nuisance parameters, this information is fully encapsulated in $\pi(\boldsymbol{\nu})$ and the control measurements do not appear further.

One can obtain the posterior p.d.f. for $\boldsymbol{\theta}$ alone by integrating over the nuisance parameters, *i.e.*,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \int p(\boldsymbol{\theta}, \boldsymbol{\nu}|\boldsymbol{x}) \, d\boldsymbol{\nu} \; . \tag{40.43}$$

Such integrals can often not be carried out in closed form, and if the number of nuisance parameters is large, then they can be difficult to compute with standard Monte Carlo methods. *Markov Chain Monte Carlo* (MCMC) techniques are often used for computing integrals of this type (see Sec. 42.6).

40.3 Statistical tests

In addition to estimating parameters, one often wants to assess the validity of certain statements concerning the data's underlying distribution. Frequentist *hypothesis tests*, described in Sec. 40.3.1, provide a rule for accepting or rejecting hypotheses depending on the outcome of a measurement. In *significance tests*, covered in Sec. 40.3.2, one gives the probability to obtain a level of incompatibility with a certain hypothesis that is greater than or equal to the level observed with the actual data. In the Bayesian approach, the corresponding procedure is based fundamentally on the posterior probabilities of the competing hypotheses. In Sec. 40.3.3 we describe a related construct called the Bayes factor, which can be used to quantify the degree to which the data prefer one or another hypothesis.

40.3.1 *Hypothesis tests*

A frequentist *test* of a hypothesis (often called the null hypothesis, H_0) is a rule that states for which data values $\boldsymbol{x}$ the hypothesis is rejected. A region of $\boldsymbol{x}$-space called the critical region, w, is specified such that there is no more than a given probability under H_0, α, called the *size* or *significance level* of the test, to find $\boldsymbol{x} \in w$. If the data are discrete, it may not be possible to find a critical region with exact probability content α, and thus we require $P(\boldsymbol{x} \in w|H_0) \leq \alpha$. If the data are observed in the critical region, H_0 is rejected.

The data $\boldsymbol{x}$ used to construct a test could be, for example, a set of values that characterizes an individual event. In this case the test corresponds to classification as, *e.g.*, signal or background. Alternatively the data could represent a set of values from a collection of events. Often one is interested in knowing whether all of the events are of a certain type (background), or whether the sample contains at least some events of a new type (signal). Here the background-only hypothesis plays the role of H_0, and in the alternative H_1 both signal and background are present. Rejecting H_0 is, from the standpoint of frequentist statistics, the required step to establish discovery of the signal process.

The critical region is not unique. Its choice should take into account the probabilities for the data predicted by some alternative hypothesis (or set of alternatives) H_1. Rejecting H_0 if it is true is called a *type-I error*, and occurs by construction with probability no greater than α. Not rejecting H_0 if an alternative H_1 is true is called a *type-II error*, and for a given test this will have a certain probability $\beta = P(\boldsymbol{x} \notin w|H_1)$. The quantity $1 - \beta$ is called the *power* of the test of H_0 with respect to the alternative H_1. A strategy for defining the critical region can therefore be to maximize the power with respect to some alternative (or alternatives) given a fixed size α.

To maximize the power of a test of H_0 with respect to the alternative H_1, the *Neyman–Pearson lemma* states that the critical region w should be chosen such that for all data values $\boldsymbol{x}$ inside w, the likelihood ratio

$$\lambda(\boldsymbol{x}) = \frac{f(\boldsymbol{x}|H_1)}{f(\boldsymbol{x}|H_0)} \tag{40.44}$$

is greater than or equal to a given constant c_α, and everywhere outside the critical region one has $\lambda(\boldsymbol{x}) < c_\alpha$, where the value of c_α is determined by the size of the test α. Here H_0 and H_1 must be simple hypotheses, *i.e.*, they should not contain undetermined parameters.

It is convenient to define the test using a scalar function of the data $\boldsymbol{x}$ called a *test statistic*, $t(\boldsymbol{x})$, such that the boundary of the critical region is given by a surface of constant $t(\boldsymbol{x})$. The Neyman–Pearson lemma is equivalent to the statement that the likelihood ratio (40.44) represents the optimal test statistic. It can be difficult in practice, however, to determine $\lambda(\boldsymbol{x})$, since this requires knowledge of the joint p.d.f.s $f(\boldsymbol{x}|H_0)$ and $f(\boldsymbol{x}|H_1)$. Often one does not have explicit formulae for these, but rather

Monte Carlo models that allow one to generate instances of $\boldsymbol{x}$ that follow the p.d.f.s.

In the case where the likelihood ratio (40.44) cannot be used explicitly, there exist a variety of other multivariate methods for constructing a test statistic that may approach its performance. These are based on machine-learning algorithms that use samples of *training data* corresponding to the hypotheses in question, often generated from Monte Carlo models. Further information on Machine Learning can be found in Sec. 41 of this Review.

The multivariate algorithms designed to classify events into signal and background types also form the basis of tests of the hypothesis that a sample of events consists of background only. Such a test can be constructed using the distributions of the test statistic $t(\boldsymbol{x})$ for event classification obtained from a multivariate algorithm such as a Neural Network output. The distributions $p(t|s)$ and $p(t|b)$ for signal and background events, respectively, are used to construct the likelihood ratio of the signal-plus-background hypothesis relative to that of background only. To the extent that the test statistic $t(\boldsymbol{x})$ approximates the likelihood ratio (or a monotonic function thereof) for individual events given by (40.44), the resulting test of the background-only hypothesis for the event sample will have maximum power with respect to the signal-plus-background alternative (see Ref. [20]).

40.3.2 *Tests of significance (goodness-of-fit)*

Often one wants to quantify the level of agreement between the data and a hypothesis without explicit reference to alternative hypotheses. This can be done by defining a statistic t whose value reflects in some way the level of agreement between the data and the hypothesis. The analyst must decide what values of the statistic correspond to better or worse levels of agreement with the hypothesis in question; the choice will in general depend on the relevant alternative hypotheses.

The hypothesis in question, H_0, will determine the p.d.f. $f(t|H_0)$ for the statistic. The significance of a discrepancy between the data and what one expects under the assumption of H_0 is quantified by giving the p-value, defined as the probability to find t in the region of equal or lesser compatibility with H_0 than the level of compatibility observed with the actual data. For example, if t is defined such that large values correspond to poor agreement with the hypothesis, then the p-value would be

$$p = \int_{t_{\rm obs}}^{\infty} f(t|H_0)\, dt \ , \tag{40.45}$$

where $t_{\rm obs}$ is the value of the statistic obtained in the actual experiment.

The p-value is a function of the data, and is therefore itself a random variable. If the hypothesis used to compute the p-value is true, then for continuous data p will be uniformly distributed between zero and one. Note that the p-value is not the probability for the hypothesis; in frequentist statistics, this is not defined.

The p-value should not be confused with the size (significance level) of a test, or the confidence level of a confidence interval (Section 40.4), both of which are pre-specified constants. We may formulate a hypothesis test, however, by defining the critical region to correspond to the data outcomes that give the lowest p-values, so that finding $p \leq \alpha$ implies that the data outcome was in the critical region. When constructing a p-value, one generally chooses the region of data space deemed to have lower compatibility with the model being tested as one having higher compatibility with a given alternative, such that the corresponding test will have a high power with respect to this alternative. For data generated according to the alternative, the distribution of the p-value of H_0 will be concentrated at low values.

When searching for a new phenomenon, one tries to reject the hypothesis H_0 that the data are consistent with known (*e.g.*, Standard Model) processes. If the p-value of H_0 is sufficiently low, then one is willing to accept that some alternative hypothesis is true. Often one converts the p-value into an effective significance Z, defined as an equivalent number of standard deviations of a Gaussian distributed random variable. In a search for an intrinsically positive signal, *i.e.*, where only upward fluctuations of the estimated rate appear signal like, this is defined as

$$Z = \Phi^{-1}(1-p) \ . \tag{40.46}$$

Here Φ is the cumulative distribution of the standard Gaussian, and Φ^{-1} is its inverse (quantile) function. In this way, a p-value of $1/2$ gives $Z = 0$, *i.e.*, having an estimated signal rate of zero corresponds to zero significance. If either positive or negative data fluctuations would indicate evidence of the signal, then one defines

$$Z = \Phi^{-1}(1-p/2) \ . \tag{40.47}$$

In this case an estimated signal rate of zero gives $p = 1$ and $Z = 0$.

Often in particle physics the level of significance where an effect is said to qualify as a discovery is $Z = 5$, *i.e.*, a 5σ effect, corresponding to a p-value of 2.87×10^{-7}. One's actual degree of belief that a new process is present, however, will depend in general on other factors as well, such as the plausibility of the new signal hypothesis and the degree to which it can describe the data, one's confidence in the model that led to the observed p-value, and possible corrections for multiple observations out of which one focuses on the smallest p-value obtained (the "look-elsewhere effect", discussed in Section 40.3.2.2).

40.3.2.1 *Treatment of nuisance parameters for frequentist tests*

Suppose one wants to test hypothetical values of parameters $\boldsymbol{\theta}$, but the model also contains nuisance parameters $\boldsymbol{\nu}$. To find a p-value for $\boldsymbol{\theta}$ we can construct a test statistic $q_{\boldsymbol{\theta}}$ such that larger values constitute increasing incompatibility between the data and the hypothesis. Then for an observed value of the statistic $q_{\boldsymbol{\theta},\rm obs}$, the p-value of $\boldsymbol{\theta}$ is

$$p_{\boldsymbol{\theta}}(\boldsymbol{\nu}) = \int_{q_{\boldsymbol{\theta},\rm obs}}^{\infty} f(q_{\boldsymbol{\theta}}|\boldsymbol{\theta},\boldsymbol{\nu})\, dq_{\boldsymbol{\theta}} \ , \tag{40.48}$$

which depends in general on the nuisance parameters $\boldsymbol{\nu}$. In the strict frequentist approach, $\boldsymbol{\theta}$ is rejected only if the p-value is less than α for all possible values of the nuisance parameters.

The difficulty described above is effectively solved if we can define the test statistic $q_{\boldsymbol{\theta}}$ in such a way that its distribution $f(q_{\boldsymbol{\theta}}|\boldsymbol{\theta})$ is independent of the nuisance parameters. Although exact independence is only found in special cases, it can be achieved approximately by use of the *profile likelihood ratio*. This is given by the profile likelihood from Eq.(40.18) divided by the value of the likelihood at its maximum, *i.e.*, when evaluated with the ML estimators $\widehat{\boldsymbol{\theta}}$ and $\widehat{\boldsymbol{\nu}}$:

$$\lambda_p(\boldsymbol{\theta}) = \frac{L(\boldsymbol{\theta}, \widehat{\widehat{\boldsymbol{\nu}}}(\boldsymbol{\theta}))}{L(\widehat{\boldsymbol{\theta}}, \widehat{\boldsymbol{\nu}})} \ . \tag{40.49}$$

Wilks' theorem [9] states that, providing certain general conditions are satisfied, the distribution of $-2\ln\lambda_{\rm p}(\boldsymbol{\theta})$, under assumption of $\boldsymbol{\theta}$, approaches a χ^2 distribution in the limit where the data sample is very large, independent of the values of the nuisance parameters $\boldsymbol{\nu}$. Here the number of degrees of freedom is equal to the number of components of $\boldsymbol{\theta}$. More details on use of the profile likelihood are given in Refs. [21, 22] and in contributions to the PHYSTAT conferences [23]; explicit formulae for special cases can be found in Ref. [24]. Further discussion on how to incorporate systematic uncertainties into p-values can be found in Ref. [25].

Even with use of the profile likelihood ratio, for a finite data sample the p-value of hypothesized parameters $\boldsymbol{\theta}$ will retain in general some dependence on the nuisance parameters $\boldsymbol{\nu}$. Ideally one would find the the maximum of $p_\theta(\boldsymbol{\nu})$ from Eq. (40.48) explicitly, but that is often impractical. An approximate and computationally feasible technique is to use $p_\theta(\widehat{\widehat{\boldsymbol{\nu}}}(\theta))$, where $\widehat{\widehat{\boldsymbol{\nu}}}(\theta)$ are the profiled values of the nuisance parameters as defined in Section 40.2.2.2. The resulting p-value is correct if the true values of the nuisance parameters are equal to the profiled values used; otherwise it could be either too high or too low. This is discussed further in Section 40.4.2 on confidence intervals.

One may also treat model uncertainties in a Bayesian manner but then use the resulting model in a frequentist test. Suppose the uncertainty in a set of nuisance parameters $\boldsymbol{\nu}$ is characterized

by a Bayesian prior p.d.f. $\pi(\boldsymbol{\nu})$. This can be used to construct the marginal (also called the prior predictive) model for the data $\boldsymbol{x}$ and parameters of interest $\boldsymbol{\theta}$,

$$P_{\rm m}(\boldsymbol{x}|\boldsymbol{\theta}) = \int P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})\pi(\boldsymbol{\nu})\,d\boldsymbol{\nu}\ . \tag{40.50}$$

The marginal model does not represent the probability of data that would be generated if one were really to repeat the experiment, as in that case one would assume that the nuisance parameters do not vary. Rather, the marginal model represents a situation in which every repetition of the experiment is carried out with new values of $\boldsymbol{\nu}$, randomly sampled from $\pi(\boldsymbol{\nu})$. It is in effect an average of models each with a given $\boldsymbol{\nu}$, where the average is carried out with respect to the prior p.d.f. $\pi(\boldsymbol{\nu})$.

The marginal model for the data $\boldsymbol{x}$ can be used to determine the distribution of a test statistic Q, which can be written

$$P_{\rm m}(Q|\boldsymbol{\theta}) = \int P(Q|\boldsymbol{\theta},\boldsymbol{\nu})\pi(\boldsymbol{\nu})\,d\boldsymbol{\nu}\ . \tag{40.51}$$

In a search for a new signal process, the test statistic can be based on the ratio of likelihoods corresponding to the experiments where signal and background events are both present, L_{s+b}, to that of background only, L_b. Often the likelihoods are evaluated with the profiled values of the nuisance parameters, which may give improved performance. It is important to note, however, that it is through use of the marginal model for the distribution of Q that the uncertainties related to the nuisance parameters are incorporated into the result of the test. Different choices for the test statistic itself only result in variations of the power of the test with respect to different alternatives.

40.3.2.2 *The look-elsewhere effect*

The "look-elsewhere effect" relates to multiple measurements used to test a single hypothesis. The classic example is when one searches in a distribution for a peak whose position is not predicted in advance. Here the no-peak hypothesis is tested using data in a given range of the distribution. In the frequentist approach the correct p-value of the no-peak hypothesis is the probability, assuming background only, to find a signal as significant as the one found or more so anywhere in the search region. This can be substantially higher than the probability to find a peak of equal or greater significance in the particular place where it appeared. There is in general some ambiguity as to what constitutes the relevant search region or even the broader set of relevant measurements. Although the desired p-value is well defined once the search region has been fixed, an exact treatment can require extensive computation.

The "brute-force" solution to this problem by Monte Carlo involves generating data under the background-only hypothesis and for each data set, fitting a peak of unknown position and recording a measure of its significance. To establish a discovery one often requires a p-value smaller than 2.87×10^{-7}, corresponding to a 5σ or larger effect. Determining this with Monte Carlo thus requires generating and fitting a very large number of experiments, perhaps several times 10^7. In contrast, if the position of the peak is fixed, then the fit to the distribution is much easier, and furthermore one can in many cases use formulae valid for sufficiently large samples that bypass completely the need for Monte Carlo (see, *e.g.*, [24]). However, this fixed-position or "local" p-value would not be correct in general, as it assumes the position of the peak was known in advance.

A method that allows one to modify the local p-value computed under assumption of a fixed position to obtain an approximation to the correct "global" value using a relatively simple calculation is described in Ref. [26]. Suppose a test statistic q_0, defined so that larger values indicate increasing disagreement with the data, is observed to have a value u. Furthermore suppose the model contains a nuisance parameter such as the peak position that is only defined under the signal model (there is no peak in the background-only model). An approximation for the global p-value is found to be

$$p_{\rm global} \approx p_{\rm local} + \langle N_u \rangle\ , \tag{40.52}$$

where $\langle N_u \rangle$, which is much smaller than one in cases of interest, is the mean number of "upcrossings" (as defined in [26]) of the statistic q_0 above the level u in the range of the nuisance parameter considered (*e.g.*, the mass range).

The value of $\langle N_u \rangle$ can be estimated from the number of upcrossings $\langle N_{u_0} \rangle$ above some much lower value, u_0, by using a relation due to Davis [27],

$$\langle N_u \rangle \approx \langle N_{u_0} \rangle e^{-(u-u_0)/2}\ . \tag{40.53}$$

By choosing u_0 sufficiently low, the value of $\langle N_u \rangle$ can be estimated by simulating only a very small number of experiments, or even from the observed data, rather than of the order 10^7 needed if one is dealing with a 5σ effect.

40.3.2.3 *Goodness-of-fit with the method of least squares*

When estimating parameters using the method of least squares, one obtains the minimum value of the quantity χ^2 (40.19). This statistic can be used to test the *goodness-of-fit*, *i.e.*, the test provides a measure of the significance of a discrepancy between the data and the hypothesized functional form used in the fit. It may also happen that no parameters are estimated from the data, but that one simply wants to compare a histogram, *e.g.*, a vector of Poisson distributed numbers $\boldsymbol{n} = (n_1, \ldots, n_N)$, with a hypothesis for their expectation values $\mu_i = E[n_i]$. As the distribution is Poisson with variances $\sigma_i^2 = \mu_i$, the χ^2 (40.19) becomes *Pearson's* χ^2 *statistic*,

$$\chi^2 = \sum_{i=1}^{N} \frac{(n_i - \mu_i)^2}{\mu_i}\ . \tag{40.54}$$

If the hypothesis $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_N)$ is correct, and if the expected values μ_i in (40.54) are sufficiently large (or equivalently, if the measurements n_i can be treated as following a Gaussian distribution), then the χ^2 statistic will follow the χ^2 p.d.f. with the number of degrees of freedom equal to the number of measurements N minus the number of fitted parameters.

Alternatively, one may fit parameters and evaluate goodness-of-fit by minimizing $-2\ln\lambda$ from Eq. (40.16). One finds that the distribution of this statistic approaches the asymptotic limit faster than does Pearson's χ^2. Therefore if one uses the asymptotic χ^2 p.d.f. as the statistic's approximate sampling distribution to compute a p-value, one obtains in general a more accurate result from $-2\ln\lambda$ than from Pearson's χ^2 (see Ref. [8] and references therein).

Assuming the goodness-of-fit statistic follows a χ^2 p.d.f., the p-value for the hypothesis is then

$$p = \int_{\chi^2}^{\infty} f(z; n_{\rm d})\,dz\ , \tag{40.55}$$

where $f(z; n_{\rm d})$ is the χ^2 p.d.f. and $n_{\rm d}$ is the appropriate number of degrees of freedom. Values are shown in Fig. 40.1 or obtained, e.g., from the ROOT function `TMath::Prob`. If the asymptotic conditions for using the χ^2 p.d.f. do not hold, the statistic can still be defined as before, but its p.d.f. must be determined by other means in order to obtain the p-value, *e.g.*, using a Monte Carlo calculation.

Since the mean of the χ^2 distribution is equal to $n_{\rm d}$, one expects in a "reasonable" experiment to obtain $\chi^2 \approx n_{\rm d}$. Hence the quantity $\chi^2/n_{\rm d}$ is sometimes reported. Since the p.d.f. of $\chi^2/n_{\rm d}$ depends on $n_{\rm d}$, however, one must report $n_{\rm d}$ as well if one wishes to determine the p-value. The p-values obtained for different values of $\chi^2/n_{\rm d}$ are shown in Fig. 40.2.

If the minimized χ^2 value indicates a low level of agreement between data and hypothesis, one may be tempted to expect a high degree of uncertainty for any fitted parameters. Poor goodness-of-fit, however, does not mean that one will have large statistical errors for parameter estimates. If, for example, the error bars (or covariance matrix) used in constructing the χ^2 are underestimated, then this will lead to underestimated statistical errors for the fitted parameters and an increased value of the minimized χ^2. The standard deviations of estimators that one finds from, say, Eq. (40.13) reflect how widely the estimates would be distributed

if one were to repeat the measurement many times, assuming that the hypothesis and measurement errors used in the χ^2 are also correct. They do not include the systematic error which may result from an incorrect hypothesis or incorrectly estimated measurement errors in the χ^2.

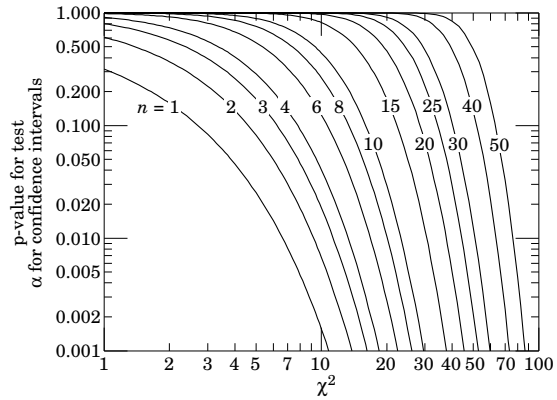

Figure 40.1: One minus the χ^2 cumulative distribution, $1 - F(\chi^2; n)$, for n degrees of freedom. This gives the p-value for the χ^2 goodness-of-fit test as well as one minus the coverage probability for confidence regions (see Sec. 40.4.2.2).

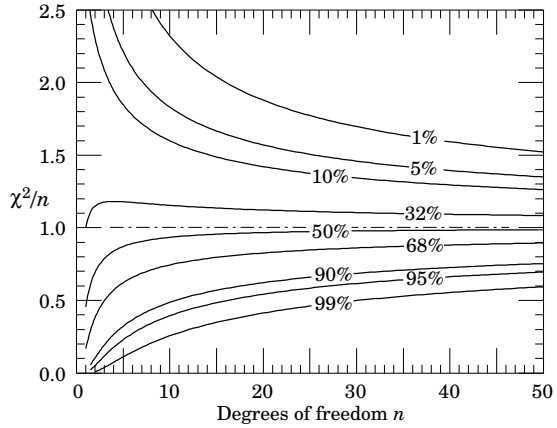

Figure 40.2: The 'reduced' χ^2, equal to χ^2/n, for n degrees of freedom. The curves show as a function of n the χ^2/n that corresponds to a given p-value.

40.3.3 *Bayes factors*

In Bayesian statistics, all of one's knowledge about a model is contained in its posterior probability, which one obtains using Bayes' theorem (Eq. (40.37)). Thus one could reject a hypothesis H if its posterior probability $P(H|\boldsymbol{x})$ is sufficiently small. The difficulty here is that $P(H|\boldsymbol{x})$ is proportional to the prior probability $P(H)$, and there will not be a consensus about the prior probabilities for the existence of new phenomena. Nevertheless one can construct a quantity called the Bayes factor (described below), which can be used to quantify the degree to which the data prefer one hypothesis over another, and is independent of their prior probabilities.

Consider two models (hypotheses), H_i and H_j, described by vectors of parameters $\boldsymbol{\theta}_i$ and $\boldsymbol{\theta}_j$, respectively. Some of the components will be common to both models and others may be distinct. The full prior probability for each model can be written in the form

$$\pi(H_i, \boldsymbol{\theta}_i) = P(H_i)\pi(\boldsymbol{\theta}_i|H_i) \; . \tag{40.56}$$

Here $P(H_i)$ is the overall prior probability for H_i, and $\pi(\boldsymbol{\theta}_i|H_i)$ is the normalized p.d.f. of its parameters. For each model, the posterior probability is found using Bayes' theorem,

$$P(H_i|\boldsymbol{x}) = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)P(H_i)\pi(\boldsymbol{\theta}_i|H_i)\, d\boldsymbol{\theta}_i}{P(\boldsymbol{x})} \; , \tag{40.57}$$

where the integration is carried out over the internal parameters $\boldsymbol{\theta}_i$ of the model. The ratio of posterior probabilities for the models is therefore

$$\frac{P(H_i|\boldsymbol{x})}{P(H_j|\boldsymbol{x})} = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i)\, d\boldsymbol{\theta}_i}{\int P(\boldsymbol{x}|\boldsymbol{\theta}_j, H_j)\pi(\boldsymbol{\theta}_j|H_j)\, d\boldsymbol{\theta}_j} \frac{P(H_i)}{P(H_j)} \; . \tag{40.58}$$

The *Bayes factor* is defined as

$$B_{ij} = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i)\, d\boldsymbol{\theta}_i}{\int P(\boldsymbol{x}|\boldsymbol{\theta}_j, H_j)\pi(\boldsymbol{\theta}_j|H_j)\, d\boldsymbol{\theta}_j} \; . \tag{40.59}$$

This gives what the ratio of posterior probabilities for models i and j would be if the overall prior probabilities for the two models were equal. If the models have no nuisance parameters, *i.e.*, no internal parameters described by priors, then the Bayes factor is simply the likelihood ratio. The Bayes factor therefore shows by how much the probability ratio of model i to model j changes in the light of the data, and thus can be viewed as a numerical measure of evidence supplied by the data in favor of one hypothesis over the other.

Although the Bayes factor is by construction independent of the overall prior probabilities $P(H_i)$ and $P(H_j)$, it does require priors for all internal parameters of a model, *i.e.*, one needs the functions $\pi(\boldsymbol{\theta}_i|H_i)$ and $\pi(\boldsymbol{\theta}_j|H_j)$. In a Bayesian analysis where one is only interested in the posterior p.d.f. of a parameter, it may be acceptable to take an unnormalizable function for the prior (an improper prior) as long as the product of likelihood and prior can be normalized. Improper priors are, however, only defined up to an arbitrary multiplicative constant, and so the Bayes factor would depend on this constant. Furthermore, although the range of a constant normalized prior is unimportant for parameter determination (provided it is wider than the likelihood), this is not so for the Bayes factor when such a prior is used for only one of the hypotheses. So to compute a Bayes factor, all internal parameters must be described by normalized priors that represent meaningful probabilities over the entire range where they are defined.

An exception to this rule may be considered when the identical parameter appears in the models for both numerator and denominator of the Bayes factor. In this case one can argue that the arbitrary constants would cancel. One must exercise some caution, however, as parameters with the same name and physical meaning may still play different roles in the two models.

Both integrals in Equation (40.59) are of the form

$$m = \int P(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})\, d\boldsymbol{\theta} \; , \tag{40.60}$$

which is similar to the marginal likelihood seen previously in Eq. (40.50) (in some fields this quantity is called the *evidence*). Computing marginal likelihoods can be difficult; in many cases it can be done with the nested sampling algorithm [28] as implemented, *e.g.*, in the program `MultiNest` [29]. A review of Bayes factors can be found in Ref. [30].

40.4 Intervals and limits

When the goal of an experiment is to determine a parameter θ, the result is usually expressed by quoting, in addition to the point estimate, some sort of interval which reflects the statistical precision of the measurement. In the simplest case, this can be given by the parameter's estimated value $\widehat{\theta}$ plus or minus an estimate of the standard deviation of $\widehat{\theta}$, $\widehat{\sigma_{\widehat{\theta}}}$. If, however, the p.d.f. of the estimator is not Gaussian or if there are physical boundaries on the possible values of the parameter, then one usually quotes instead an interval according to one of the procedures described below.

In reporting an interval or limit, the experimenter may wish to

- communicate as objectively as possible the result of the experiment;
- provide an interval that is constructed to cover on average the true value of the parameter with a specified probability;
- provide the information needed by the consumer of the result to draw conclusions about the parameter or to make a particular decision;
- draw conclusions about the parameter that incorporate stated prior beliefs.

With a sufficiently large data sample, the point estimate and standard deviation (or for the multiparameter case, the parameter estimates and covariance matrix) satisfy essentially all of these goals. For small data samples, no single method for quoting an interval will achieve all of them.

In addition to the goals listed above, the choice of method may be influenced by practical considerations such as ease of producing an interval from the results of several measurements. Of course the experimenter is not restricted to quoting a single interval or limit; one may choose, for example, first to communicate the result with a confidence interval having certain frequentist properties, and then in addition to draw conclusions about a parameter using a judiciously chosen subjective Bayesian prior. It is recommended, however, that there be a clear separation between these two aspects of reporting a result. In the remainder of this section, we assess the extent to which various types of intervals achieve the goals stated here.

40.4.1 *Bayesian intervals*

As described in Sec. 40.2.6, a Bayesian posterior probability may be used to determine regions that will have a given probability of containing the true value of a parameter. In the single parameter case, for example, an interval (called a Bayesian or credible interval) $[\theta_{\rm lo}, \theta_{\rm up}]$ can be determined which contains a given fraction $1-\alpha$ of the posterior probability, *i.e.*,

$$1-\alpha = \int_{\theta_{\rm lo}}^{\theta_{\rm up}} p(\theta|\boldsymbol{x})\, d\theta \,. \tag{40.61}$$

Sometimes an upper or lower limit is desired, *i.e.*, $\theta_{\rm lo}$ or $\theta_{\rm up}$ can be set to a physical boundary or to plus or minus infinity. In other cases, one might be interested in the set of θ values for which $p(\theta|\boldsymbol{x})$ is higher than for any θ not belonging to the set, which may constitute a single interval or a set of disjoint regions; these are called highest posterior density (HPD) intervals. Note that HPD intervals are not invariant under a nonlinear transformation of the parameter.

If a parameter is constrained to be non-negative, then the prior p.d.f. can simply be set to zero for negative values. An important example is the case of a Poisson variable n, which counts signal events with unknown mean s, as well as background with mean b, assumed known. For the signal mean s, one often uses the prior

$$\pi(s) = \begin{cases} 0 & s < 0 \\ 1 & s \geq 0 \end{cases} \,. \tag{40.62}$$

This prior may be regarded as providing an interval whose frequentist properties can be studied, rather than as representing a degree of belief. For example, to obtain an upper limit on s, one may proceed as follows. The likelihood for s is given by the Poisson distribution for n with mean $s+b$,

$$P(n|s) = \frac{(s+b)^n}{n!} e^{-(s+b)} \,, \tag{40.63}$$

along with the prior (40.62) in (40.37) gives the posterior density for s. An upper limit $s_{\rm up}$ at confidence level (or here, rather, *credibility* level) $1-\alpha$ can be obtained by requiring

$$1-\alpha = \int_{-\infty}^{s_{\rm up}} p(s|n) ds = \frac{\int_{-\infty}^{s_{\rm up}} P(n|s)\,\pi(s)\,ds}{\int_{-\infty}^{\infty} P(n|s)\,\pi(s)\,ds} \,, \tag{40.64}$$

where the lower limit of integration is effectively zero because of the cut-off in $\pi(s)$. By relating the integrals in Eq. (40.64) to incomplete gamma functions, the solution for the upper limit is found to be

$$s_{\rm up} = \frac{1}{2} F_{\chi^2}^{-1}\left[p, 2(n+1)\right] - b \,, \tag{40.65}$$

where $F_{\chi^2}^{-1}$ is the quantile of the χ^2 distribution (inverse of the cumulative distribution). Here the quantity p is

$$p = 1 - \alpha\left(1 - F_{\chi^2}\left[2b, 2(n+1)\right]\right) \,, \tag{40.66}$$

where F_{χ^2} is the cumulative χ^2 distribution. For both F_{χ^2} and $F_{\chi^2}^{-1}$ above, the argument $2(n+1)$ gives the number of degrees of freedom. For the special case of $b=0$, the limit reduces to

$$s_{\rm up} = \frac{1}{2} F_{\chi^2}^{-1}(1-\alpha; 2(n+1)) \,. \tag{40.67}$$

It happens that for the case of $b=0$, the upper limit from Eq. (40.67) coincides numerically with the frequentist upper limit discussed in Section 40.4.2.3. Values for $1-\alpha = 0.9$ and 0.95 are given by the values $\mu_{\rm up}$ in Table 40.3. The frequentist properties of confidence intervals for the Poisson mean found in this way are discussed in Refs. [2] and [31].

As in any Bayesian analysis, it is important to show how the result changes under assumption of different prior probabilities. For example, one could consider the Jeffreys prior as described in Sec. 40.2.6. For this problem one finds the Jeffreys prior $\pi(s) \propto 1/\sqrt{s+b}$ for $s \geq 0$ and zero otherwise. As with the constant prior, one would not regard this as representing one's prior beliefs about s, both because it is improper and also as it depends on b. Rather it is used with Bayes' theorem to produce an interval whose frequentist properties can be studied.

If the model contains nuisance parameters then these are eliminated by marginalizing, as in Eq. (40.43), to obtain the p.d.f. for the parameters of interest. For example, if the parameter b in the Poisson counting problem above were to be characterized by a prior p.d.f. $\pi(b)$, then one would first use Bayes' theorem to find $p(s,b|n)$. This is then marginalized to find $p(s|n) = \int p(s,b|n)\pi(b)\,db$, from which one may determine an interval for s. One may not be certain whether to extend a model by including more nuisance parameters. In this case, a Bayes factor may be used to determine to what extent the data prefer a model with additional parameters, as described in Section 40.3.3.

40.4.2 *Frequentist confidence intervals*

The unqualified phrase "confidence intervals" refers to frequentist intervals obtained with a procedure due to Neyman [32], described below. The boundary of the interval (or in the multiparameter case, region) is given by a specific function of the data, which would fluctuate if one were to repeat the experiment many times. The *coverage probability* refers to the fraction of intervals in such an ensemble that contain the true parameter value. Confidence intervals are constructed so as to have a coverage probability greater than or equal to a given *confidence level*, regardless of the true parameter's value. It is important to note that in the frequentist approach, such a probability is not meaningful for a fixed interval. In this section we discuss several techniques for producing intervals that have, at least approximately, this property of coverage.

40.4.2.1 *The Neyman construction for confidence intervals*

Consider a p.d.f. $f(x;\theta)$ where x represents the outcome of the experiment and θ is the unknown parameter for which we want to construct a confidence interval. The variable x could (and often does) represent an estimator for θ. Using $f(x;\theta)$, we can find using a pre-defined rule and probability $1-\alpha$ for every value of θ, a set of values $x_1(\theta,\alpha)$ and $x_2(\theta,\alpha)$ such that

$$P(x_1 < x < x_2; \theta) = \int_{x_1}^{x_2} f(x;\theta)\, dx \geq 1-\alpha \,. \tag{40.68}$$

If x is discrete, the integral is replaced by the corresponding sum. In that case there may not exist a range of x values whose summed probability is exactly equal to a given value of $1-\alpha$, and one requires by convention $P(x_1 < x < x_2; \theta) \geq 1-\alpha$.

This is illustrated for continuous x in Fig. 40.3: a horizontal line segment $[x_1(\theta,\alpha), x_2(\theta,\alpha)]$ is drawn for representative values of θ. The union of such intervals for all values of θ, designated in the figure as $D(\alpha)$, is known as a *confidence belt*. Typically the curves $x_1(\theta,\alpha)$ and $x_2(\theta,\alpha)$ are monotonic functions of θ, which we assume for this discussion.

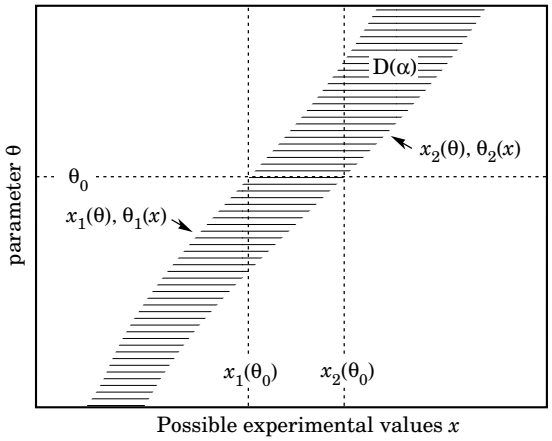

Figure 40.3: Construction of the confidence belt (see text).

Upon performing an experiment to measure x and obtaining a value x_0, one draws a vertical line through x_0. The confidence interval for θ is the set of all values of θ for which the corresponding line segment $[x_1(\theta,\alpha), x_2(\theta,\alpha)]$ is intercepted by this vertical line. Such confidence intervals are said to have a *confidence level* (CL) equal to $1-\alpha$.

Now suppose that the true value of θ is θ_0, indicated in the figure. We see from the figure that θ_0 lies between $\theta_1(x)$ and $\theta_2(x)$ if and only if x lies between $x_1(\theta_0)$ and $x_2(\theta_0)$. The two events thus have the same probability, and since this is true for any value θ_0, we can drop the subscript 0 and obtain

$$1-\alpha = P(x_1(\theta) < x < x_2(\theta)) = P(\theta_2(x) < \theta < \theta_1(x)) \ . \quad (40.69)$$

In this probability statement, $\theta_1(x)$ and $\theta_2(x)$, *i.e.*, the endpoints of the interval, are the random variables and θ is an unknown constant. If the experiment were to be repeated a large number of times, the interval $[\theta_1, \theta_2]$ would vary, covering the fixed value θ in a fraction $1-\alpha$ of the experiments.

The condition of coverage in Eq. (40.68) does not determine x_1 and x_2 uniquely, and additional criteria are needed. One possibility is to choose *central intervals* such that the probabilities to find x below x_1 and above x_2 are each $\alpha/2$. In other cases, one may want to report only an upper or lower limit, in which case one of $P(x \le x_1)$ or $P(x \ge x_2)$ can be set to α and the other to zero. Another principle based on *likelihood ratio ordering* for determining which values of x should be included in the confidence belt is discussed below.

When the observed random variable x is continuous, the coverage probability obtained with the Neyman construction is $1-\alpha$, regardless of the true value of the parameter. Because of the requirement $P(x_1 < x < x_2) \ge 1-\alpha$ when x is discrete, one obtains in that case confidence intervals that include the true parameter with a probability greater than or equal to $1-\alpha$.

An equivalent method of constructing confidence intervals is to consider a test (see Sec. 40.3) of the hypothesis that the parameter's true value is θ (assume one constructs a test for all physical values of θ). One then excludes all values of θ where the hypothesis would be rejected in a test of size α or less. The remaining values constitute the confidence interval at confidence level $1-\alpha$. If the critical region of the test is characterized by having a p-value $p_\theta \le \alpha$, then the endpoints of the confidence interval are found in practice by solving $p_\theta = \alpha$ for θ.

In the procedure outlined above, one is still free to choose the test to be used; this corresponds to the freedom in the Neyman construction as to which values of the data are included in the confidence belt. One possibility is to use a test statistic based on the *likelihood ratio*,

$$\lambda(\theta) = \frac{f(x;\theta)}{f(x;\widehat{\theta})} \ , \quad (40.70)$$

where $\widehat{\theta}$ is the value of the parameter which, out of all allowed values, maximizes $f(x;\theta)$. The confidence belt is taken to contain the values of x that give the greatest values of $\lambda(\theta)$. This results in the intervals described in Ref. [33] by Feldman and Cousins.

If the model contains nuisance parameters $\boldsymbol{\nu}$, then these can be incorporated into the test (or the p-values) used to determine the limit by profiling as discussed in Section 40.3.2.1. As mentioned there, the strict frequentist approach is to regard the parameter of interest θ as excluded only if it is rejected for all possible values of $\boldsymbol{\nu}$. The resulting interval for θ will then cover the true value with a probability greater than or equal to the nominal confidence level for all points in $\boldsymbol{\nu}$-space.

If the p-value is based on the profiled values of the nuisance parameters, *i.e.*, with $\boldsymbol{\nu} = \widehat{\widehat{\boldsymbol{\nu}}}(\theta)$ used in Eq. (40.48), then the resulting interval for the parameter of interest will have the correct coverage if the true values of $\boldsymbol{\nu}$ are equal to the profiled values. Otherwise the coverage probability may be too high or too low. This procedure has been called *profile construction* in particle physics [34] (see also [25]).

40.4.2.2 *Gaussian distributed measurements*

An important example of constructing a confidence interval is when the data consists of a single random variable x that follows a Gaussian distribution; this is often the case when x represents an estimator for a parameter and one has a sufficiently large data sample. If there is more than one parameter being estimated, the multivariate Gaussian is used. For the univariate case with known σ, the probability that the measured value x will fall within $\pm\delta$ of the true value μ is

$$1-\alpha = \frac{1}{\sqrt{2\pi}\sigma}\int_{\mu-\delta}^{\mu+\delta} e^{-(x-\mu)^2/2\sigma^2}\,dx$$
$$= \mathrm{erf}\left(\frac{\delta}{\sqrt{2}\,\sigma}\right) = 2\Phi\left(\frac{\delta}{\sigma}\right) - 1 \ , \quad (40.71)$$

where erf is the Gaussian error function, which is rewritten in the final equality using Φ, the Gaussian cumulative distribution. Fig. 40.4 shows a $\delta = 1.64\sigma$ confidence interval unshaded. The choice $\delta = \sigma$ gives an interval called the *standard error* which has $1-\alpha = 68.27\%$ if σ is known. Values of α for other frequently used choices of δ are given in Table 40.1.

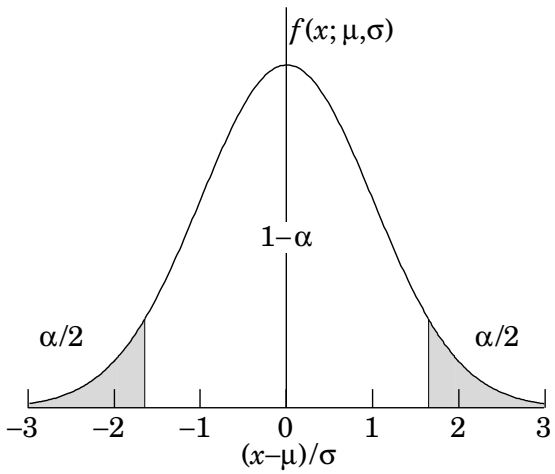

Figure 40.4: Illustration of a symmetric 90% confidence interval (unshaded) for a Gaussian-distributed measurement of a single quantity. Integrated probabilities, defined by $\alpha = 0.1$, are as shown.

Table 40.1: Area of the tails α outside $\pm\delta$ from the mean of a Gaussian distribution.

α	δ	α	δ
0.3173	1σ	0.2	1.28σ
4.55×10^{-2}	2σ	0.1	1.64σ
2.7×10^{-3}	3σ	0.05	1.96σ
6.3×10^{-5}	4σ	0.01	2.58σ
5.7×10^{-7}	5σ	0.001	3.29σ
2.0×10^{-9}	6σ	10^{-4}	3.89σ

We can set a one-sided (upper or lower) limit by excluding above $x+\delta$ (or below $x-\delta$). The values of α for such limits are half the values in Table 40.1.

The relation (40.71) can be re-expressed using the cumulative distribution function for the χ^2 distribution as

$$\alpha = 1 - F(\chi^2; n) \,, \tag{40.72}$$

for $\chi^2 = (\delta/\sigma)^2$ and $n = 1$ degree of freedom. This can be seen as the $n = 1$ curve in Fig. 40.1 or obtained by using, e.g., the ROOT function `TMath::Prob`. For multivariate measurements of, say, M parameter estimates $\widehat{\boldsymbol{\theta}} = (\widehat{\theta}_1, \ldots, \widehat{\theta}_M)$, construction of the confidence region requires the full covariance matrix $V_{ij} = \mathrm{cov}[\widehat{\theta}_i, \widehat{\theta}_j]$, which can be estimated as described in Sections 40.2.2 and 40.2.3. Under fairly general conditions with the methods of maximum-likelihood or least-squares in the large sample limit, the estimators will be distributed according to a multivariate Gaussian centered about the true (unknown) values $\boldsymbol{\theta}$, and furthermore, the likelihood function itself will take on a Gaussian shape.

The standard error ellipse for the pair $(\widehat{\theta}_i, \widehat{\theta}_j)$ is shown in Fig. 40.5, corresponding to a contour $\chi^2 = \chi^2_{\min} + 1$ or $\ln L = \ln L_{\max} - 1/2$. The ellipse is centered about the estimated values $\widehat{\boldsymbol{\theta}}$, and the tangents to the ellipse give the standard deviations of the estimators, σ_i and σ_j. The angle of the major axis of the ellipse is given by

$$\tan 2\phi = \frac{2\rho_{ij}\sigma_i\sigma_j}{\sigma_j^2 - \sigma_i^2} \,, \tag{40.73}$$

where $\rho_{ij} = \mathrm{cov}[\widehat{\theta}_i, \widehat{\theta}_j]/\sigma_i\sigma_j$ is the correlation coefficient.

The correlation coefficient can be visualized as the fraction of the distance σ_i from the ellipse's horizontal center-line at which the ellipse becomes tangent to vertical, *i.e.*, at the distance $\rho_{ij}\sigma_i$ below the center-line as shown. As ρ_{ij} goes to $+1$ or -1, the ellipse thins to a diagonal line.

It could happen that one of the parameters, say, θ_j, is known from previous measurements to a precision much better than σ_j, so that the current measurement contributes almost nothing to the knowledge of θ_j. However, the current measurement of θ_i and its dependence on θ_j may still be important. In this case, instead of quoting both parameter estimates and their correlation, one sometimes reports the value of θ_i, which minimizes χ^2 at a fixed value of θ_j, such as the PDG best value. This θ_i value lies along the dotted line between the points where the ellipse becomes tangent to vertical, and has statistical error σ_{inner} as shown on the figure, where $\sigma_{\mathrm{inner}} = (1-\rho_{ij}^2)^{1/2}\sigma_i$. Instead of the correlation ρ_{ij}, one reports the dependency $d\widehat{\theta}_i/d\theta_j$, which is the slope of the dotted line. This slope is related to the correlation coefficient by $d\widehat{\theta}_i/d\theta_j = \rho_{ij} \times \frac{\sigma_i}{\sigma_j}$.

As in the single-variable case, because of the symmetry of the Gaussian function between $\boldsymbol{\theta}$ and $\widehat{\boldsymbol{\theta}}$, one finds that contours of constant $\ln L$ or χ^2 cover the true values with a certain, fixed probability. That is, the confidence region is determined by

$$\ln L(\boldsymbol{\theta}) \geq \ln L_{\max} - \Delta \ln L \,, \tag{40.74}$$

or where a χ^2 has been defined for use with the method of least-squares,

$$\chi^2(\boldsymbol{\theta}) \leq \chi^2_{\min} + \Delta\chi^2 \,. \tag{40.75}$$

Values of $\Delta\chi^2$ or $2\Delta \ln L$ are given in Table 40.2 for several values of the coverage probability $1-\alpha$ and number of fitted parameters

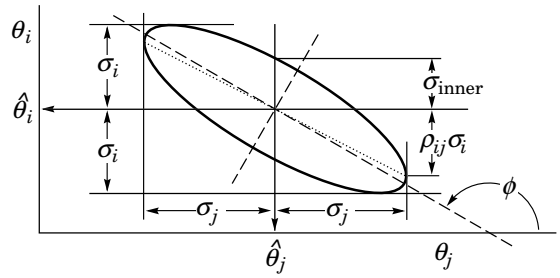

Figure 40.5: Standard error ellipse for the estimators $\widehat{\theta}_i$ and $\widehat{\theta}_j$. In the case shown the correlation is negative.

M. For Gaussian distributed data, these are related by $\Delta\chi^2 = 2\Delta \ln L = F^{-1}_{\chi^2_M}(1-\alpha)$, where $F^{-1}_{\chi^2_M}$ is the chi-square quantile (inverse of the cumulative distribution) for M degrees of freedom.

Table 40.2: Values of $\Delta\chi^2$ or $2\Delta \ln L$ corresponding to a coverage probability $1-\alpha$ in the large data sample limit, for joint estimation of M parameters.

$(1-\alpha)$ (%)	$M=1$	$M=2$	$M=3$
68.27	1.00	2.30	3.53
90.	2.71	4.61	6.25
95.	3.84	5.99	7.82
95.45	4.00	6.18	8.03
99.	6.63	9.21	11.34
99.73	9.00	11.83	14.16

For non-Gaussian data samples, the probability for the regions determined by Equations (40.74) or (40.75) to cover the true value of $\boldsymbol{\theta}$ becomes independent of $\boldsymbol{\theta}$ only in the large-sample limit. So for a finite data sample these are not exact confidence regions according to our previous definition. Nevertheless, they can still have a coverage probability only weakly dependent on the true parameter, and approximately as given in Table 40.2. In any case, the coverage probability of the intervals or regions obtained according to this procedure can in principle be determined as a function of the true parameter(s), for example, using a Monte Carlo calculation.

One of the practical advantages of intervals that can be constructed from the log-likelihood function or χ^2 is that it is relatively simple to produce the interval for the combination of several experiments. If N independent measurements result in log-likelihood functions $\ln L_i(\boldsymbol{\theta})$, then the combined log-likelihood function is simply the sum,

$$\ln L(\boldsymbol{\theta}) = \sum_{i=1}^{N} \ln L_i(\boldsymbol{\theta}) \,. \tag{40.76}$$

This can then be used to determine an approximate confidence interval or region with Eq. (40.74), just as with a single experiment.

40.4.2.3 *Poisson or binomial data*

Another important class of measurements consists of counting a certain number of events, n. In this section, we will assume these are all events of the desired type, *i.e.*, there is no background. If n represents the number of events produced in a reaction with cross section σ, say, in a fixed integrated luminosity $\mathcal{L}$, then it follows a Poisson distribution with mean $\mu = \sigma\mathcal{L}$. If, on the other hand, one has selected a larger sample of N events and found n of them to have a particular property, then n follows a binomial distribution where the parameter p gives the probability for the event to possess the property in question. This is appropriate, *e.g.*, for estimates of branching ratios or selection efficiencies based on a given total number of events.

For the case of Poisson distributed n, limits on the mean value μ can be found from the Neyman procedure as discussed in Sec-

tion 40.4.2.1 with n used directly as the statistic x . The upper and lower limits are found to be

$$\mu_{\rm lo} = \frac{1}{2} F^{-1}_{\chi^2}(\alpha_{\rm lo}; 2n) \ , \tag{40.77a}$$

$$\mu_{\rm up} = \frac{1}{2} F^{-1}_{\chi^2}(1-\alpha_{\rm up}; 2(n+1)) \ , \tag{40.77b}$$

where confidence levels of $1-\alpha_{\rm lo}$ and $1-\alpha_{\rm up}$ refer separately to the corresponding intervals $\mu \geq \mu_{\rm lo}$ and $\mu \leq \mu_{\rm up}$, and $F^{-1}_{\chi^2}$ is the quantile of the χ^2 distribution (inverse of the cumulative distribution). For central confidence intervals at confidence level $1-\alpha$, set $\alpha_{\rm lo} = \alpha_{\rm up} = \alpha/2$.

Table 40.3: Lower and upper (one-sided) limits for the mean μ of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

	$1-\alpha$ =90%		$1-\alpha$ =95%	
n	$\mu_{\rm lo}$	$\mu_{\rm up}$	$\mu_{\rm lo}$	$\mu_{\rm up}$
0	–	2.30	–	3.00
1	0.105	3.89	0.051	4.74
2	0.532	5.32	0.355	6.30
3	1.10	6.68	0.818	7.75
4	1.74	7.99	1.37	9.15
5	2.43	9.27	1.97	10.51
6	3.15	10.53	2.61	11.84
7	3.89	11.77	3.29	13.15
8	4.66	12.99	3.98	14.43
9	5.43	14.21	4.70	15.71
10	6.22	15.41	5.43	16.96

It happens that the upper limit from Eq. (40.77b) coincides numerically with the Bayesian upper limit for a Poisson parameter, using a uniform prior p.d.f. for μ. Values for confidence levels of 90% and 95% are shown in Table 40.3. For the case of binomially distributed n successes out of N trials with probability of success p, the upper and lower limits on p are found to be

$$p_{\rm lo} = \frac{nF^{-1}_F[\alpha_{\rm lo}; 2n, 2(N-n+1)]}{N-n+1 \ + \ nF^{-1}_F[\alpha_{\rm lo}; 2n, 2(N-n+1)]} \ , \tag{40.78a}$$

$$p_{\rm up} = \frac{(n+1)F^{-1}_F[1-\alpha_{\rm up}; 2(n+1), 2(N-n)]}{(N-n) \ + \ (n+1)F^{-1}_F[1-\alpha_{\rm up}; 2(n+1), 2(N-n)]} \ . \tag{40.78b}$$

Here F^{-1}_F is the quantile of the F distribution (also called the Fisher–Snedecor distribution; see Ref. [4]).

40.4.2.4 *Parameter exclusion in cases of low sensitivity*

An important example of a statistical test arises in the search for a new signal process. Suppose the parameter μ is defined such that it is proportional to the signal cross section. A statistical test may be carried out for hypothesized values of μ, which may be done by computing a p-value, p_μ, for all μ. Those values not rejected in a test of size α, *i.e.*, for which one does not find $p_\mu \leq \alpha$, constitute a confidence interval with confidence level $1-\alpha$.

In general one will find that for some regions in the parameter space of the signal model, the predictions for data are almost indistinguishable from those of the background-only model. This corresponds to the case where μ is very small, as would occur, *e.g.*, in a search for a new particle with a mass so high that its production rate in a given experiment is negligible. That is, one has essentially no experimental sensitivity to such a model.

One would prefer that if the sensitivity to a model (or a point in a model's parameter space) is very low, then it should not be excluded. Even if the outcomes predicted with or without signal are identical, however, the probability to reject the signal model will equal α, the type-I error rate. As one often takes α to be 5%, this would mean that in a large number of searches covering a broad range of a signal model's parameter space, there would inevitably be excluded regions in which the experimental sensitivity is very small, and thus one may question whether it is justified to regard such parameter values as disfavored.

Exclusion of models to which one has little or no sensitivity occurs, for example, if the data fluctuate very low relative to the expectation of the background-only hypothesis. In this case the resulting upper limit on μ may be anomalously low. As a means of controlling this effect one often determines the mean or median limit under assumption of the background-only hypothesis, as discussed in Sec. 40.5.

One way to mitigate the problem of excluding models to which one is not sensitive is the $\rm CL_s$ method, where the measure used to test a parameter is increased for decreasing sensitivity [35,36]. The procedure is based on a statistic called $\rm CL_s$, which is defined as

$$\mathrm{CL_s} = \frac{p_\mu}{1-p_{\rm b}} \ , \tag{40.79}$$

where $p_{\rm b}$ is the p-value of the background-only hypothesis. In the usual formulation of the method, both p_μ and $p_{\rm b}$ are defined using a single test statistic, and the definition of $\rm CL_s$ above assumes this statistic is continuous; more details can be found in Refs. [35,36].

A point in a model's parameter space is regarded as excluded if one finds $\mathrm{CL_s} \leq \alpha$. As the denominator in Eq. (40.79) is always less than or equal to unity, the exclusion criterion based on $\rm CL_s$ is more stringent than the usual requirement $p_\mu \leq \alpha$. In this sense the $\rm CL_s$ procedure is conservative, and the coverage probability of the corresponding intervals will exceed the nominal confidence level $1-\alpha$. If the experimental sensitivity to a given value of μ is very low, then one finds that as p_μ decreases, so does the denominator $1-p_{\rm b}$, and thus the condition $\mathrm{CL_s} \leq \alpha$ is effectively prevented from being satisfied. In this way the exclusion of parameters in the case of low sensitivity is suppressed.

The $\rm CL_s$ procedure has the attractive feature that the resulting intervals coincide with those obtained from the Bayesian method in two important cases: the mean value of a Poisson or Gaussian distributed measurement with a constant prior. The $\rm CL_s$ intervals overcover for all values of the parameter μ, however, by an amount that depends on μ.

The problem of excluding parameter values to which one has little sensitivity is particularly acute when one wants to set a one-sided limit, *e.g.*, an upper limit on a cross section. Here one tests a value of a rate parameter μ against the alternative of a lower rate, and therefore the critical region of the test is taken to correspond to data outcomes with a low event yield. If the number of events found in the search region fluctuates low enough, however, it can happen that all physically meaningful signal parameter values, including those to which one has very little sensitivity, are rejected by the test.

Another solution to this problem, therefore, is to replace the one-sided test by one based on the likelihood ratio, where the critical region is not restricted to low rates. This is the approach followed in the Feldman-Cousins procedure described in Section 40.4.2.1. The critical region for the test of a given value of μ contains data values characteristic of both higher and lower rates. As a result, for a given observed rate one can in general obtain a two-sided interval. If, however, the parameter estimate $\hat{\mu}$ is sufficiently close to the lower limit of zero, then only high values of μ are rejected, and the lower edge of the confidence interval is at zero. Note, however, that the coverage property of $1-\alpha$ pertains to the entire interval, not to the probability for the upper edge $\mu_{\rm up}$ to be greater than the true value μ. For parameter estimates increasingly far away from the boundary, *i.e.*, for increasing signal significance, the point $\mu = 0$ is excluded and the interval has nonzero upper and lower edges.

An additional difficulty arises when a parameter estimate is not significantly far away from the boundary, in which case it is natural to report a one-sided confidence interval (often an upper limit). It is straightforward to force the Neyman prescription to produce only an upper limit by setting $x_2 = \infty$ in Eq. (40.68). Then x_1 is uniquely determined and the upper limit can be obtained. If, however, the data come out such that the parameter estimate is not so close to the boundary, one might wish to report a central confidence interval (*i.e.*, an interval based on a two-sided test with equal upper and lower tail areas). As pointed out by Feldman and

Cousins [33], if the decision to report an upper limit or two-sided interval is made by looking at the data ("flip-flopping"), then in general there will be parameter values for which the resulting intervals have a coverage probability less than $1-\alpha$. With the confidence intervals suggested in [33], the prescription determines whether the interval is one- or two-sided in a way which preserves the coverage probability (and are thus said to be *unified*).

The intervals according to this method for the mean of Poisson variable in the absence of background are given in Table 40.4. (Note that α in Ref. [33] is defined following Neyman [32] as the coverage probability; this is opposite the modern convention used here in which the coverage probability is $1-\alpha$.) The values of $1-\alpha$ given here refer to the coverage of the true parameter by the whole interval $[\mu_1, \mu_2]$. In Table 40.3 for the one-sided upper limit, however, $1-\alpha$ refers to the probability to have $\mu_{\rm up} \geq \mu$ (or $\mu_{\rm lo} \leq \mu$ for lower limits).

Table 40.4: Unified confidence intervals $[\mu_1, \mu_2]$ for a the mean of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

	$1-\alpha$ =90%		$1-\alpha$ =95%	
n	μ_1	μ_2	μ_1	μ_2
0	0.00	2.44	0.00	3.09
1	0.11	4.36	0.05	5.14
2	0.53	5.91	0.36	6.72
3	1.10	7.42	0.82	8.25
4	1.47	8.60	1.37	9.76
5	1.84	9.99	1.84	11.26
6	2.21	11.47	2.21	12.75
7	3.56	12.53	2.58	13.81
8	3.96	13.99	2.94	15.29
9	4.36	15.30	4.36	16.77
10	5.50	16.50	4.75	17.82

A potential difficulty with unified intervals arises if, for example, one constructs such an interval for a Poisson parameter s of some yet to be discovered signal process with, say, $1-\alpha = 0.9$. If the true signal parameter is zero, or in any case much less than the expected background, one will usually obtain a one-sided upper limit on s. In a certain fraction of the experiments, however, a two-sided interval for s will result. Since, however, one typically chooses $1-\alpha$ to be only 0.9 or 0.95 when setting limits, the value $s = 0$ may be found below the lower edge of the interval before the existence of the effect is well established. It must then be communicated carefully that in excluding $s = 0$ at, say, 90% or 95% confidence level from the interval, one is not necessarily claiming to have discovered the effect, for which one would usually require a higher level of significance (*e.g.*, 5 σ).

Another possibility is to construct a Bayesian interval as described in Section 40.4.1. The presence of the boundary can be incorporated simply by setting the prior density to zero in the unphysical region. More specifically, the prior may be chosen using formal rules such as the reference prior or Jeffreys prior mentioned in Sec. 40.2.6.

In particle physics a widely used prior for the mean μ of a Poisson distributed measurement has been the uniform distribution for $\mu \geq 0$. This prior does not follow from any fundamental rule nor can it be regarded as reflecting a reasonable degree of belief, since the prior probability for μ to lie between any two finite values is zero. The procedure above can be more appropriately regarded as a way for obtaining intervals with frequentist properties that can be investigated. The resulting upper limits have a coverage probability that depends on the true value of the Poisson parameter, and is nowhere smaller than the stated probability content. Lower limits and two-sided intervals for the Poisson mean based on uniform priors undercover, however, for some values of the parameter, although to an extent that in practical cases may not be too severe [2, 31].

In any case, it is important to always report sufficient information so that the result can be combined with other measurements. Often this means giving an unbiased estimator and its standard deviation, even if the estimated value is in the unphysical region.

It can also be useful with a frequentist interval to calculate its subjective probability content using the posterior p.d.f. based on one or several reasonable guesses for the prior p.d.f. If it turns out to be significantly less than the stated confidence level, this warns that it would be particularly misleading to draw conclusions about the parameter's value from the interval alone.

40.5 Experimental sensitivity

In this section we describe methods for characterizing the sensitivity of a search for a new physics signal. As discussed in Sec. 40.3, an experimental analysis can often be formulated as a test of hypothetical model parameters. Therefore we may quantify the sensitivity by giving the results that we expect from such a test under specific assumptions about the signal process.

Here to be concrete we will consider a parameter μ proportional to the rate of a signal process, although the concepts described in this section may be easily generalized to other parameters. One may wish to establish discovery of the signal process by testing and rejecting the hypothesis that $\mu = 0$, and in addition one often wants to test nonzero values of μ to construct a confidence interval (*e.g.*, limits) as described in Sec. 40.4. In the frequentist framework, the result of each tested value of μ is the p-value p_μ or equivalently the significance $Z_\mu = \Phi^{-1}(1-p_\mu)$, where as usual Φ is the standard Gaussian cumulative distribution and its inverse Φ^{-1} is the standard Gaussian quantile.

Prior to carrying out the experiment, one generally wants to quantify what significance Z_μ is expected under given assumptions for the presence or absence of the signal process. Specifically, for the significance of a test of $\mu = 0$ (the discovery significance) one usually quotes the Z_0 one would expect if the signal is present at a given nominal rate, which we can define in general to correspond to $\mu = 1$. For limits, one often gives the expected limit under assumption of the background-only ($\mu = 0$) model. These quantities are used to optimize the analysis and to quantify the experimental sensitivity, that is, to characterize how likely it is to make a discovery if the signal is present, and to say what values of μ one may be able to exclude if the signal is in fact absent.

First we clarify the notion of *expected significance*. Because the significance Z_μ is a function of the data, it is itself a random quantity characterized by a certain sampling distribution. This distribution depends on the assumed value of μ, which is not necessarily the same as the hypothesized value of μ being tested. We may therefore consider the distribution $f(Z_\mu|\mu')$, *i.e.*, the distribution of Z_μ that would be obtained by considering data samples generated under assumption of μ'. In a similar way one can talk about the sampling distribution of an upper limit for μ, $f(\mu_{\rm up}|\mu')$.

One can identify the expected significance or limit with either the mean or median of these distributions, but the median may be preferred since it is invariant under monotonic transformations. For example, the monotonic relation between p-value and significance, $p = 1-\Phi(Z)$, then gives $\mathrm{med}[p_\mu|\mu'] = 1-\Phi(\mathrm{med}[Z_\mu|\mu'])$, whereas the corresponding relation does not hold in general for the mean.

In some cases one may be able to write down approximate formulae for the distributions of Z_μ and for limits, but more generally they must be determined from Monte Carlo calculations. In many cases of interest, the significance Z_μ and the limits on μ will have approximate Gaussian distributions.

As an example, consider a Poisson counting experiment, where the result consists of an observed number n of events, modeled as a Poisson distributed variable with a mean of $\mu s + b$. Here s and b, the expected numbers of events from signal and background processes, are taken to be known. If we are interested in discovering the signal process we test and try to reject the hypothesis $\mu = 0$. To characterize the experimental sensitivity, we want to give the discovery significance expected under the assumption of $\mu = 1$.

In the limit where its mean value is large, the Poisson variable n can be approximated as an almost continuous Gaussian variable with mean $\mu s + b$ and standard deviation $\sigma = \sqrt{\mu s + b}$. In the usual case where a physical signal model corresponds to $\mu > 0$,

the p-value of $\mu = 0$ is the probability to find n greater than or equal to the value observed,

$$p_0 = \Phi\left(\frac{n-b}{\sqrt{b}}\right) , \tag{40.80}$$

and the corresponding significance is $Z_0 = \Phi^{-1}(1-p_0) = (n-b)/\sqrt{b}$. The median (here equal to the mean) of n assuming $\mu = 1$ is $s+b$, and therefore the median discovery significance is

$$\mathrm{med}[Z_0|\mu = 1] = \frac{s}{\sqrt{b}} . \tag{40.81}$$

The figure of merit "$s/\sqrt{b}$" has been widely used in particle physics as a measure of expected discovery significance. A better approximation for the Poisson counting experiment, however, may be obtained by testing $\mu = 0$ using the likelihood ratio (40.49) $\lambda(0) = L(0)/L(\hat{\mu})$, where

$$L(\mu) = \frac{(\mu s + b)^n}{n!} e^{-(\mu s + b)} \tag{40.82}$$

is the likelihood function, and $\hat{\mu} = (n-b)/s$ is the ML estimator. In this example there are no nuisance parameters, as s and b are taken to be known. For the case where the relevant signal models correspond to positive μ, one may test the $\mu = 0$ hypothesis with the statistic $q_0 = -2\ln\lambda(0)$ when $\hat{\mu} > 0$, *i.e.*, an excess is observed, and $q_0 = 0$ otherwise. One can show (see, *e.g.*, [24]) that in the large-sample limit, the discovery significance is then $Z_0 = \sqrt{q_0}$, for which one finds

$$Z_0 = \sqrt{2\left(n\ln\frac{n}{b} + b - n\right)} \tag{40.83}$$

for $n > b$ and $Z_0 = 0$ otherwise. To approximate the expected discovery significance assuming $\mu = 1$, one may simply replace n with the expected value $E[n|\mu = 1] = s+b$ (the so-called "Asimov data set"), giving

$$\mathrm{med}[Z_0|\mu = 1] = \sqrt{2\left((s+b)\ln\left(1+\frac{s}{b}\right) - s\right)} . \tag{40.84}$$

This has been shown in Ref. [24] to provide a good approximation to the median discovery significance for values of s of several and for b well below unity. The right-hand side of Eq. (40.84) reduces to $s/\sqrt{b}$ in the limit $s \ll b$.

Beyond the simple Poisson counting experiment, in general one may test values of a parameter μ with more complicated functions of the measured data to obtain a p-value p_μ, and from this one can quote the equivalent significance Z_μ or find, *e.g.*, an upper limit μ_{up}. In this case as well one may quantify the experimental sensitivity by giving the significance Z_μ expected if the data are generated with a different value of the parameter μ'. In some problems, finding the sampling distribution of the significance or limits may be possible using large-sample formulae as described, *e.g.*, in Ref. [24]. In other cases a Monte Carlo study may be needed. Using whatever method of calculation is most appropriate, one usually quotes the expected (mean or, preferably, median) significance or limit as the primary measures of experimental sensitivity.

Even if the true signal is present at its nominal rate, the actual discovery significance Z_0 obtained from the real data is subject to statistical fluctuations and will not in general be equal to its expected value. In an analogous way, the observed limit will differ from the expected limit even if the signal is absent. Upon observing such a difference one would like to know how large this is compared to expected statistical fluctuations. Therefore, in addition to the observed significance and limits it is useful to communicate not only their expected values but also a measure of the width of their distributions.

As the distributions of significance and limits are often well approximated by a Gaussian, one may indicate the intervals corresponding to plus-or-minus one and/or two standard deviations. If the distributions are significantly non-Gaussian, one may use instead the quantiles that give the same probability content, *i.e.*, $[0.1587, 0.8413]$ for $\pm 1\sigma$, $[0.02275, 0.97725]$ for $\pm 2\sigma$. An upper limit found significantly below the background-only expectation may indicate a strong downward fluctuation of the data, or perhaps as well an incorrect estimate of the background rate.

The procedures described above pertain to frequentist hypothesis tests and limits. Bayesian limits, just like those found from a frequentist procedure, are functions of the data and one may therefore find, usually with approximations or Monte Carlo studies, their sampling distribution and corresponding mean (or, preferably, median) and standard deviation.

When trying to establish discovery of a signal process, the Bayesian approach may employ a Bayes factor as described in Sec. 40.3.3. In the case of the Poisson counting experiment with the likelihood from Eq. (40.82), the log of the Bayes factor that compares $\mu = 1$ to $\mu = 0$ is $\ln B_{10} = \ln(L(1)/L(0)) = n\ln(1+s/b) - s$. That is, the expectation value, assuming $\mu = 1$, of $\ln B_{10}$ for this problem is

$$E[\ln B_{10}|\mu = 1] = (s+b)\ln\left(1+\frac{s}{b}\right) - s . \tag{40.85}$$

Comparing this to Eq. (40.84), one finds $\mathrm{med}[Z_0|1] = \sqrt{2E[\ln B_{10}|1]}$. Thus for this particular problem the frequentist median discovery significance can be related to the corresponding Bayes factor in a simple way.

In some analyses, the goal may not be to establish discovery of a signal process but rather to measure, as accurately as possible, the signal rate. If we consider again the Poisson counting experiment described by the likelihood function of Eq. (40.82), the ML estimator $\hat{\mu} = (n-b)/s$ has a variance, assuming $\mu = 1$, of

$$V[\hat{\mu}] = V\left[\frac{n-b}{s}\right] = \frac{1}{s^2}V[n] = \frac{s+b}{s^2} , \tag{40.86}$$

so that the standard deviation of $\hat{\mu}$ is $\sigma_{\hat{\mu}} = \sqrt{s+b}/s$. One may therefore use $s/\sqrt{s+b}$ as a figure of merit to be maximized in order to obtain the best measurement accuracy of a rate parameter. The quantity $s/\sqrt{s+b}$ is also the expected significance with which one rejects s assuming the signal is absent, and thus can be used to optimize the expected upper limit on s.

41. Machine Learning

Written November 2021 by K. Cranmer (NYU), U. Seljak (UC Berkeley; LBNL) and K. Terao (SLAC; Stanford U.).

41.1 Introduction

This chapter gives an overview of the core concepts of machine learning that are relevant to particle physics with some examples of applications to the energy, intensity, cosmic, and accelerator frontiers. Machine learning (ML) is an enormous field that has grown substantially in the last decade, propelled largely by the emergence of so-called deep learning (DL) [1, 2]. ML has a long history in particle physics going back to the late 1980s and early 1990s, see Refs. [3–5] for recent reviews.

Physicists are exploring and contributing to machine learning at an unprecedented rate, which poses a challenge for those that wish to have an up-to-date view of the field. This motivated an effort to create *A Living Review of Machine Learning for Particle and Nuclear Physics* [6], which can be downloaded here: `https://github.com/iml-wg/HEPML-LivingReview`. As of the time of this writing, the Living Review includes over 500 references organized hierarchically by topic. While we make references to some of these papers, this chapter focuses on the methodology and does not attempt to give a comprehensive review of the applications.

Despite the connotations of machine learning and artificial intelligence as a mysterious and radical departure from traditional approaches, we stress that machine learning has a mathematical formulation that is closely tied to statistics, the calculus of variations, approximation theory, and optimal control theory.

The topic can be organized along a few axes, which we use to organize this section. First, there are different learning paradigms, for example supervised learning, unsupervised learning, and reinforcement learning. We focus on the first two in this review, since reinforcement learning is less commonly used in particle physics. Within these paradigms there are various tasks; for example, classification and regression – which have been the primary use of ML in particle physics – are examples of supervised learning. In addition to the learning paradigm and tasks, there are various types of machine learning models that generically process some input and produce some output. The types of models vary based on what it is they are modelling (*e.g.* so-called discriminative vs. generative

models), as well as the way that they are implemented (*e.g.* neural networks, decision trees, and kernel machines). Next, there are the issues around training or learning within the context of a given task and model class, which connects to optimization and regularization. We will briefly discuss the various considerations that emerge in the application of machine learning methods to physics, such as the treatment of systematic uncertainty, the interpretability of the models, the incorporation of symmetry, *etc.*.

41.1.1 *A gentle introduction with a representative example*

We will use a specific, familiar example to introduce the various ingredients in context before factorizing and abstracting them. Consider the task of *classifying* energy deposits in a particle detector as electrons or protons. For this example, let the detector data consist of energy deposits in d sensors so that the data can be represented as *feature vector* $x \in \mathbb{R}^d$. Different components of x may have different units (e.g. units of energy, momentum, position etc.). Due to the complex interactions of particles in the detector, we do not have an explicit probability model for the high-dimensional data for the electron and proton scenarios, but we do have a simulator that allows us to generate Monte Carlo samples for each. This allows us to assemble a *training dataset* $\{x_i, y_i\}_{i=1,\ldots,n}$, where y is used as a *label* to identify how the example was generated (*e.g.* $y = 0$ for electrons and $y = 1$ for protons). We would like to find a function $f : x \to y$ that is able to accurately *predict* the label on new data. Because we have feature-label pairs, this is considered a *supervised learning* problem. We can use a *neural network* to provide a flexible family of functions $f_\phi : \mathbb{R}^d \to \mathbb{R}$, where ϕ denotes the internal parameters of the neural network (*i.e.* the weights and biases that we will discuss in Sec.41.5.3). The goal of the *training procedure* is to find the value of the parameters ϕ that provide the 'best' predictions, but since no model is perfect, we must be explicit about the tradeoffs. This is made concrete through a *loss function* $\mathcal{L}(f_\phi(x), y)$. For this example, instead of the obvious zero-one loss (which is 0 if $f_\phi(x)$ equals y and 1 if they are not), we choose to use the squared-loss $\mathcal{L}_{\text{sq}}(f_\phi(x), y) = (y - f_\phi(x))^2$ (which may seem *ad hoc* now, but will be motivated in Sec. 41.3.1.3). We can evaluate the average of the loss on the training set of size n, which is referred to as the *emprical risk* $\mathcal{R}_{\text{emp}}(f_\phi) = \sum_{i=1}^n \mathcal{L}(f_\phi(x), y)/n$. *Training* refers to numerically minimizing the empirical risk (often referred to as the *training loss* through some abuse of terminology). We can numerically optimize the model through *gradient descent*, which iteratively adjusts the parameters of the network according to $\phi^{t+1} = \phi^t - \lambda \nabla_\phi \mathcal{R}_{\text{emp}}(f_\phi)$, where λ is referred to as the *learning rate*. Once the optimization is complete and we obtain the solution $\hat{\phi}$, it is natural to assess the quality of the trained model $f_{\hat{\phi}}$ on an independent *testing dataset*. The empirical risk evaluated on the testing set is often larger than on the training set, and large differences indicate *overfitting*, which indicates that the model does not generalize well to the unseen data. The ability to accurately predict on unseen data is referred to as *generalization* and the empirical risk on the test data provides a measure of the *generalization error*. In order to reduce the *generalization error* one might explore different model choices (*e.g.* neural network architectures), additional regularization terms in the loss function, different learning rates, optimization algorithms, or early stopping criterion in the optimization. Once trained, the model can be applied to data. In order to produce a binary electron vs. proton decision from the continuous ouptut of the neural network, we must threshold (*i.e.* classify as proton if $f_{\hat{\phi}}(x) > k$). The choice of the threshold k is often referred to as a working point and it sets the tradeoff between electron and proton efficiency, fake-rates, purity, etc. These familiar concepts in particle physics are usually referred to in different terms in machine learning and a *receiver operating characteristic curve*, or ROC curve, is used to summarize the tradeoff between true positive rate (TPR) and false positive rate (FPR). Importantly, the characterization of the efficiency / rejection (or equivalently the ROC curve) requires labeled data. In a particle physics context, it is recognized that the simulation is not perfect and the mismodelling is associated to the presence of systematic uncertainty. In machine learning, the discrepancy between the distribution of the training dataset and the distribution of the data that the model will be applied to in practice is referred to as *domain shift* or *distribution shift*. While mismodelling in the training dataset might lead to a less-than-optimal classifier in practice, the real source of systematic uncertainty comes from mismatch between the data used to characterize the performance of the classifier and the unlabeled data that the classifier is applied to. This motivates the use of data-driven methods to calibrate the resulting model.

This example provides a vertical slice through the various aspects of supervised machine learning in particle physics. Now we factorize and abstract the various ingredients in order to provide a more general treatment with a broader scope.

41.2 Fundamental concepts

41.2.1 *Loss, risk, empirical risk*

The term *learning* in machine learning generally refers to optimization of some objective, which can be thought of as maximizing utility or minimizing *risk*. The risk brings together three main ingredients. The first is the *model family* $\mathcal{F}$ (where $f \in \mathcal{F}$ is the quantity that we vary during optimization), the second is the *loss function* $\mathcal{L}$, and the third is a data distribution $p(u)$. The *risk* for a model $f \in \mathcal{F}$ is defined as its expected loss

$$\mathcal{R}[f] \coloneqq \mathbb{E}_{p(u)}[\mathcal{L}(u, f(u))] \equiv \int \mathcal{L}(u, f(u)), p(u)\, \mathrm{d}u \,, \tag{41.1}$$

where $\mathbb{E}_p[\cdot]$ refers to the expectation with respect to the distribution p. In the context of supervised learning, the distribution $p(u)$ describes a joint distribution over the features x and the labels y (*i.e.* $p(u) = p(x, y)$), the model only depends on the features $f(u) = f(x)$, and the loss function takes on the special form $\mathcal{L}(u, f(u)) = \mathcal{L}(y, f(x))$. In the context of unsupervised learning there are no labels, and $u = x$. Written this way, the risk is a functional, and the idealized goal for machine learning is to solve the optimization problem

$$f^* = \arg\min_{f \in \mathcal{F}} \mathcal{R}[f] \,, \tag{41.2}$$

where $\mathcal{F}$ would include all possible functions.

One of the defining characteristics of machine learning in practice is that one does not know the data distribution $p(u)$, but does have access to samples from that distribution, *i.e.* $\{u_i\}_{i=1,\ldots,n}$ with $u_i \overset{i.i.d.}{\sim} p(u)$. This leads to the corresponding *empirical risk*

$$\mathcal{R}_{\text{emp}}[f] \coloneqq \mathbb{E}_{\hat{p}(u)}[\mathcal{L}(u, f(u))] \equiv \frac{1}{n} \sum_{i=1}^{n} \mathcal{L}(u_i, f(u_i)) \,, \tag{41.3}$$

where $\hat{p}(u) = \frac{1}{n} \sum_{i=1}^n \delta(u - u_i)$ is referred to as the empirical distribution of the dataset $\{u_i\}_{i=1,\ldots,n}$. The *empirical risk minimization* principle is a core idea in statistical learning theory [7], which approximates f^* with its empirical analogue

$$\hat{f} = \arg\min_{f \in \hat{\mathcal{F}}} \mathcal{R}_{\text{emp}}[f] \,, \tag{41.4}$$

where $\hat{\mathcal{F}}$ are all possible functions parametrized by the model parameters ϕ. In an idealized infinite parameter limit machine learning functions, such as neural networks, are universal approximators, such that they cover all functions and $\mathcal{F} = \hat{\mathcal{F}}$. For finite size networks this may or may not be a valid assumption. Expressivity of the network characterizes this universality property and is a function of the network architecture and its parameters such as width and depth of neural network layers. If the expressivity is too small it leads to underfitting. However, an equally important consideration is the risk of overfitting if we optimize equation 41.4 for too long.

While the loss function may quantify some well-motivated notion of (negative) utility, it is also common to design loss functions so that f^* has some desired property. While in practice one does not know the data distribution $p(u)$, it is constructive to imagine that one does and analyze Eq. 41.2 with the calculus of variations. In Secs. 41.3 we will consider several such loss functions where one can show that the corresponding f^* has the desired property even

if the form of the loss is not obvious from the point of view of utility. Furthermore, there are often multiple loss functions that can lead to the same f^*. Then one can think of machine learning as applied calculus of variations where one solves Eq. 41.4 with a sufficiently flexible model, powerful optimization algorithms, and practical considerations to break the degeneracy between different loss functions that lead to the same f^*.

41.2.2 *Generalization*

With a sufficiently flexible model, it is possible to fit the training dataset very well, though the model might not *generalize* well to unseen data due to overfitting. More concretely, for a non-negative loss function one might have $\mathcal{R}_{\text{emp}}[\hat{f}] \to 0$, while the true risk might be large ($\mathcal{R}[\hat{f}] \gg 0$). The gap between the $\mathcal{R}[\hat{f}] - \mathcal{R}_{\text{emp}}[\hat{f}]$ is typically referred to as the *excess risk*[1]. While it is generally not possible to evaluate $\mathcal{R}[\hat{f}]$ exactly because we do not know $p(u)$, we can use an independent testing dataset (also called validation dataset) to obtain an unbiased estimate of it. This *cross-validation* method motivates the test – train split of the data.

Intuitively, a model with many parameters has more flexibility and is more prone to overfitting. A common and intuitive heuristic is that one should not fit a model with more parameters than there are data points. However, a more careful treatment reveals that this heuristic can be both pessimistic and optimistic. For example, the single-parameter model $f_\phi(x) = \text{sign}(\sin(\phi x))$ can perfectly classify any assignment of labels on data (x_i, y_i) with $x \in \mathbb{R}$ and $y \in \{-1, 1\}$ and generalize poorly. Conversely, sometimes highly over-parameterized models (that have large subspaces of their parameters where $\mathcal{R}_{\text{emp}}[\hat{f}_\phi] \to 0$) might generalize well [8,9]. Often this is achieved through *regularization*, both explicit and implicit (section 41.3.1.2).

Structural risk minimization is a modification to the empirical risk minimization principle that was introduced by Vapnik and Chervonenkis to account for the potential for overfitting [7]. However, the bounds are based on a worst-case type analysis and are often very weak. Recall that while one cannot calculate the true risk, one can obtain an unbiased estimate of it with a held-out, independent testing sample. Thus one can empirically compare the generalization error of two models and find that one generalizes better than the other even if the bounds might suggest the opposite. One of the major conceptual shifts that happened with the rise of deep learning was to more fully appreciate that these bounds and structural risk minimization were not a good learning principle in practice and that more theoretical work is needed to close the gap between formal bounds and empirical estimates of generalization error.

41.3 Common tasks and their associated loss functions

We now move to common tasks encountered in machine learning and their associated loss functions.

41.3.1 *Supervised learning*

Supervised learning generally refers to the class of problems where the training dataset are presented as input-output pairs $\{x_i, y_i\}_{i=1,\ldots,n}$, where $x_i \in \mathcal{X}$ are the input features and $y_i \in \mathcal{Y}$ are the corresponding target labels. Furthermore, it is typically assumed that $(x_i, y_i) \overset{i.i.d.}{\sim} p(x, y)$, though $p(x, y)$ is usually not known explicitly. Finally, the loss function in supervised learning takes on the special form $\mathcal{L}(y, f(x))$. The resulting trained model is then used to predict the labels for dataset where labels are not available.

In what follows we will make use of the equalities $p(x, y) = p(x|y)p(y) = p(y|x)p(x)$ and Bayes theorem, which is discussed in Sec. 39.1. We will also use the notation $x \sim p(x)$ to indicate that the random variable x is being drawn, sampled, or generated from the distribution $p(x)$.

[1] Similarly, the gap between the true risk of the learned model and the true risk of the optimal model (*i.e.* $\mathcal{R}[\hat{f}] - \mathcal{R}[f^*]$) is referred to as the *regret*. This quantity is mainly of interest for theoretical analysis of machine learning algorithms, and not of practical concern since usually neither term is tractable.

41.3.1.1 *Regression*

The goal of regression is to predict a label $y \in \mathcal{Y}$ given an input feature vector $x \in \mathcal{X}$. Typically, the label is a real-valued scalar, but $\mathcal{X}$ can be $\mathbb{R}^d$ or some more structured target (*e.g.* an image, sequence, graph, quantile, or distribution). When $\mathcal{Y}$ is discrete, the task is usually referred to as classification; however, the two are closely related and *logistic regression* is an example where the model predicts a continuous probability associated to the possible label values. In elementary statistical language, the target label y is often called a dependent variable, while the feature x is called the independent variable. In classical statistics, one often assumes a model for the data such as

$$y_i = f_\phi(x_i) + e_i \ , \tag{41.5}$$

where e_i is an additive error term that is often assumed to be independent of x and often assumed to be normally distributed. This leads to classic approaches like least-squares (see Sec. 40.2.3), and when the model f_ϕ is linear in ϕ (not in x!) one has linear regression that has a closed-form solution. However, we can relax these assumptions and consider the general case of an arbitrary joint distribution $p(x, y)$, which can be written as $p(y|x)p(x)$ without loss of generality. Consider the *squared error* as a loss function, which leads to the mean-squared error (MSE) for the empirical risk:

$$\mathcal{L}_{\text{MSE}}(y, f(x)) = (y - f(x))^2 \ . \tag{41.6}$$

One might expect that the squared error would only be appropriate in the case that the conditional distribution $p(y|x)$ is normally distributed, but one can use the calculus of variations to show that in general

$$f^*_{\text{MSE}}(x) = \mathbb{E}_{p(y|x)}[y] \ , \tag{41.7}$$

that is the optimal regressor for the MSE is the conditional expectation of y given x.

One issue with the squared-error as a loss function is that it is sensitive to outliers. Alternatively, one can use the absolute error $|y - f(x)|$ as a loss function[2]. However, the discontinuous derivative of the absolute (L1) error leads to challenges in optimization. As a result there are various other loss functions, such as the Huber loss, that aim to be both robust and more amenable to optimization that we do not discuss here.

Note that these this framing of regression yields a function $f(x)$ that only provides a point estimate for y. An alternative approach to regression is to model the full conditional distribution $p(y|x)$. One such example is Gaussian Process regression, which is discussed in Sec. 41.5.1. In that probabilistic approach, one can still obtain a point estimator, such as the conditional expectation or the maximum a posteriori (MAP) estimator

$$f^*(x) = \arg\max_y p(y|x) \ , \tag{41.8}$$

and one can also derive uncertainty estimates on the predicted value y. In this setting, the prior distribution on the model family is closely related to the concept of regularization, which we touch on in Sec. in Sec. 41.3.1.2 and in Sec. 41.5.1.

When one directly models $p(y|x)$, or goes further to model the joint distribution $p(x, y) = p(y|x)p(x)$, then one can use maximum likelihood for the loss function. In that approach, the problem is really one of density estimation, which is a type of unsupervised learning that we discuss in Sec. 41.3.2.1. These two approaches are a classic examples of two different approaches to modelling. Regression with $f^*_{\text{MSE}}(x)$ is the prototypical example of *descriminative* modelling, while modelling the joint distribution is a prototypical example of *generative* modelling. Generally, discriminative approaches with supervised learning out perform generative approaches when there is sufficient data, but generative approaches can be beneficial in data-starved settings [10].

[2] The absolute error and squared error are often denoted as L1 and L2 errors, respectively, in reference to the corresponding norms.

41.3.1.2 *A note on regularization*

The trained model $\hat{f}$, or equivalently, the parameters of the trained model $\hat{\phi}$ can be thought of as point estimates of f^*, and there is a correspondence to the issues of bias and variance discussed in Sec. 40.2 on parameter estimation. Generically, there is a bias–variance tradeoff, and when the number of parameters is large and the number of data points is not much larger, introducing a small bias can often lead to a significant reduction in variance. This motivates the explicit addition of a *regularization* term to the loss function, which will introduce some bias $f^*_{\text{reg}} \neq f^*$. A common form for of regularization is to penalize by the L2 norm of the parameters (*i.e.* $\|\phi\|^2$), which is referred to as *Tikhonov regularization*. This appears in the form of penalized maximum likelihood, and it is also commonly used in unfolding [11]. One can also interpret the regularization term as an explicit prior on the parameters, and the resulting model as the Bayesian maximum a posteriori (MAP) estimator. When paired with linear regression this is known as *ridge regression*, and when paired with kernel machines (see Sec. 41.5.1) this gives rise to kernel ridge regression or Gaussian process regression.

Another form of regularization is to restrict the model class $\hat{\mathcal{F}}$. For example, a neural network and a sequence of narrow step functions (delta functions) can both be shown to be universal approximators in infinite parameter size limit, but on real world examples the former generalizes much better than the latter. Within the class of neural network models, convolutional neural networks are a subset of generic feedforward neural networks that enforce translational symmetry (see Sec. 41.5.3.5 for more discussion). Similarly, one might restrict to Lipschitz continuous functions. These types of choices are often encoded in the architecture of a neural network and are broadly referred to as *inductive bias* in the model.

In addition to explicit regularization terms in the loss function or through restrictions to the model class, it is also possible to regularize implicitly. One implicit regularization is through early stopping [11, 12], where we monitor the loss on training dataset and the loss on test dataset. While the training dataset loss continues to decrease with more gradient descent cycles, the test loss may not, and early stopping stops the training when test loss flattens out or begins to increase. Another powerful form of regularization used in deep learning models is known as *dropout* [13], which randomly removes some some parts of the model during training and can be thought of as implementing a type of model averaging [14]. What is more surprising is that in the case of highly over-parameterized models where there is a large degenerate parameter space that achieves zero loss, $\Phi_0 = \{\phi | \mathcal{R}_{\text{emp}}[f_\phi]\} = 0$, that the dynamics of the optimization algorithm that is used will break the degeneracy and favor some particular $\hat{\phi} \in \Phi_0$ as if an additional regularization term was secretly included. Despite zero loss and over-parametrization, the corresponding generalization error may be small, a phenomenon called *benign overfitting* [15]. Importantly, the dynamics of different optimization algorithms will have different implicit regularization effects, and thus favor different parameter points in Φ_0 that will have different generalization error [16]. Understanding this interaction is a topic of contemporary research in machine learning [17].

41.3.1.3 *Classification*

The goal of classification is to predict one of a finite number of class labels $y \in \mathcal{Y}$ given an input feature vector $x \in \mathbb{X}$. It is similar to regression in this way, but the focus is on discrete target space $\mathcal{Y}$. An important special case is when the label can only take on one of two values (*e.g.* "signal" or "background"), which is referred to as binary classification and is equivalent to simple hypothesis testing in statistics. It is common for a classifier to be the composition of a model $g : \mathcal{X} \to \mathbb{R}^{|\mathcal{Y}|}$ that predicts continuous probabilities for each class (*i.e.* $g(x) \approx p(y|x)$) followed by an operation that then chooses the discrete label $y \in \mathcal{Y}$, such as a fixed threshold or $f(x) = \arg\max g(x) \approx \arg\max_y p(y|x)$. This is the case for both classical methods like logistic regression and modern, deep learning approaches to classification; therefore, we will use the term probabilistic classifier for $g(x)$ or just classifier when it is clear in context.

An intuitive loss function for classification is the zero-one loss, which simply counts the number of mis-classifications:

$$\mathcal{L}_{0/1}(y, f(x)) = \begin{cases} 0, & \text{if } f(x) = y \\ 1, & \text{otherwise .} \end{cases} \tag{41.9}$$

The zero-one loss can also be written as $\mathcal{L}_{0/1}(y, f(x)) = \mathbf{1}(y \neq f(x))$, where $\mathbf{1}(\cdot)$ is the indicator function. The zero-one loss is non-differentiable, so it does not pair well with gradient-based optimization.

For binary classification, one can use $y = \{0, 1\}$ as numerical values for the class labels and the mean-squared error $\mathcal{L}_{\text{MSE}}(y, f(x))$ in Eq. 41.6 for the loss function. The resulting model will approximate f^*_{MSE}, the conditional expectation of Eq. 41.7 takes on the form

$$\begin{aligned} f^*_{\text{MSE}}(x) &= \mathbb{E}_{p(y|x)}[y] \to p(y = 1|x) \\ &= \frac{p(x|y = 1)p(y = 1)}{p(x|y = 0)p(y = 0) + p(x|y = 1)p(y = 1)} \ . \end{aligned} \tag{41.10}$$

That is the MSE loss for binary classification leads to the Bayesian posterior probability that the label $y = 1$ given the feature vector x.

Equation 41.10 highlights an important general feature of supervised learning relevant for particle physics, which is that the joint distribution $p(x, y)$ of the training dataset implies a prior distribution $p(y)$ on the labels or classes. This prior distribution need not reflect a degree of belief or the frequency in real data, it represents the frequency in the training dataset. However, it is important to keep in mind that when applying the resulting model to a different dataset with the same conditional distribution (data likelihood) $p(x|y)$ for the features and a different prior $p'(y)$ for the labels that the probabilistic interpretation of the result will not be properly calibrated. A common choice for binary classification is to use a balanced training dataset with $p(y = 0) = p(y = 1) = \frac{1}{2}$, while in many cases the true $p'(y = 1)$ in the experimental data might be very small (*i.e.* low signal-to-background), unknown, or zero (*i.e.* a hypothetical particle that does not exist).

If $p'(y)$ and $p(y)$ are known then the Bayes theorem can be used to re-calibrate the posterior $p(y|x)$ from one prior to another. One example of such re-calibration is the correspondence of binary classification to simple hypothesis tests in frequentist statistics discussed in Sec. 40.3.1 of the Statistics chapter. In that setting, the Neyman-Pearson lemma states that the optimal classifier is given by the likelihood-ratio. Adapting to the notation of this chapter, we have

$$f^*_{\text{N.P.}}(x) = \frac{p(x|y = 1)}{p(x|y = 0)} \ , \tag{41.11}$$

which does not depend on the prior probabilities $p'(y = 0)$ or $p'(y = 1)$ as in Eq. 41.10, or, equivalently, assumes equal priors $p'(y = 0) = p'(y = 1)$. From Bayes theorem, we have the identity $p(y = 1|x)/p(y = 0|x) = [p(x|y = 1)p(y = 1)]/[p(x|y = 0)p(y = 0)]$, which can be used to show that the two functions are related by a one-to-one, monotonic transformation

$$f^*_{\text{N.P.}}(x) = \frac{p(y = 0)}{p(y = 1)} \frac{f^*_{\text{MSE}}(x)}{1 - f^*_{\text{MSE}}(x)} \ , \tag{41.12}$$

which is referred to as the *likelihood-ratio trick*, which plays an important role in simulation-based inference (see Sec. 41.3.5). Importantly, the monotonic transformation does not impact the tradeoff of type-I and type-II error (or, equivalently, the FPR and TPR), therefore the ROC curve for $f_{\text{N.P.}}(x)$ and $f_{\text{MSE}}(x)$ are identical and do not depend on the prior probabilities $p(y)$. This property has been leveraged in the context of *weakly supervised* approaches [18] and enables one to train a classifier on data without access to labels as long as one has two datasets with different ratios $p(y = 1)/p(y = 0)$ and the same conditional distribution $p(x|y)$ of the features given the labels.

A generalization of the binary loss function for classification of Eq. 41.10, which applies to multiple classes, is the *cross-entropy* loss

$$\mathcal{L}_{\text{xe}}(y, f(x)) = -\sum_{c\in|\mathcal{Y}|} \mathbf{1}(y=c)\log(f_c(x)) \,, \tag{41.13}$$

where $f : \mathcal{X} \to \mathbb{R}^{|\mathcal{Y}|}$ and the indicator function picks out the term in the sum for the corresponding class label y. This loss can be derived from maximizing the posterior of Eq. 41.57 using a discrete set of class labels y, which identifies $f_c(x) = \tilde{f}(y=c|x) = p(y=c|x)$ and thus enforces the constraint $\sum_c f_c(x) = 1$ and $f_c(x) \geq 0$ (for all $x \in \mathcal{X}$, *e.g.* by using the *softmax* function). The notation is aligned with the interpretation of $\tilde{f}(y|x)$ as a conditional distribution, i.e. an approximation to the true posterior $p(y|x)$. The risk associated to the cross entropy loss function is

$$\begin{aligned}\mathcal{R}_{\text{xe}}[f] &= \mathbb{E}_{p(x,y)}\left[-\sum_{c\in|\mathcal{Y}|}\mathbf{1}(y=c)\log f_c(x)\right] \\ &= -\sum_{c\in|\mathcal{Y}|} p(y=c)\mathbb{E}_{p(x|y)}[\log\tilde{f}(y=c|x)] \,.\end{aligned} \tag{41.14}$$

This is equivalent to $\mathcal{R}_{\text{xe}}[f] = \mathbb{E}_{p(x)}[H[p(y|x), \tilde{f}(y|x)]]$, where $H[p,f] = \mathbb{E}_p[-\log f]$ is the cross-entropy between the two distributions. One can use a Lagrange multiplier λ to enforce the normalization constraint (e.g. equation 41.10) and the calculus of variations to show that

$$f^*_{\text{x.e.},c}(x) = \lambda p(x, y=c) = \lambda p(y=c|x)p(x) = p(y=c|x) \,. \tag{41.15}$$

This approach is closely related to the loss functions that are used for density estimation, the forward Kullback–Leibler (KL) divergence, and the maximum likelihood estimation. Minimizing cross entropy $H[p, f_\phi]$ with respect to ϕ is equivalent to minimizing the forward KL divergence

$$KL(p||f_\phi) \coloneqq \mathbb{E}_p[\log p(x)) - \log f_\phi] = H[p, f_\phi] - H[p] \,, \tag{41.16}$$

where $H[p] \coloneqq \int p(x)\log p(x)dx$ is the entropy and independent of f_ϕ. The KL divergence $KL[p||f] \geq 0$, and equal if and only if $p = f$.

One can also consider the reverse KL divergence $KL[f_\phi||p]$, which is also minimized by $f_\phi = p$; however, this requires one to be able to generate samples $x_i \sim f_\phi(x)$ and be able to evaluate the probability density $p(x_i)$. Often this is not the case for real world data, but this approach is useful in the context of variational inference, where $f_\phi(x)$ is an approximation to the posterior of x, and $p(x)$ is the likelihood times the prior, which can be evaluated on samples x_i drawn from f_ϕ. Because likelihood times prior is not normalized this KL divergence optimizes the lower bound to the normalization (Evidence Lower Bound Objective or ELBO).

The forward KL is also closely related to the variational free energy principle in statistical mechanics where $H[f_\phi]$ represents the entropy of the variational distribution, $p(x) \propto \exp(-E(x)/kT)$ is the Boltzman factor for the state x with energy $E(x)$, and $H[f_\phi, p] = \mathbb{E}_{f_\phi}[E(x)]$ represents the expected energy for the variational distribution. As is well known to physicists, minimizing the free energy involves a balance between minimizing the energy and maximizing the entropy.

In some cases it is possible to augment the training dataset with an unbiased, stochastic estimate of $p(y=c|x)$ that we denote $s_c(x,z)$. For example, when the simulation involves latent variables z (*i.e.* Monte Carlo truth quantities), then the simulation encodes $p(x,z|y)$, the joint distribution over the observed features x and the latent variables z conditioned on the class y. In many cases the simulation evolves through a Markov process (*e.g.* the detector response only depends on the momenta of the incoming particles z, not the details of the hard scattering y). In that case, it is often possible to calculate $s_c(x,z) = p(y=c|x,z)$ for each training sample [19]. Using the identity, $\mathbb{E}_{p(z|x)}[p(y|x,z)] = p(y|x)$, we see that $s_c(x,z)$ is an unbiased estimator of $p(y=c|x)$. In this case, one can use $s_c(x,z)$ in place of the indicator function in Eq. 41.13 to construct an improved (lower-variance) loss function that reproduces the same cross-entropy risk function[3,4]

$$\begin{aligned}\mathcal{R}'_{\text{xe}}[f] &= \mathbb{E}_{p(x,y,z)}\left[-\sum_{c\in|\mathcal{Y}|} s_c(x,z)\log f_c(x)\right] \\ &= -\sum_{c\in|\mathcal{Y}|}\mathbb{E}_{p(x)}[p(y=c|x)\log f_c(x)] \,,\end{aligned} \tag{41.17}$$

which yields the same optimal classifier $f^*_{\text{x.e.},c}(x) = p(y=c|x)$ [20, 21].

We note that unlike in the binary classification case, the multiclass classifier is sensitive to the priors $p(y)$ used in training. This leads to complications as often the class proportions are unknown. For example, one might be interested in classifying a signal when multiple backgrounds are present and the relative proportion of those different background components is uncertain. Ideally one would like the class proportions for the background components used in training to match those in the data, which presents an additional training challenge if those proportions are heavily unbalanced.

41.3.2 *Unsupervised learning*

Unsupervised learning generally refers to the class of problems that use unlabeled training dataset $\{x_i\}_{i=1,\ldots,n}$, where $x_i \in \mathcal{X}$ are the input features. Furthermore, it is typically assumed that $(x_i) \overset{i.i.d.}{\sim} p(x)$, though $p(x)$ is usually not known explicitly. Finally, the loss function in supervised learning takes on the special form $\mathcal{L}(x, f(x))$.

A related concept is that of self-supervised learning, which also aims to distill useful features in the data without requiring supervision labels for every sample in the input data. Self-supervised methods can make use of large unsupervised datasets and build meaningful representations by performing data augmentation, and learning the latent space mapping that is insensitive to it. For example, in the case of galaxy images one may augment the data by performing image rotations, adding noise, size scaling, adding point spread function smoothing etc., all of which are realistic transformations expected in a real galaxy image survey [22]. Self-supervised learning then learns the latent space representation where all of these augmentations of the same training sample result in the same latent space position. This training is augmented with contrastive learning, which ensures that different training samples do not all collapse to the same latent space position. When this latent space representation is used for downstream tasks such as classification it outperforms other forms of supervised learning [23].

41.3.2.1 *Density estimation*

The goal of density estimation is to estimate a distribution $p(x)$ based on samples $\{x_i\}_{i=1,\ldots,n}$ with $x_i \overset{i.i.d.}{\sim} p(x)$. Conceptually, this is the same goal as when fitting a parameterized distribution $f(x;\theta)$ to data using the method of maximum likelihood as described in Sec. 40.2.2 of the chapter on statistics. In practice, the difference in the machine learning context has to do with the flexibility of the model and the dimensionality of the data. A highly-flexible model, which can effectively approximate any distribution, is referred to as a non-parametric model (though, ironically, usually this means the model has many parameters). In contrast, typical maximum likelihood fits in particle physics are based on restricted families of distributions with relatively few parameters and the data is typically one- or two-dimensional, though occasionally five- or six-dimensional.

Maximizing the likelihood function in Eq. 40.10 $\mathcal{L}(\theta) =$

[3] A similar approach can also be used for the squared-error, see Ref. [20].

[4] The right hand side of Eqs. 41.14 and 41.17 are written in a different form, but are equivalent.

$\prod_{i=1}^{n} f(x_i;\theta)$ is equivalent to minimizing the empirical risk:

$$\mathcal{R}_{\text{emp,xe}}[f_\phi] = -\frac{1}{n}\sum_{i=1}^{n} \log f_\phi(x) \ , \tag{41.18}$$

where we adopt the notion used in this chapter. The loss is simply $\mathcal{L}(x, f_\phi(x)) = -\log f_\phi(x)$, and the corresponding risk is

$$\mathcal{R}_{\text{xe}}[f_\phi] = \mathbb{E}_{p(x)}[-\log f_\phi(x)] \ , \tag{41.19}$$

which is the cross entropy $H[p, f_\phi]$. For density estimation, the model is usually constructed to enforce $\int f_\phi(x)dx = 1$ and $f_\phi(x) \geq 0$ so that it can be interpreted as a distribution. With this constraint, one can show that $f^*_{\text{xe}}(x) = p(x)$.

The concepts of generalization and overfitting are particularly acute in unsupervised learning, where the likelihood maximization of equation 41.18, combined with universal approximator assumption, must converge onto $\hat{p}(x) = \frac{1}{n}\sum_{i=1}^{n} \delta(x - x_i)$, the empirical distribution of the dataset $\{x_i\}_{i=1,\ldots,n}$. This distribution has the highest likelihood on the training dataset and the lowest likelihood on the test data where it gives $\hat{p}(x) = 0$. as long as the test dataset are not identical to the training dataset. So the empirical distribution of the training dataset has the worst possible generalization property, yet it is the solution we converge to for sufficiently expressive architectures in the absence of any regularization. In contrast, in supervised learning we often observe the phenomenon of benign overfitting, where even zero loss can generalize well.

In addition to approaches to density estimation that involve learning in the sense of minimizing a loss or risk function, we note that there are also classical density estimation techniques such as histogramming and kernel density estimation [24–26].

41.3.2.2 *Representation learning, compression, and auto-encoders*

A recurring topic in machine learning and statistics is how to represent the data. Much of classical statistics involves constructing a low-dimensional summary statistic that extracts the relevant information from the data for a particular task (a sufficient statistic in language of classical statistics). There is a spectrum of representations with trade-offs. At one end of this spectrum is lossless compression that allows you to encode the data into a smaller, intermediate representation that carries all the information since it can be decoded back into the original data. At the other end of the spectrum is something like the likelihood-ratio, which is a single scalar that carries the relevant information needed for hypothesis testing for a single hypothesis, but it discards all the other information that might be needed for other tasks (such as testing other hypotheses). An intermediate point in this spectrum is the process of feature engineering, which refers to the creation of new features $\mathcal{X}'$ from the original features $\mathcal{X}$ in hopes that the down-stream task will be easier with the new features. For example, instead of working directly with the energy and momentum of particles, one might compute invariant masses, angles between particles, etc. This type of feature engineering generally improved performance for shallow neural networks, decision trees, *etc.*; however, with the rise of deep learning this is often no longer necessary and often limits performance compared to working with the original features. One can think of the intermediate layers of a neural network between the input and the output a representation of the data that is good for the task at hand, and by training all the layers of the network simultaneously (or "end-to-end") one can see the intermediate layers as a learned representations. For a review see Ref. [27].

An example of a linear dimensionality reduction representation and data compression is principal component analysis (PCA) of data $x \in \mathbb{R}^d$ at fixed latent space dimensionality k (k<d), which finds the orthogonal linear transformation, O,

$$O : \mathbb{R}^k \to \mathbb{R}^d, z \mapsto Oz, \ OO^T = I_d \tag{41.20}$$

that maximizes the data variance in the latent space. Maximizing the variance of the transformed data is equivalent to minimizing the average reconstruction error (the residual variance in data space),

$$\mathcal{L}_{a.e.}(x, f(x)) = \|x - f(x)\|^2 \ . \tag{41.21}$$

A PCA can thus be interpreted as a linear, orthogonal model that is trained to minimize the L_2-distance between the input data and the reconstructed data given the fixed dimensionality k. In practice, the PCA problem can be solved analytically without the use of optimization algorithms or the loss function: the principal components are given by the eigenvectors of the data covariance matrix.

A suitable latent space dimensionality, k, is chosen by ordering the eigenvalues, λ_i, of the data covariance in descending order, and keeping only the first few eigenvectors that correspond to the largest eigenvalues. The cut is often made at dimensionalities that capture around 90% of the data variance. For many data sets this results in $k \ll d$. The average reconstruction error that originates from the discarded eigenvalues is $\sigma^2_{\text{recon}} = \sum_{i=k+1}^{d} \lambda_i$.

Another common type of representation learning and nonlinear dimensionality reduction is based on the *auto-encoder* $f = g \circ e : \mathcal{X} \to \mathcal{X}$, where $e : \mathcal{X} \to \mathcal{Z}$ is referred to as the *encoder* and $g : \mathcal{Z} \to \mathcal{X}$ is referred to as the *generator* or *decoder*. Typically the dimensionality of $\mathcal{Z}$ is much less than $\mathcal{X}$, and $z = e(x)$ can be thought of as a compressed representation of the input. The intermediate space $\mathcal{Z}$ is sometimes referred to as the bottleneck or the latent space of the auto-encoder. If the bottleneck is sufficiently large and the encoder and decoder are sufficiently flexible, then the function f could just be the identity (*i.e.* lossless compression). However, if the encoder and decoder are not sufficiently flexible or the dimensionality of the latent space is not large enough there will be some reconstruction error. Therefore the reconstruction error of Eq. 41.21 serves as a natural loss function of an auto-encoder.

Once trained, the encoder $e(x)$ can be used independently of the decoder to provide a generic low-dimensional representation of the data. The flexibility of this approach is attractive; however, there are no guarantees that this representation will be optimal for the other task. Indeed, the transition from pre-trained auto-encoders to end-to-end learning is one of the important trends that characterized the onset of the deep learning era.

While achieving zero reconstruction error may seem good as it would imply lossless compression, it often performs poorly in practice. First, the encoder may be overfit to the training dataset and not generalize well to held out data. Secondly, it may not be robust to domain shift (see Sec. 41.7.2). One approach to address these issues is the *denoising auto-encoder*, which uses a form of regularization that corrupts the input with noise $x' \sim q(x'|x)$ while still targeting reconstruction of the uncorrupted input x.

$$\mathcal{L}_{d.a.e.}(x, f(x)) = \|x - f(x')\|^2 \qquad \text{with} \qquad x' \sim q(x'|x) \ , \tag{41.22}$$

where $q(x'|x)$ is some probability distribution such as a multivariate normal.

41.3.2.3 *Clustering*

The goal of clustering is to group the data $\{x_i\}_{i=1,\ldots,n}$ into k groups, or *clusters*, usually with $k \ll n$. Intuitively, if two data points belong to the same cluster, then they should be similar in some sense. Conversely, if two data points are very different, then they should be assigned to different clusters. The notion of similarity usually is based on some heuristic, and there are a variety of algorithmic and probabilistic clustering algorithms. In some cases k is specified, while in others it is determined by the clustering algorithm. There is also a distinction between flat clustering that directly partitions the data into k clusters and hierarchical clustering where clusters are nested hierarchically as the name suggests. In many cases clustering uses some notion of distance $d(x_i, x_j)$, which may be the L_p norm $\|x_i - x_j\|_p$.

One of the most common clustering algorithms is known as k-means, where k is specified by the user and results in sets $S = \{S_1, \ldots, S_k\}$ that minimize the variance of each cluster. Thus,

the objective is

$$\begin{aligned}\arg\min_{\mathbf{S}} \sum_{i=1}^{k} \sum_{\mathbf{x}\in S_i} \|\mathbf{x}-\boldsymbol{\mu}_i\|^2 &= \arg\min_{\mathbf{S}} \sum_{i=1}^{k} |S_i| \operatorname{Var} S_i \\ &= \arg\min_{\mathbf{S}} \sum_{i=1}^{k} \frac{1}{2|S_i|} \sum_{\mathbf{x},\mathbf{y}\in S_i} \|\mathbf{x}-\mathbf{y}\|^2\end{aligned} \tag{41.23}$$

where μ_i is the mean of points in S_i.

While k-means and many other clustering algorithms are defined in terms of an optimization problem, the optimization objective is often not representative of the actual notions of performance in a given context. As a result, there are a number of quantities used for the evaluation and assessment of the resulting clustering. These include Davies–Bouldin index, Dunn index, Rand index, Jaccard index, purity, F-measure, Hopkins statistic, *etc.* [28].

41.3.3 *Optimal control, reinforcement learning, and active learning*

Many problems in science and engineering can be cast as a control problem, which comprises a cost functional that is a function of state and some control variables that specify some underlying dynamical system. This is relevant for the control of accelerators where the dynamical system is physical. This formalism can also be used to describe the design of experiments, planning of an observational survey, and other decision making processes relevant to the scientific method. There is a tremendous amount of literature on the subject, and it is closely connected to planning, dynamic programming, and reinforcement learning. Optimal control can be seen as an extension of the calculus of variations, and thus generalizes the framing of learning presented in Sec. 41.2.

Optimal control theory deals with finding a control for a dynamical system over a period of time such that the objective function is optimized. The underlying system can be discrete or continuous and may be deterministic or stochastic. The commonalities and differences between optimal control and reinforcement learning can be best understood through the formalism of a Markov decision process (MDP), which is a discrete-time stochastic control process. We follow common notation, such as that found in Wikipedia.

A Markov decision process comprises four components often organized as a 4-tuple (S, A, P_a, R_a), where: S is a set of states called the state space, A is a set of actions called the action space, $P_a(s,s') = \Pr(s_{t+1} = s' \mid s_t = s, a_t = a)$ is the probability that action a in state s at time t will lead to state s' at time $t+1$, $R_a(s,s')$ is the immediate reward (or expected immediate reward) received after transitioning from state s to state s', due to action a.

The policy function π is a mapping from state space to action space that can be either deterministic or probabilistic. For examples, the policy that drives a computer chess playing system, decides which move to make given the current state of the board. Similarly, policies dictate which experiment should be built next, which field of the sky should be observed, or how to adjust the operational parameters of an accelerator. The dynamics of the resulting system are then fixed by combining the policy with the underlying MDP. The evolution of the resulting dynamical system behaves like a Markov chain since the action chosen in state s is completely determined by $\pi(s)$ and $\Pr(s_{t+1} = s' \mid s_t = s, a_t = a)$ implies the Markov transition matrix $\Pr(s_{t+1} = s' \mid s_t = s)$.

The objective optimal control is to choose a policy π that will maximize a cumulative function of the instantaneous rewards R_a. A common choice is the expected discounted sum:

$$\mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R_{a_t}(s_t, s_{t+1})\right], \tag{41.24}$$

where $a_t \sim \pi(s_t)$ are the actions given by the policy, the expectation computed with respect to the distribution $s_{t+1} \sim P_{a_t}(s_t, s_{t+1})$, and γ is the discount factor satisfying $0 \leq \gamma \leq 1$. The discount factor is usually close to 1 and sometimes reparameterized as $\gamma = 1/(1+r)$, where r is called the discount rate. A lower discount factor motivates the decision maker to favor taking actions early, rather than postpone them indefinitely.

A policy that maximizes the objective function is called an optimal policy and denoted π^*, though the optimal policy need not be unique. Importantly, the Markov property implies that the optimal policy is only a function of the current state. Dynamic programming can be used to find the optimal policy for MDPs with finite state and action spaces. For instance, in value iteration (a.k.a. backward induction) can be used to solve the "Bellman equation" [29]. For continuous-time systems, the optimal policy is defined by the Hamilton–Jacobi–Bellman equation [30].

In many settings, it is assumed that the state s is fully known when action is to be taken and there are no latent variables. When this assumption is not true, the problem is called a partially observable MDP. These problems are generally more difficult and the dynamic programming algorithms do not directly apply [31].

Reinforcement learning The main difference between the classical dynamic programming methods and reinforcement learning (RL) algorithms is that the latter do not assume knowledge of an exact mathematical model of the MDP and they target large MDPs where exact methods become infeasible. For example, RL was used in the context of jet physics to search for the most likely jet clustering when the number of constituents was too large for the exact dynamic programming algorithm to be used [32]. In addition, RL can be used when the probabilities or rewards are unknown. Instead, the transition probabilities are often accessed indirectly through interaction with a real or simulated environment. For example, in Q-learning one uses experience to estimate the array $Q(s,a)$ defined as

$$Q(s,a) = \sum_{s'} P_a(s,s')(R_a(s,s') + \gamma V(s')). \tag{41.25}$$

While this function is also unknown, it can be estimated during learning based on (s,a) pairs together with the outcome s'.

Numerous variations to RL exist, which include so-called model-based and model-free approaches (referring to models of the instantaneous rewards and the state transitions) and on-policy and off-policy (which describes how the actions taken during learning are related to the current policy). See Ref. [33] for an introduction and Ref. [34] for a recent review.

Multi-arm bandits Multi-arm bandit problems are a classic reinforcement learning problem where one tries to maximize the expected gain by allocating a limited set of resources to various alternatives. The name is a reference to a gambler with a fixed amount of money that must choose between multiple slot machines (or "one-armed" bandits) when the payoff for the individual machines is unknown. A hallmark of multi-arm bandit problems is that they involve a trade-off between exploration (playing machines to estimate their payoff) and exploitation (playing machines with the highest estimated payoff). Multi-armed bandits are used to manage large projects, organizations, and scheduling problems. The theory has a long history going back to Robbins in 1952 that used it to study the sequential design of experiments [35] and Gittins who derived an optimal policy under some conditions [36].

Bayesian optimization A closely related set of techniques involve optimizing some expensive black box function $f(x)$. For instance, the function may be computationally expensive to evaluate or low-latency, *e.g.* it may involve manually re-configuring a system. This is particularly relevant for analysis optimization in particle physics where evaluating $f(x)$ involves processing large numbers of simulated collisions. Another common use case involves optimizing the hyperparameters of a learning algorithm.

Without any assumptions about the function $f(x)$ this is hopeless; however, if one assumes something about the functions (*e.g.*

some notion of smoothness) then one can leverage function evaluations evaluations $\{f(x_t)\}_{t=1,\ldots,T}$ to say something about what value the function might take on at other values of x. This is usually cast in Bayesian terms, and Gaussian processes (Section 41.5.1) are often used to model the distribution over $f(x)$. The optimization techniques that use this framing are generically referred to as Bayesian Optimization [37].

Optimization in this context is usually characterized by an *exploration-exploitation* trade-off, similar to what is found in multi-arm bandits. Here, exploration refers to function evaluations that characterize the function in regions that haven't been evaluated, while exploitation refers to evaluations near what is predicted to be its maximum. This setting is similar to reinforcement learning in that it involves sequential decisions (*i.e.* where to evaluate the function next), but usually the target function $f(x)$ is assumed to be static. In that sense, the state referred to in the language of an MDP is the state of knowledge about the function after sequential evaluations $\{f(x_t)\}_{t=1,\ldots,T}$. The reward at time t is not the value of the function $f(x_t)$, but some quantity that characterizes what was learned about the function's maximum. In this literature, one often refers to the *acquisition function*, which plays a similar role as the expected value of the reward in RL. Common acquisition functions include the probability of improvement, the expected improvement, and an upper-confidence bound [38].

Connection to experimental design In the context of physics experiments we often want to build the next generation experiment which can reach certain target precision on parameters of interest that the experiment can measure. To achieve this precision we may deploy the concept of *experimental design*, where we the objective is to optimize some objective that quantifies the expected performance of an experiment. Moreover, we would like to achieve this within some constraints such as a minimal cost. Such problems are often solved using the Fisher matrix optimization, where Fisher matrix can be viewed as the expectation of the inverse covariance matrix. We can define

$$t(x|\theta_0) \coloneqq \nabla_\theta \log p(x|\theta)|_{\theta_0} \ , \tag{41.26}$$

where $t(x|\theta_0)$ is referred to by statisticians as the score [20]. The score plays an important role in the classical statistics as it is a sufficient statistic when $p(x|\theta)$ is in the exponential family, and through the Rao-Cramér-Fréchet bound on the variance of an estimator for θ, and is used to define the Fisher information matrix $I_{ij}(\theta) \coloneqq \mathbb{E}_{p(x|\theta)}[t_i(x|\theta)t_j(x|\theta)]$. The Fisher information, in turn is an important object in experimental design. In particle physics, the score is closely related to the concept of optimal observables. The corresponding diagonal element of the inverse of the Fisher matrix thus provides expected uncertainty estimation of a given parameter, and is a lower bound to the error of an unbiased estimator (Cramér-Rao bound). In experimental design we vary the experiment parameters within the constraints such as the total cost to minimize this uncertainty. This framework has been widely used in cosmology, where Fisher analysis is the foundation of any experiment proposal.

Active learning Active learning is closely related to Bayesian optimization, described above. In Bayesian optimization one estimates the function $f(x)$ from some set of evaluations $\{y_t = f(x_t)\}_{t=1,\ldots,T}$; however, the goal is to find the maximum $x^* = \arg\max_x f(x)$. In active learning, the goal is not to find the maximum of $f(x)$, but to approximate the function as one does in supervised learning. The main difference compared to vanilla supervised learning is that the labeled training dataset isn't provided a priori in a passive way, but the learning algorithm actively decides where to generate $(x_t, y_t = f(x_t))$ pairs. The function $f(x)$ is sometimes referred to as an *oracle*. Active learning is particularly attractive when obtaining labelled data is a costly process.

More broadly, a challenge of many machine learning applications is obtaining labeled data, which can be a costly process. If a system could learn from small amounts of data, and choose by itself what data it would like the user to label via an external process called oracle, it would make machine learning more powerful. Such frameworks are also called Experiment Design or Active Learning. In Active Learning, a model is trained on a small amount of data (the initial training dataset), and an acquisition function (often based on the model's uncertainty) decides on which data points to ask for a label. The acquisition function selects one or more points from a pool of unlabelled data points, with the pool points lying outside of the training dataset. Once we label the selected data points, these are added to the training dataset, and a new model is trained on the updated training dataset. This process is then repeated, with the training dataset increasing in size over time. The advantage of such systems is that they often result in dramatic reductions in the amount of labelling required to train an ML system (and therefore cost and time).

41.3.4 *Anomaly detection and out-of-distribution detection*

Unsupervised anomaly detection techniques detect anomalies in an unlabeled test data set under the assumption that the majority of the in-distribution data are normal under some measure, while out-of-distribution (OOD) data are not. In the context of auto-encoders a popular technique is to use the reconstruction error of Eq. 41.21 to identify an outlier as one with a large reconstruction error [39, 40]. One issue with this method is that for higher dimensional latent space and flexible neural network architectures the encoder-decoder map become identity for any input data, $f(x) = x$, regardless of whether input x is from the in-distribution training dataset or from the out-of-distribution data. The choice of auto-encoder latent space dimensionality is thus an important hyperparameter that must be tuned.

Another set of anomaly detection techniques construct a model representing normal behavior from a given In Distribution training dataset, and then test the likelihood of a test instance to be generated by the utilized model. For instance, one can use density estimation methods such as normalizing flows (section 41.5.4.3) to learn the density (likelihood) of the In Distribution training dataset $p(x)$, and apply it to the test data. The expectation is that out-of-distribution data will have a lower density (likelihood) under the in-distribution density model. This expectation is however not always met in high dimensions and the method suffers because likelihood based training is sensitive to the smallest variance directions [41]: for example, a zero variance pixels leads to an infinite $p(x)$, and noise must be added to regularize it. But low variance directions may contain little or no information on the global structure of the image, so there is a mismatch between the training objective and outlier detection objective. A related issue is that of typicality: an in-distribution likelihood will typically be lower than the maximum value. For a Gaussian likelihood the typical set is on average be $n/2$ in log likelihood below the peak value, where n is the dimensionality of the data. So an out-of-distribution dataset that is closer to the peak would be preferred in terms of likelihood even though its distribution does not match the in-distribution data. If this happens by chance on low variance directions which dominate the likelihood, normalizing flows can assign higher likelihoods to out-of-distribution data than to in-distribution training dataset [42]. A number of techniques have been proposed to circumvent these limitations, such as likelihood regret [43], likelihood-ratio [41], likelihood in auto-encoder latent space [44], and Wasserstein distance training of the likelihood $p(x)$ [45]. These methods can achieve better anomaly detection performance than the auto-encoder reconstruction error [44, 46].

Supervised anomaly detection techniques require a data set that has been labeled as in-distribution and out-of-distribution and involves training a classifier (the key difference to many other statistical classification problems is the inherent unbalanced nature of outlier detection). These methods assume some form for what out-of-distribution data may look like, and their success relies on whether the assumed form is a realistic representation of actual out-of-distribution data. When this assumption is valid these methods can be more powerful than unsupervised methods, but the reverse is also true. A hybrid between the two approaches is to train a classifier without labels [47]. All these approaches are largely complementary to each other [48]. An example of different anomaly detection methods applied to HEP is LHC Olympics

2020 and Dark Machines challenges [49, 50].

41.3.5 *Simulation-based inference*

The goal of simulation-based inference (related to, but distinct from, likelihood-free inference) is to extend the statistical procedures described in the Chapter on Statistics (*e.g.* parameter estimation, hypothesis tests, confidence intervals, and Bayesian posterior distributions) to the situation where one does not know the explicit likelihood $p(x|\theta)$, the probability of the data given the parameters θ, but has access to a simulator that defines the likelihood $p(x|\theta)$ implicitly [51, 52]. In a typical setup we would like to solve the so called inverse problem of getting the posterior of the parameters given the data, $p(\theta|x)$, but we cannot use Bayes theorem directly because we do not have explicit $p(x|\theta)$.

In particle physics, the simulators usually use Monte Carlo event generators (see Sec. 43) to sample unobserved latent variables z, such as the z_p phase space of the hard scattering (see Sec. 49.4), z_s associated to showering and hadronization, and z_d associated to the interaction of particles with the detector (see Sec. 34). As such, the full simulation chain can be expressed symbolically as

$$\begin{aligned} p(x|\theta) &= \int dz p(x,z|\theta) \\ &= \int \mathrm{d}z_d \int \mathrm{d}z_s \int \mathrm{d}z_p \, p(x|z_d)p(z_d|z_s)p(z_s|z_p)p(z_p|\theta) \ , \end{aligned} \tag{41.27}$$

where θ are the Lagrangian parameters that dictate the hard scattering. Evaluating the likelihood is intractable as it would require evaluating the integral above for each event.

While the likelihood is intractable, simulators provide the ability to generate synthetic data $x_i \overset{i.i.d.}{\sim} p(x|\theta)$ for any value of the parameters θ. One can use a suitable proposal distribution $\tilde{p}(\theta)$, sample $\theta_i \overset{i.i.d.}{\sim} \tilde{p}(\theta)$, generate synthetic data $x_i \sim p(x|\theta_i)$, and then assemble a training dataset $\{x_i, \theta_i\}_{i=1,\ldots,n}$ that can be used to train various machine learning models.

There is thus a close analogy between Simulation-based Inference and data driven machine learning tasks discussed so far, replacing θ with y. One difference is that in simulation-based inference we can always generate new samples by running additional simulations, while we typically view training dataset in machine learning as fixed. This property of Simulation-based Inference enables Active Learning, where the additional simulations are chosen such as to minimize the error on the desired statistical inference task. Another difference is that we often have access to the joint likelihood $p(x, z|\theta)$, where z are unobserved latent variables[5].

Typically in particle physics, one uses histograms or kernel density estimation to model the distribution of observables (low-dimensional summary statistics such as the invariant mass) of simulated data [53]. Alternatively, one can use an explicit parametric family (such as a falling exponential, a Gaussian distribution, *etc.*) to model $\hat{f}(x|\theta) \approx p(x|\theta)$. That model is then used as as a surrogate for the unknown density implicitly defined by the simulator. A related approach is known as Approximate Bayesian Computation (ABC), which approximates the likelihood through an acceptance probability that synthetic data is sufficiently close to the observed data [54, 55]. In practice, these techniques are limited to low-dimensional representations of the data. Thus the potential of recent machine learning approaches to simulation-based inference is to extend this approach to higher-dimensional data, while maintaining the already well-established statistical procedures.

For instance, one can use normalizing flows (see Sec. 41.5.4.3) and the loss functions for density estimation (see Sec. 41.3.2.1) to learn a surrogate model for the likelihood $\hat{f}(x|\theta) \approx p(x|\theta)$ [56]. Similarly, one can use conditional density estimation to learn a surrogate model for the posterior $\hat{f}(\theta|x) \approx p(\theta|x)$, which may involve including the prior-to-proposal ratio $\tilde{p}(\theta)/p(\theta)$ [57]. In addition to the unsupervised learning techniques, one can also use supervised learning to learn the likelihood-ratio $r(x|\theta_0, \theta_1) = p(x|\theta_0)/p(x|\theta_1)$ by leveraging the *likelihood-ratio trick* of Eq. 41.12 [20, 58].

In some cases one can also augment the training dataset to include the joint likelihood-ratio

$$r(x_i, z_i|\theta_0, \theta_1) \coloneqq p(x_i, z_i|\theta_0)/p(x_i, z_i|\theta_1) \ , \tag{41.28}$$

which can be used to reduce the variance for the squared-error loss or the improved cross-entropy estimator of Eq. 41.17 [20, 21]. While the marginal likelihood $p(x|\theta)$ is intractable due to the high-dimensional integral over the latent space, the joint likelihood is often tractable since no integration is necessary. In addition, one can often augment the training dataset with the joint score

$$t(x_i, z_i|\theta_0) \coloneqq \nabla_\theta \log p(x_i, z_i|\theta)|_{\theta_0} \ . \tag{41.29}$$

Regressing on the joint score with the squared loss function $\mathcal{L}(t(x, z|\theta_0), f(x)) = (t(x, z|\theta_0) - f(x))^2$ corresponds to risk functional

$$\mathcal{R}_{\text{score}}[f] \coloneqq \mathbb{E}_{p(x,z|\theta_0)}[(\nabla_\theta \log p(x_i, z_i|\theta)|_{\theta_0} - f(x))^2] \ . \tag{41.30}$$

One can show with the calculus of variations that the risk is minimized by the score of equation 41.26.

41.3.5.1 *Differentiable simulations*

One of the approaches to make inference feasible in high dimensional latent space is to make simulations differentiable with respect to all of its parameters, global variables θ and latent variables z. Latent variable models are known in Machine Learning as generative models and are discussed below, but latent variable models are also common in scientific applications. As an example, in cosmology one can view the initial conditions of the large scale structure or cosmic microwave background as Gaussian distributed latent variables.

While differentiable simulations have traditionally not been developed for scientific applications, the success of Machine Learning, where backpropagation algorithm combined with gradient descent optimization (see Sec. 41.6.1) is the basis of its recent advances, has inspired a new look at this. One recent example is FlowPM cosmological N-body simulation, which takes advantage of Mesh-Tensorflow to achieve a GPU-accelerated, distributed, and differentiable simulation [59].

One broad class of inference problems where gradients make the problem simpler are the so called inverse problems. As a simple example let's assume the data x are observed with some Gaussian noise with known variance σ^2, equal for all data points. The likelihood of the data can be written as

$$\log p(x|z,\theta) = -\frac{N}{2}\log[2\pi\sigma^2] - \frac{||x - g(z,\theta)||^2}{2\sigma^2}. \tag{41.31}$$

Here $g(z, \theta)$ is the forward model (generator or decoder), i.e. the simulation output in the absence of noise. The joint distribution is $p(x, z|\theta) = p(x|z, \theta)p(z|\theta)$, where $p(z|\theta)$ is the prior of latent space variables, assumed to be known, with a known gradient with respect to θ and z. In this case the gradients $\nabla_\theta \log p(x, z|\theta)$ and $\nabla_z \log p(x, z|\theta)$ are available when the simulation forward model gradients $\nabla_\theta g(z, \theta)$ and $\nabla_z g(z, \theta)$ are available.

Availability of simulation gradients in turn enables gradient based optimization or sampling. In sampling approach one can use Monte Carlo Markov Chains to obtain the posterior samples of latent space z and parameter space θ [60]. In optimization approach one can find the best-fit point $\hat{z}$, which is the MAP estimate of the latent space variables z given x and fixed θ [61]. Another optimization approach is Variational Inference, which attempts to model the posterior probability distribution using optimization. This is discussed further in Section 41.5.4.

41.3.5.2 *Unfolding as an inverse problem*

While much of the work on simulation-based inference described above is aimed at inferring the parameters θ of the simulator, there is also work that aims to to infer the latent variables z. Here it is useful to think of the parameters θ as parameters of a theory, such as masses, coupling constants, or Lagrangian parameters, while z

[5] For this reason we prefer to use simulation-based inference instead of likelihood-free inference: joint likelihood $p(x, z|\theta)$ is often available, it is the marginal integral over latent space z that is assumed to be intractable.

might describe the kinematics of a collision before the detector response.

Inferring the distribution $p(z|\{x_1, \ldots, x_n\})$ from a dataset of multiple observations is commonly referred to as unfolding in particle physics, and deconvolution in other contexts. Unfolding is a classic inverse problem, and the collection of ideas being used for machine-learning based simulation-based inference are also being applied in this setting. Examples of recent work exploring these approaches are Refs. [62–73]. In addition, there has been work to infer the posterior distribution for an individual event $p(z|x_i)$ using probabilistic programming techniques [74–76].

41.4 Data representations, inductive bias, and example applications

In Sec. 41.3 we describe the input data as living in an abstract space $x_i \in \mathcal{X}$. In this section, we briefly describe some of the common types of structured data that are encountered in physics and refer to the corresponding models classes that have been developed to work with them. We will describe the model classes in more detail in the following section.

The most basic and common type of data structure is when $\mathcal{X} = \mathbb{R}^d$. This is often referred to as *tabular data* since the entire data set $\{x_i\}_{i=1,\ldots,n}$ can be thought of as a table with n rows and d columns. It is common to think of an individual entry x_i as a vector in d-dimensional Euclidean space, where the coordinates correspond to the columns of this table. In some cases individual components of x_i might be integers or take on only discrete values, in which case describing the space of the data as real-valued is a slight abuse of notation and representation. For many years this was the dominant type of data in high energy physics as it is a natural input type for shallow neural networks, multi-layer perceptrons, support vector machines, and tree-based methods found in popular tools such as `TMVA` [77].

For categorical data, one typically uses a numerical representation such as *integer encoding* where different categories are mapped to integers with a corresponding dictionary. Another common representation of categorical data is based on the so-called *one-hot encoding* (aka 'one-of-K' or 'dummy'), in which case the category is mapped to a k-dimensional binary vector where k is the number of categories and each component of this vector corresponds to a particular category. In the one-hot encoding, only one of the components is non-zero. Finally, there are approaches in one learns an *embedding* that maps discrete categories into $\mathbb{R}^d$; an example of this is `Word2Vec` [78]. Interestingly, such embeddings can preserve various types of semantics; for instance, the vector `walking-walk` is similar to the vector`swimming-swam` as are the vectors connecting countries and their capital cities. This allows for a loose sense of algebra on the word embedings such as `walking-swimming+swam = walk`. Similar types of embeddings have also been used in a number of scientific use-cases including biological sequences (e.g. DNA, RNA, and Proteins) for bioinformatics applications [79].

Particle physics data often is represented with an extension of the simple tabular data structure where the number of columns is not fixed. For instance, if the rows correspond to data for individual collisions, the number of electrons (and positrons) reconstructed in the event is variable. Thus the number of columns needed to represent the energy, momentum, and charge of these particles is also variable. A common solution to this problem is to fix a maximum number of particles and then *truncate* and *zero-pad* to fit the data into a fixed tabular representation, though this is not the natural representation of the data and it leads to a loss of information.

Sequential data is also commonly encountered in physics (*e.g.* in time series). Here an individual entry $x_i = (x_i^1, \ldots, x_i^t, \ldots x_i^{T_i})$ where t is index for the ordered sequence, T_i is the length of the sequence (which might be variable), and the data associated to each "time" $x_i^t \in \mathbb{R}^d$. This is similar to the previous example where the energy, momentum, and charge of the t-th electron in the i-the event would be x_i^t and the electrons might be sorted according to their energy or transverse momentum. Sequential data is also encountered in natural language processing, where x_i^t correspond to individual words in a sentence. Recurrent neural networks (see Sec. 41.5.3.9) are particularly well suited to sequential data. Examples applications from the Living Review include [80–85].

Image-like data is one of the most dominant forms of data in industrial applications of deep learning, is very relevant for astronomy and cosmology, and also appears in particle physics in various forms. Image-like data typically involves d-dimensional features associated to a regular grid or lattice that does not vary across the individual instances x_i. The canonical example is a standard image from a camera with $W \times H$ pixels where the p-th pixel has data $x_i^p \in \mathbb{R}^3$ corresponding to the three *channels* in the RGB color model. It is important to recognize that the data corresponding to the 2-dimensional image is not 2-dimensional; instead, it is $(W \times H \times c)$-dimensional, where c is the number of channels. In astronomy, an image may be grey scale ($c = 1$) or there may be more *channels* ($c > 3$) corresponding to different color filters. In other applications, the grid or lattice might be 3- or 4-dimensional. For example, the data associated to a regularly segmented calorimeter can be thought of as a 3-dimensional image and the data associated to a lattice simulation of a classical or quantum system can be thought of as a 4-dimensional image. Convolutional neural networks, described in Sec. 41.5.3.5, are particularly well suited to image-like data. Example applications from the Living Review include [81, 86–108].

It is also possible that the the data (or features) associated to one "pixel" or lattice site may itself be structured. For example, the single read-out plane of a Liquid Argon time projection chamber (LArTPC) may involve a 1-dimensional or 2-dimensional grid, but the data associated to each "pixel" is itself a sequence or waveform. Example applications in Neutrino Physics from the Living Review include [109–139]. Similarly, in lattice quantum chromodynamics, the data associate to a particular site (or link) would be group valued (*e.g.* $x_i^p \in SU(3)$ as in Refs. [140, 141]).

Both sequential and image-like data have a notion of temporal or spatial structure. While it is possible to unroll an image into a $(W \times H \times c)$-dimensional vector, that would erase the spatial structure and obfuscate the fact that nearby pixels are highly correlated. Similarly, one could permute the time index for sequential data, but that would destroy the temporal structure of the data. The complementary point of view is that the model class should also be aware of the structure of the data. Recurrent neural networks and convolutional neural networks are good examples of what is called *inductive bias* as the models do incorporate something about the structure of the data that they are expected to be used with. In some cases this can be formalized in terms of symmetry. For example, if we train model to classify images of cats and dogs, we would like it's prediction to be invariant to where in the image the cat is. This type of translational invariance can be enforced in the design of the model class.

While permuting the elements of a sequence destroys the temporal structure of a time series, attaching a temporal index t to a set of objects with features x_i^t can also be problematic. If the data corresponding to x_i really are a set $\{x_i^1, \ldots, x_i^{T_i}\}$ (*e.g.* a point cloud), then we would like the output of the model to be *permutation invariance*. A standard sequential or convolutional model will not generally be permutation invariant, but recently models such as Deep Sets, various types of graph neural networks, and transformers can be made to enforce permutation symmetry. Example applications from the Living Review include [100, 142–152]

The temporal and spatial structure of sequences and image like data can also be generalized. For instance, a 1-dimensional sequence can be generalized to a tree structured data like one finds in the hierarchical clustering of jets or as in a directed-acyclic graph (DAG). Generalizations of recurrent neural networks have been constructed that can operate over these more complex data structures [153, 154]. More generally, one can considered graph-structured data composed of nodes and edges or multi-graphs that group together three nodes into faces or k nodes into k-edges. Graph neural networks are a class of models that work with this type of data. The emerging subfield of geometric deep learning aims to unify the notation, terminology, and theory that connect these considerations of the structure of the data and the corresponding model architecture. Example applications in the Living Review include [121, 128, 131, 132, 134, 155–181].

If the data are expected to have a symmetry associated to them but one is working with a model class that does not enforce this symmetry, then *data augmentation* is a common procedure used to improve generalization performance. Here one starts with an initial dataset $\{x_i\}_{i=1,\ldots,n}$ and produces an augmented dataset $\{x'_i\}_{i'=1,\ldots,n'}$ through some data augmentation strategy. For example, one might apply a random rotation $R_{i'}$ to an image to produce $x'_i = R_{i'}(x_i)$ if one assumes rotational invariance in the underlying problem.

In some cases some of the individual features (components) of x are functions of other features. For instance, one may include components of a four-vector (E, p_x, p_y, p_z) as well as redundant information such as transverse momentum, azimuthal angles, rapidity, etc. In this case, the data is restricted to a lower-dimensional surface embeded in $\mathcal{X}$. Even if the features aren't redundant, statistically the data are often effectively restricted to a small subspace of statistically likely samples and those that are exceedingly unlikely. For instance, the space of natural images is a small and highly structured subspace of all possible images, which are dominated by what we would perceive visually as noise. The term *data manifold* is used to describe this restricted subspace where the data are to be found, even though it does not necessarily satisfy the formal requirements of a manifold in the mathematical sense.

These considerations on the structure of the data not only apply not to the input data $x_i \in \mathcal{X}$, but also to the output data $y_i \in \mathcal{Y}$. For instance, one might want a sequence-to-sequence model as in machine translation of written text [182] or to learn a function that takes sets as input and produces graphs as output as in the Set2Graph mode [183]. One might also want the input and output of the model to be different in representations of an underlying symmetry group and for the model to enforce group-equivariance [140, 141]. The development of the necessary modelling components to enable practitioners to compose and train these types of models is a significant development for the field of physics.

41.5 Flavors of ML models

41.5.1 *Support vector machines and kernel machines*

Support Vector Machines (SVM) are a class of supervised learning models used for classification and regression. The learning algorithm involves a convex optimization problem that has a unique solution and can be solved with quadratic programming techniques. In this sense, they are robust and easier to characterize than neural networks that involve non-convex optimization. While their history goes back to Vapnik and Chervonenkis in the 1960s, they gained popularity after Bernhard Boser, Isabelle Guyon and Vladimir Vapnik suggested a way to create nonlinear classifiers by applying the kernel trick in 1992 [184]. Originally they were developed for binary classification and only supported therestricted case where the training dataset can be separated without errors, but in 1995 Cortes and Vapnik extended the technique to non-separable training dataset [185]. A variant targeting regression, known as support vector regression (SVR), was developed in 1997 [186]. The theory around support vector machines was well developed, and they dominated machine learning research for roughly a decade before the rise of deep learning (see Sec. 41.5.3.4).

Maximum-margin classifiers Linear support vector machines are used for binary classification, where $\mathcal{X} = \mathbb{R}^d$ and the target labels are conventionally defined as $\mathcal{Y} = \{-1, 1\}$. The classification is simply based on which side of a hyperplane the data lie. Any hyperplane can be written as the set of points x satisfying $w^T x - b = 0$, where $w, b \in \mathbb{R}^d$ are the parameters of the model. The vector w is normal to the hyperplane, but not necessarily normalized. The quantity $\frac{b}{\|w\|}$ quantifies the offset of the hyperplane from the origin along the normal vector w.

If the training dataset is linearly separable, then there is a region bounded by two parallel hyperplanes, called the *margin*, that separate the two classes of data. The maximum margin classifier is uniquely defined by making the distance between these two hyperplanes as large as possible. The boundaries of the margin can be defined by $w^T x_i - b = \pm 1$, and the width of the margin is given by $\frac{2}{\|w\|}$. Figure 41.1 illustrates this for $x \in \mathbb{R}^2$.

Since the width of the margin is maximized when $\|w\|$ is minimized, we can state the goal of the (hard) maximum-margin classifier in the linear separable case as the following constrained optimization problem: Minimize $\|w\|^2$ subject to the constraint $y_i(w^T x_i - b) \geq 1$ for $i = 1, \ldots, n$. The w and b that solve this problem uniquely determine the resulting classifier, $\hat{y}(x) = \mathrm{sgn}(w^T x - b)$.

This geometric description makes it clear that the maximum-margin hyperplane is completely determined by those x_i that lie nearest to it: the eponymous *support vectors*.

Soft margins and slack variables Often the data will not be linearly separable and thus the hard-margin optimization problem described above has no solution. Such a non-separable case can be accommodated with the use of so-called *slack variables*. One slack variable $\xi_i > 0$ is introduced for each data point. As shown in Figure 41.1 (right), if a data point x_i is outside the margin and correctly classified as in the separable case, then $\xi_i = 0$. If it within the margin but still correctly classified, then $0 < \xi_i < 1$. If it is misclassified, then $\xi_i > 1$. The new constrained optimization problem is to minimize

$$\sum_i \xi_i + \lambda \|w\|^2 \tag{41.32}$$

subject to the constraints $y_i(w^T x_i - b) \geq 1 - \xi_i$ and $\xi_i > 0$ for $i = 1, \ldots, n$. Effectively, this corresponds to minimizing $\sum_i \max(0, 1 - y_i(w^T x_i - b)) + \lambda \|w\|^2$, where the first term is called the *hinge loss*.

The dual problem In the language of convex optimization, linear programming, and quadratic programming the optimization problems stated above for the hard and soft maximum-margin classifiers define the *primal* objective to be minimized. There is a *Lagrange dual* problem where the solution corresponds to maximization with $\min_\phi L(\phi) = \sup_{\alpha > 0} \bar{L}(\phi, \alpha)$, where α are Lagrange multipliers. While it is not apparent in the primal formulation of the constrained optimization problems, the solution to the dual problem takes on the form

$$\hat{y}(x) = \mathrm{sgn}\Big(\sum_i y_i \alpha_i x_i^T x - b\Big) \,, \tag{41.33}$$

where the $\alpha_i > 0$ for the support vectors and otherwise zero. This reformulation is plausible since the orientation of the maximum-margin hyperplanes defined by w is completely specified by the support vectors. The crucial observation for the kernel trick described below is that the final model is defined in terms of coefficients and the inner product $\langle x_i, x \rangle_{\mathcal{X}} = x_i^T x$.

The kernel trick One approach to obtain non-linear decision boundaries is introduce a non-linear mapping $\varphi \colon \mathcal{X} \to \mathcal{V}$ that embeds the data in some higher-dimensional space $\mathcal{V}$. One can then use the linear SVM described above in the space $\mathcal{V}$. This is not unlike the many neural network models where the first layers use a non-linear activation function while the last layer is linear.

The *kernel trick* avoids the explicit mapping φ that is needed to get linear learning algorithms to learn a nonlinear function or decision boundary. This is possible because the solution to the dual problem in Eq. 41.33 is represented in terms of inner products $\langle \varphi(x_i), \varphi(x) \rangle_{\mathcal{V}} = \varphi(x_i)^T \varphi(x)$ corresponding to the candidate point x and the support vectors x_i. Thus all that is needed is a way to evaluate the inner products. A *kernel* or a kernel function $k \colon \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a function that can be expressed as an inner product in another space $\mathcal{V}$ via $k(x, x') = \langle \varphi(x), \varphi(x') \rangle_{\mathcal{V}}$. Critically, one does not need to ever evaluate the map $\varphi(x')$, which is implicitly defined by the kernel. In some cases the kernel is straight forward to evaluate, even though the target space $\mathcal{V}$ implicitly defined by the kernel would be infinite dimensional.

The choice of the kernel is roughly the analog of the architecture of a neural network. It dictates the types of non-linearities the

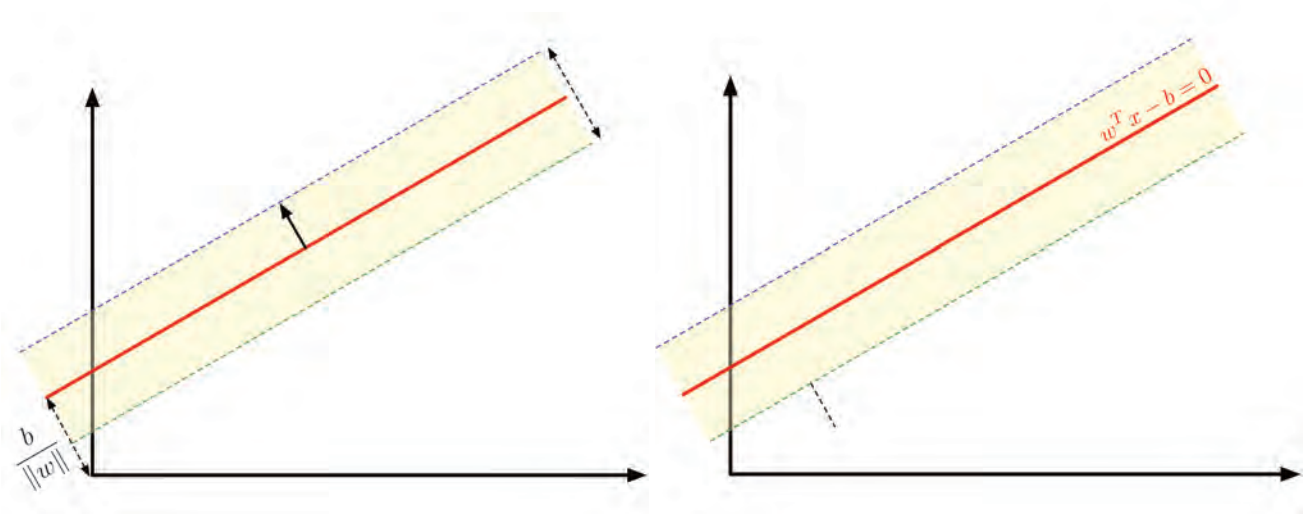

Figure 41.1: Illustration of a maximum margin classifier for a linear support vector machine in the separable case (left) and with the soft-margin and slack variables ξ (right).

SVM can implement in the input space. It also provides an opportunity to encode prior knowledge from physics such as symmetries, length scales, *etc.* There are also connections between very wide neural networks with random weights and biases and the kernel of a Gaussian process [187–189], which, when applied to deep networks, lead to the concept of neural tangent kernel [190]. While it is beyond the scope of this chapter, the interested reader may also be curious to understand the connections as formalized in the language of Reproducing kernel Hilbert spaces (RKHS) [191].

Support vector regression There are a few flavors of SVR. In Vapnik's ϵ-SVR formulation is similar to the picture for classification, but the boundary hyperplane serves as the prediction and the width of the margin for which there is no penalty is ϵ. Again, one can introduce a non-linear map $\phi(x)$ explicitly or implicitly via the corresponding kernel $k(x, x')$. One can view the predictive model as $\hat{y}(x) = w^T\phi(x) - b$ and the goal of the optimization problem is to minimize

$$\|w\|^2 + C\sum_i(\xi_i + \xi_i^*) \tag{41.34}$$

where ξ_i and ξ_i^* are slack variables associated to the model over or under-estimating $y_i \in \mathbb{R}$. The constrained optimization is subject to $w^T x_i - b - y_i \leq \epsilon + \xi_i$, $y_i - w^T x_i + b \leq \epsilon + \xi_i^*$, $\xi_i, \xi_i^* \geq 0$ for $i = 1 \ldots, n$. The solution to the dual problem leads to a kernelized representation of the solution

$$\hat{y}(x) = \sum_i(\alpha^* - \alpha)K(x, x_i) - b\ , \tag{41.35}$$

where the α_i, α_i^* are the parameters of the dual problem. In libraries like `LibSVM` the output of the algorithm is just $\alpha_i^* - \alpha_i$ for $i = 1 \ldots, n$.

Kernel ridge regression Kernel Ridge Regression (KRR) uses the same model as in SVR; however, it uses a different loss function. KRR uses the squared error loss while support vector regression uses the ϵ-insensitive loss function (*i.e.* no penalty is encured if the prediction is within ϵ). Both are combined with l2 regularization (the $\|w\|^2$ term). While SVR leads to a sparse solution that only depends on the support vectors, it can be slow to solve the constrained convex optimization problem. In contrast, KRR can be done in closed-form and is typically faster to train for medium-sized datasets. The consequence is that the learned model is non-sparse and thus slower than SVR to evaluate at prediction-time.

Gaussian Process Regression (krigging) Another variation on kernel-based regression is Gaussian process regression (GPR), also referred to as *krigging*. Again the model is based on the kernel trick. While KRR aims to minimize the mean-squared error loss $(y_i - \hat{y}(x_i))^2$ along with an l2 regularization term proportional to $\|w\|^2$, GPR elevates these terms to a probabilistic interpretation where the first is proportional to a log-likelihood for Gaussian $N(y_i|\hat{y}(x_i)), \sigma)$ likelihood and the second corresponds to the log of a Gaussian prior on w_i. This is related to the discussion on Tikhonov regularization found in Sec. 41.3.1.2. GPR goes further and uses a mean function $m(x)$ and kernel $k(x, x')$ to define a probabilistic model for $y(x)$ and $y(x')$ that includes correlations. For any finite number of points $\{x_j\}_{j=1,\ldots,m}$, the Gaussian process defines the joint distribution for the values that $f(x_i)$ might take. Typically, one specifies the prior mean $m(x)$ and prior covariance function $k(x, x')$ and then conditions on the training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$. The posterior can then be evaluated for an independent set of points $\{x_j\}_{j=1,\ldots,m}$. The posterior mean is typically used as the prediction equivalent to SVR and KRR, but GPR also gives a meaningful notion of uncertainty in the predictions, and can be viewed as a realization of kernel Bayesian regression [192].

One advantage of GPR is that one can work with a family of kernel functions parameterized by some hyperparameters η. One can then optimize the hyperparameters via gradient-ascent on the marginal likelihood function. In contrast, hyperparameter tuning in SVR and KRR typically requires a grid search or some other black-box optimization procedure evaluated on held out data or some form of cross-validation.

Rasmussen and Williams provides an excellent review of Gaussian processes [193]. Numerically, Gaussian Process libraries are confronted with computing the log determinant of the covariance kernel, which naively scales like $\mathcal{O}(n^3)$ in computational complexity. However, recently there have been a number of numerical advances that make these methods fast and scalable to large datasets [194, 195]. While Gaussian Processes are used more widely in cosmology, they are not widely used in particle physics or astro-particle physics. Recent works explore the design of physics-inspired kernels and use Gaussian Processes to model the intensity for a Poisson point process like those found in experimental particle physics and γ-ray and X-ray astronomy [196–198]. Gaussian Processes are also extensively used in Bayesian Optimization (Section 41.3.3).

41.5.2 *Decision trees*

Tree-based models Classification and Regression Trees (CART) typically partition the input space into J disjoint regions $\mathcal{X} = \mathcal{X}^1 \cup \cdots \cup \mathcal{X}^J$ through a sequence of $J-1$ binary splits based

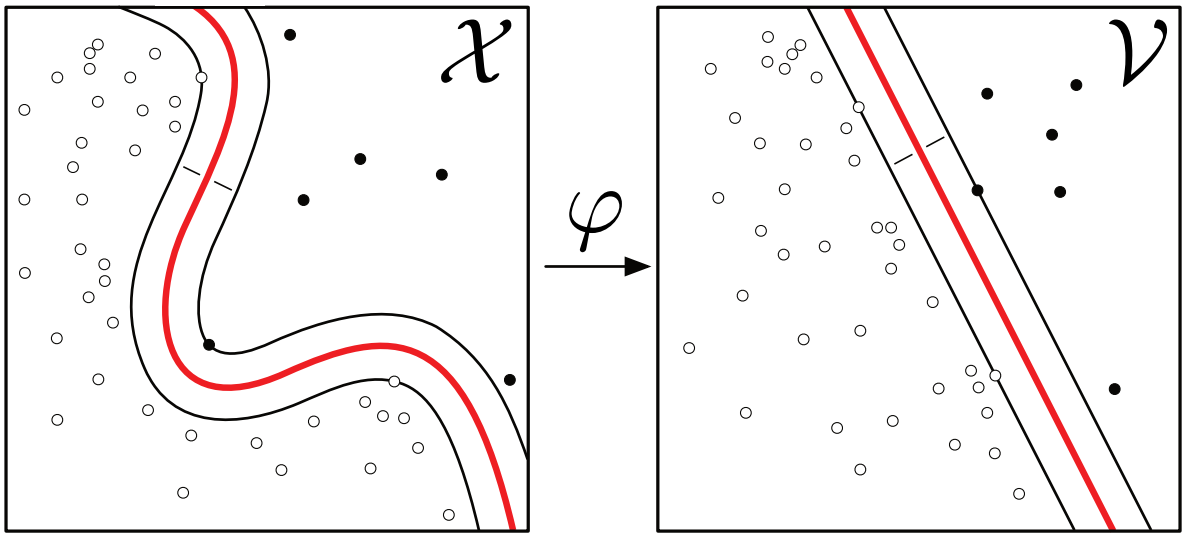

Figure 41.2: Figure depicting the nonlinear SVM decision boundary in $\mathcal{X}$ (left) and the corresponding linear maximum margin classifier in $\mathcal{V}$ (right). Figure adapted from Kernel_Macine.svg Wikimedia Commons (CC BY-SA 4.0) by Cranmer.

on an individual components of $x \in \mathcal{X}$ (*e.g.* $x_4 < 0.7$) [199]. The model is piecewise constant and assigns the value $b_j \in \mathcal{Y}$ to the j-th terminal region $\mathcal{X}^j$. The model can be written

$$\hat{y}(x) = f_\phi(x) = \sum_j b_j \mathbf{1}(x \in \mathcal{X}^j) \,. \tag{41.36}$$

The parameters ϕ of the model comprise the components index and thresholds for the successive splittings and the coefficients b_j.

Tree learning refers to the algorithm used to choosing the tree structure and determining the predictions at leaf nodes. Optimization of the tree structure involves a difficult discrete optimization since the change in the loss with respect to the tree structure is non-differentiable and it is intractable to explore the combinatorially large space of possible trees with brute force. Therefore, the discrete optimization component of tree learning typically involves some approximate algorithm based on heuristics. In contrast, optimization of the b_j for a given tree structure can exploit gradient-based optimization algorithms.

Common approaches to building the decision tree start with a root node and grow with splits based on individual attributes (components of x). These are referred to as top-down induction strategies. There are various impurity heuristics used for choosing the best attribute to split on such as the Gini index, cross-entropy and mis-classification error. Generally they aim to find a split that will refine the the terminal nodes such that they have higher purity than the parent node.

Because most tree learning algorithms consider splits aligned with individual feature components, there are some failure modes for tree-based models. However, tree-based models work well with tabular data that is composed of a mix of continuous and discrete features. Tools such as `XGBoost` [200] are widely used in data science competitions such as Kaggle and the boosted decision trees (BDTs) implemented in `StatPatternRecognition` [201] and `TMVA` [77] have been one of the most used techniques in particle physics [3].

Individual trees are often referred to as weak-learners and they can be combined in various ways described below. Regularization is also an important consideration with tree-based models as one can always learn a tree that assigns exactly one training dataset point per terminal node and memorize the training dataset exactly. One approach to this is called *pre-pruning*, which simply terminates the growing of the trees if the number of training samples reaching the terminal node drops below some threshold, the purity of a terminal nodes is below some threshold, or if the improvement in purity due to a proposed split is not above a threshold. Another regularization approach is called *post-pruning*, which uses a validation data set that is disjoint from the training dataset to probe generalization performance. In this approach, after initially growing a tree with the training dataset, one considers a sequences of pruned trees where splits are removed based on some heuristic. One finds the tree in this sequence of pruned trees that minimizes the generalization error on the validation set. Alternatively, in tools such as *XGBoost* there is an explicit regularization term included in the loss function (see Eq. 41.43).

Ensemble methods The idea of ensemble methods is to combine multiple models into a more performant one by exploiting the bias-variance tradeoff [202]. This is most commonly achieved through averaging (*e.g.* bagging and random forests), which primarily reduces variance, or boosting (*e.g.* AdaBoost and gradient boosting), which primarily reduces bias. Here bias refers to the difference between the Bayes optimal model and the average model produced by the learning procedure with different training sets and variance quantifies how much the learned model varies from one training set to another.

The motivation of boosting is to combine the outputs of many "weak" models to produce a more expressive model. Compared to averagaing techniques like bagging and random forests, the model is built sequentially on modified versions of the data and the final predictions are combined through a weighted sum

$$\hat{y}(x) = \sum_{t=1}^{T} \beta_t \hat{y}_t(x) \,, \tag{41.37}$$

where β_t expand the parameters of the model ϕ.

Bagging The idea behind bagging (bootstrap aggregating) is to create T bootstrap training datasets $B_1, \ldots, B_T$ drawn from the training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$, then learn a model $\hat{y}_t$ for each, and finally construct an average model $\hat{y}(x) = (1/T)\sum_t \hat{y}_t(x)$. If one had T independent training datasets each of size n, then the bias of the average model would be the same as the original model, but the variance would be reduced by a factor of T. By using bootstrap resampling, the bias may increase but the reduction in variance often dominates, which leads to improved performance.

Random forests Random forests refers to a type of "perturb and combine algorithm" that combines bagging and random attribute subset selection. Again one builds trees $\hat{y}_t(x)$ from bootstrap training datasets B_t, but instead of choosing the best split

among all attributes, one select the best split among a random subset of k attributes. If k includes all attributes, then it is equivalent to bagging.

AdaBoost In AdaBoost (adaptive boost) the sequence of trees $\hat{y}_1, \ldots, \hat{y}_T$ are trained with reweighted versions of the original training dataset such that the weight of individual training sample is based on the prediction error in the previous iteration [203]. This requires working with a loss function that and learning procedure for the individual iterations that is amenable to weighted training dataset $\{x_i, y_i, w_i\}_{i=1,\ldots,n}$. Incorporating the weights w_i is straight forward when the risk is expressed as an expectation, since the emperical risk of Eq. 41.3 is just replaced with the weighted average. Similarly, the heuristic for many of the tree-based learning algorithms (*e.g.* the Gini index) also have natural generalizations with weighted events.

In the context of classification, the weighted error of the model $\hat{y}_t(x)$ is

$$\mathrm{err}_t = \frac{\sum_i w_i^{(t)} \mathbf{1}[y_i \neq \hat{y}_t(x_i)]}{\sum_i w_i^{(t)}} \,. \tag{41.38}$$

Based on this weighted error, the coefficient β_t of the component $\hat{y}_t(x)$ in Eq. 41.37 is given by

$$\beta_t = \log\left(\frac{1-\mathrm{err}_t}{\mathrm{err}_t}\right) \,. \tag{41.39}$$

Then for the next iteration the weights of the misclassified events are updated as $w^{(t+1)} = w^{(t)} \exp(\beta_t)$ and then renormalized so that the sum of all weights is 1. This reweighted dataset is then used to train the next model $\hat{y}_{t+1}(x)$ and the entire procedure is initialized with uniform weights $w_i^{t=0} = 1/n$.

There is an analogous procedure for regression with the squared loss function based on the residuals $r_i = y_i - \hat{y}_t(x_i)$ (see for example Ref. [77] for details).

Gradient boosting One of the most powerful forms of tree based models, which is implemented in the tool `XGBoost` is referred to as *gradient boosting* [204]. In this setup, the model is purely additive as in the case of random forests, so the model is Eq. 41.37 with all $\beta_t = 1$. Note this is without loss of generality since the β_t can be absorbed into the b_j of Eq. 41.36. As with AdaBoost, the model is built sequentially through the sequence $\hat{y}_1, \ldots, \hat{y}_T$.

At each iteration, a new term f_t will be added to the sum in Eq. 41.37. For a given decision tree defined by splits on attributes, one can approximate the objective function (the loss function $\mathcal{L}$ plus a regularization term Ω) as a function of b_j in a second order Taylor series:

$$\mathrm{obj}^{(t)} = \sum_{i=1}^{n} [\mathcal{L}(y_i, \hat{y}_i^{(t-1)}) + g_i f_t(x_i) + \frac{1}{2} h_i f_t^2(x_i)] + \Omega(f_t) + \\ + \text{constant} \,, \tag{41.40}$$

where

$$g_i = \partial_{\hat{y}_i^{(t-1)}} \mathcal{L}(y_i, \hat{y}_i^{(t-1)}) \tag{41.41}$$

and

$$h_i = \partial^2_{\hat{y}_i^{(t-1)}} \mathcal{L}(y_i, \hat{y}_i^{(t-1)}) \tag{41.42}$$

In `XGBoost`, the regularization term is taken to be

$$\Omega(f) = \gamma J + \frac{1}{2}\lambda \sum_{j=1}^{J} b_j^2 \,, \tag{41.43}$$

where J is the number of terminal nodes in the tree. With the second-order approximation of the objective, one can directly solve for the optimal b_j for the next tree and the corresponding value of the optimized objective function. The improvement in the objective function can then be used as a heuristic for choosing the best split. Specifically, define $G_j = \sum_{i \in I_j} g_i$ and $H_j = \sum_{i \in I_j} h_i$, where I_j is the set of indices of data points assigned to the j-th leaf. The heuristic used in `XGBoost` for splitting a node is

$$\mathrm{Gain} = \frac{1}{2}\left[\frac{G_L^2}{H_L+\lambda} + \frac{G_R^2}{H_R+\lambda} - \frac{(G_L+G_R)^2}{H_L+H_R+\lambda}\right] - \gamma \,. \tag{41.44}$$

This formula can be interpreted as the score on the new left leaf plus the score on the new right leaf minus the score on the original leaf minus a regularization penalty on the additional leaf. If the gain from splitting a leaf is smaller than γ, then the total Gain is negative and the split will not be added, which can be seen as implementing a form of pruning.

41.5.3 *Neural networks*

In this section we focus on the different types of components used in modern neural network architectures. Gradient-based optimization techniques are most commonly used for training neural networks, and they are described in Sec. 41.6.1. Similarly, other important aspects to effectively training neural network models such as parameter initialization, early stopping, *etc.* are discussed in Sec. 41.6.

The vanishing and exploding gradient problem is a common challenge for gradient-based optimization of neural networks and is described in Sec. 41.6.5. That problem is referred to repeatedly in this section because it has motivated the development of numerous architectural components described below.

41.5.3.1 *Feed-forward multi-layer perceptron*

One of the core components in neural networks is the fully-connected, feedforward network or*multi-layer perceptron* (MLP), which is composed of L *layers*: $f = f^{(L)} \circ \cdots \circ f^{(1)}$. The l^{th} layer defines a function that maps a d_{l-1}-dimensional input vector, called *features*, to an d_l-dimensional output $f^{(l)} : \mathbb{R}^{d_{l-1}} \to \mathbb{R}^{d_l}$. A unit responsible for producing an individual output in d_l-dimesional output is called a *neuron* or a *filter* interchangeably. For $l < L$, the functions f_l are called hidden layers, and the number of neurons (d_l) is referred to as the width of the hidden layers. The layers in an MLP take on the form:

$$f^{(l)}(u) = \sigma^{(l)}(W^{(l)}u + b^{(l)}) \,, \tag{41.45}$$

where $W^{(l)} \in \mathbb{R}^{d_l \times d_{l-1}}$ is called the *weight matrix*, the components of the vector $b^{(l)} \in \mathbb{R}^{d_l}$ are referred to as the *biases*, $u \in \mathbb{R}^{d_{l-1}}$ is the input from the previous layer, $W^{(l)}u$ denotes a matrix-vector product, and $\sigma^{(l)}$ is a non-linear *activation function* that is usually applied element-wise. The parameters of the network comprise the full collection of weights and biases, $\phi = (W^{(1)}, \ldots, W^{(L)}, b^{(1)}, \ldots, b^{(L)})$.

41.5.3.2 *Activation functions*

The activation functions σ in neural networks are nonlinear functions and key to the expressiveness of the resulting family of functions. Two traditionally used functions are *logistic* and *hyperbolic tangent* functions. These functions are bounded to be $(0, 1)$ and $(-1, 1)$ respectively, and are symmetric about the input value of zero. On the other hand, away from the zero input value, a gradient of both functions quickly vanishes and this poses a challenge in using gradient-based optimization method (see Sec. 41.6.1). This can be avoided, to some extent, by normalizing the input values and carefully initializing the values of $W^{(l)}$ and $b^{(l)}$. These are discussed in Sec. 41.6.7, 41.6.8 and 41.6.9. Yet, it becomes difficult to maintain a null input value for a *deep* neural network, a model with many layers. Instead, a popular choice for a deep neural network is *Rectified Linear Unit* (ReLU):

$$\sigma(x) = \begin{cases} x & \text{if } x > 0 \\ 0 & \text{otherwise} \end{cases} \tag{41.46}$$

which computational cost is small and provides the gradient does not vanish for $x \in (0, +\inf)$ [205,206]. An alternative to preserve a non-zero gradient in negative input values are called *Leaky ReLU* and modifies the output to $0.01x$ for $x \in (-inf, 0)$ [207]. Another variant, called *Parametric ReLU* (PReLU), turns the coefficient

0.01 into a variable that is optimized as a part of the model during optimization [208].

The choice of activation functions depends on the model architecture and applications. As described, while the use of ReLU types are a typical choice for a deep neural network, a logistic function is a popular choice at the final layer for classification tasks. Recently, in the area of neural scene representation, sinusoidal activation functions have been found to be surprisingly effective [209].

41.5.3.3 *Softmax*

A softmax function is often used to normalize elements of a discrete vector u, or to interpret the output as a probability over a set of n discrete categories. Given a real-valued input vector $u \in \mathbb{R}^n$, the softmax function computes the output vector $v \in \mathbb{R}^n$ the i-th component is given by:

$$v_i = \frac{\exp(u_i)}{\sum_{j=1}^{n} \exp(u_j)} \ . \tag{41.47}$$

The result has the property that $v_i \in (0,1)$ and $\sum v_i = 1$. The components of the input vector u are often referred to as *logits* in reference to their connection to the logistic function used in logistic regression. The softmax function is commonly used as the last layer in multi-class classifier. The softmax is also used in the context of attention (see Sec. 41.5.3.11).

41.5.3.4 *The rise of deep learning*

There are a number of universal approximation theorems in the theory of neural networks. One of the first was that even with one hidden layer ($L = 2$), an MLP can approximate any continuous function if the non-linear activation function σ not a polynomial and the width d_1 is large enough [210]. However, it is often more efficient (in terms of the number of parameters) to increase the *depth* of the network L [211].

Training a deep network (*i.e.* $L > 2$) that generalizes well can be more difficult, requiring large training datasets, many gradient updates, and suitable regularization. The introduction of large labeled training sets, advances in computing (*e.g.* graphic processing units or GPUs which enabled orders of magnitude acceleration in parallel computation including matrix multiplies [212]), development of ReLU, research progress in initialization and optimization algorithms for model parameters, and regularization techniques like *dropout* [13] all played an important role in the rise of *deep learning* [2, 213]. Though the name deep learning was originally a reference to the depth L of such networks, modern deep learning is characterized more by the composition of various types of modules that are trained through gradient-based optimization. Below we introduce some other common network architectures.

41.5.3.5 *Convolutional neural networks*

Convolutional Neural Networks (CNNs) are widely used for image-like data. They implement the convolution of the input image u and a *filter* W (also referred to as a kernel). The parameters of the filter are learnable and the convolution involves traversing over input and calculating the inner product of the filter W with the part of the input in the *receptive field*, which has the same spatial shape as the filter and is centered at the target pixel. At each location – indexed by i and j below – there is a pixel that may have a vector of features associated with it. In the context of CNNs, these components of these features – indexed by c and c' below – are often referred to as *channels* in reference to the red, green, and blue color channels in a traditional image. The convolution operation is often denoted with a $*$, and the result can be expressed as

$$v_c(j) = (W * u_c)(j) = \sum_{c'} \sum_{i} W_{c,c'}(i) u_{c'}(\text{“}j - i\text{”}) \ , \tag{41.48}$$

where “$j - i$” is shorthand for the pixel index corresponding to the translation from pixel j to i. By repeating the operation over all pixels, the result of a kernel convolution is also an image as illustrated in Figure 41.3. Note that the the number of channels in the output v does not need to be the same as in the input, and the collection of filters $W_{c,c'}$ is often referred to as a filter bank. The entire image for a fixed channel index is often referred to as a *feature map*.

A key feature of the CNN architecture is that it is *equivariant* to translations, meaning that if the input image is shifted (*e.g.* $u(i) \to u'(i) = u(i-k)$), then the output is also shifted by the same amount (*e.g.* $v(j) \to v'(j) = v(j-k)$). This equivariance property is a natural consequence of using convolutions. A fully connected MLP would not generally have this symmetry; however, it is enlightening to imagine transferring the computation performed by a CNN to the weights and biases of a fully connected MLP, which would result in duplicating the weights of the filters multiple times. In this view, the CNN can be interpreted as a fully connected MLP with *shared weights*, which would maintain the equivariance property. This view is helpful for gaining intuition about the inductive bias of models and makes clear that a CNN is a subset of the fully connected MLPs that satisfy the translation equivariance property.

The discussion above makes it clear that CNNs will have fewer parameters than the corresponding fully connected MLP, which can alleviate the optimization challenge. In addition, the convolutional structure allows for data to be reused effectively as patterns in one part of an image in the training dataset effectively contribute to learning that pattern anywhere in the image. Larger kernel sizes allow for the filters to learn more complicated patterns, but at the expense of having more parameters and needing more data to train (the extreme case being a kernel size that is the the size of the entire image, which would be equivalent to a fully connected MLP). In practice, kernel sizes of 3 are popular, 5 is sometimes used, and larger kernels are rarely used.

A kernel convolution involves three hyperparameters, the size of kernel (typically an odd number so that the filter has an unambiguous center), *stride*, and *padding*. The stride is the number of pixels between each target pixel (*i.e.* the center of the filter). The stride size of 1 implies the target pixels are adjacent, and a stride of 2 implies skipping 1 pixel in between (along each spatial axis). Padding is an operation to expand the input image by a specified number of pixels (i.e. “padding size") for when the target pixel is near the edge and the filter would extend beyond the input image. In Figure 41.3, the input image is 4×4 pixels, the kernel is of size 3, and no (zero) padding is applied. The result is a smaller image. Alternatively, With the padding of size 1, the output would retain the 4×4 shape of the input image.

A kernel size of 1 is also frequently used and is referred to as a *1×1 convolution*. While it cannot capture a geometrical features, it can perform linear operations on the input features, including increasing or decreasing the number of features. When combined with a non-linearity and stacked repeatedly this can be seen as a small MLP attached to an individual pixel, and for this reason the 1×1 convolution is sometimes referred to as a *network-in-network* [214]. This is often used to extract more powerful features to be used by the latter layers, and also to compress features when the next layers may be computationally demanding such as a block of many convolution layers with a large kernel size [215, 216].

One may wonder how CNNs identify features with a spatial size larger than a typical kernel size. One mechanism for this is by stacking multiple convolutional layers – *e.g.* the composition of two 3×3 kernels will lead to an effective 4×4 kernel. In addition, a typical CNN architecture uses pooling (described below), which effectively down-samples the image so that it can be processed at different resolutions. The effective receptive field in the input image may be much larger than the kernel size in this case. An alternative approach is to use an *inception module* which is designed to extract features simultaneously using kernels of different size [215].

41.5.3.6 *Pooling*

Pooling plays an important role in convolutional neural networks both practically and in terms of their mathematical properties. A pooling operation is a type of aggregation or down-sampling that takes many pixels as input and produce one pixel for output. Typically, the pooling operation is applied indepen-

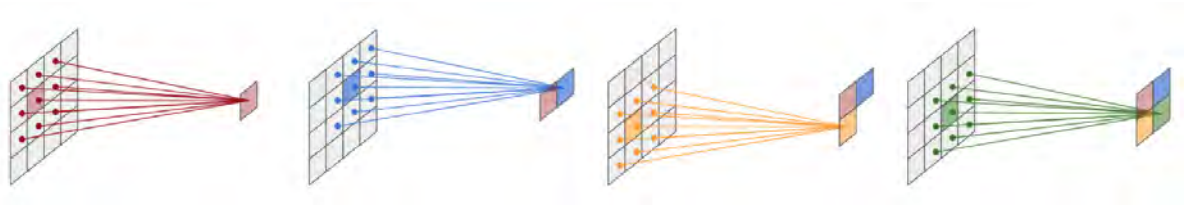

Figure 41.3: A pictorial description of a kernel convolution over four input pixels. It takes a product of the weight matrix (kernel) and the local input matrix centered at a target pixel. The operation is repeated over the input image using the same kernel. The size of the output image depends on the size of the kernel, stride, and padding. In this figure, the kernel size of 3, stride of 1, and padding of 0 is used.

dently for each channel or feature component. The most popular pooling operations are *max* and *average* pooling. Max-pooling picks the highest activation pixel value within the specified receptive field, while the average pooling computes the average pixel value in the receptive field. The idea of pooling generalizes to other architectures, including graph neural networks where the receptive field includes the neighbors of a particular node in the graph (see Sec. 41.5.3.14). The pooling operation gives rise to robustness of the model to small, local deformations in the input, a property called *geometric stability* [217–219]. This type of local deformation is important and distinct from the equivariance to rigid translations provided by the convolutional structure. Repeated pooling operations that eventually lead to a single feature vector with no spatial index is what gives rise to the invariance of common CNN architectures to translations (*i.e.* an image with a dog will be labeled 'dog' even independent of where the dog is in the image).

On the practical side, it is also beneficial to reduce the dimensionality of the input to a smaller hidden state representation. This can be done either a convolution operation with the stride size larger than 1, or employing a *pooling*.

A typical CNN for extracting a 1-dimensional array of features is designed with repeating blocks of convolution layers and pooling operations [220]. Figure 41.4 shows an example evolution of a data tensor through the succession of a convolution and pooling operations in order to extract a 1-dimensional array of features, which then can be fed into a block of MLP for an image classification (or a regression) task. This type of an architecture is referred to as an *encoder* or *feature extractor*.

The reduction in the spatial size of an image is performed *slowly*, typically by a factor of 2, which is the minimum possible reduction factor. After the reduction of the spatial extent, the number of channels is typically increased (also by a factor of 2 in most cases), converging one set of feature maps into a larger number of down-sampled feature maps. There may be more than one convolution layer within each spatial resolution (*i.e.* in between pooling operations). Following these design principles, CNN encoders typically become *deep*, consisting of dozens or sometimes hundreds of convolution layers, and face challenges of vanishing gradients problem (see Sec. 41.6.5). A standard practice to mitigate this issue is explicitly *normalize* the input tensor input at each convolution layer using algorithms like *Batch Normalization*. This will be discussed in Sec. 41.6.9.

41.5.3.7 *CNN architectures for image analysis*

There are three major categories of computer vision tasks where CNNs are often used:

- *Image classification or regression* requires a prediction of single value for the whole image (*i.e.* a category or target value)
- *Object detection* produces a list location information for arbitrary number of objects in the input image
- *Semantic segmentation* outputs an image of the same spatial dimension as the input, in which every pixel is segmented by a predicted value for a target task (classification or regression).

As discussed previously, a CNN feature extractor followed by MLP is often used for image classification and regression tasks in wide range of applications including particle physics. Many successful CNN architectures for object detection and semantic segmentation applications share key designs which we briefly discuss below.

Region Convolutional Neural Network (R-CNN) is one of the most successful design for object detection [221]. R-CNN is explored in HEP experiments where the number and location of signal (e.g. neutrino interactions) are not known apriori in large image data such as neutrino detectors [3, 116, 222].

R-CNN consists of multiple CNNs. The first is a feature extractor which produces a spatially compressed feature tensor. The second CNN applies 1×1 convolution to predict two information: an *object score* which indicates whether there is an object in this (spatially compressed) pixel or not, and prediction of the location and size of a rectangular, axis-aligned bounding box that contains the object (if exists). This second CNN is called *Region Proposal Network* (RPN), and the bounding box is called *Region of Interest* (ROI). The the size of a bounding box is not directly solved by a regression. Instead, the model requires a set of pre-defined *anchor* boxes, which sizes and aspect ratios are hyperparameters, and predict the object score, location, and size (as a multiplicative factor to the defined anchor box) for each anchor box. This allows RPN to detect multiple objects with different aspect ratios even if they are within the same receptive field in the original input image. For each ROI with an object score above threshold (hyperparameter), the third CNN operates in the corresponding sub-field of an already-compressed tensor (*i.e.* by the first CNN) to perform a classification for an object inside the ROI.

This approach can produce multiple ROIs for the same object with a high overlap. Those predictions are reduced using Non-Maximum Suppression (NMS) algorithm. Given a list of bounding boxes with confidence scores, NMS takes the box with the highest score, and computes the Intersection-over-Union (IoU) of this box and all the rest of boxes. Boxes with the IoU higher than a threshold (hyperparameter) are eliminated as they are likely to represent the same object. Then NMS repeats the same operation for the box with the second highest score among the remaining boxes. This is repeated till the list is exhausted.

U-Net is one of the of most successful models used for semantic segmentation [223]. As the output of U-Net is also an image, it gives some interpretability compared to models for an image-level classification or regression tasks. The model is used widely in HEP experiments in both 2D and 3D image data [112,113,118,125,127].

The architecture of U-Net consists of a CNN encoder and *decoder*. A decoder consists of convolution and *convolution-transpose* layer (also called strided transpose-convolution, or rarely deconvolution). The operation of a convolution transpose can be seen an opposite of a convolution: for every pixel in an input image, its value is multiplied to the kernel and copied to the output. $3x3$ kernel in transpose-convolution layer fills $3x3$ pixels in the output tensor. The concept of padding and the stride are also applied to the output tensor. For instance, the stride 2 transpose-convolution fills $3x3$ fields centered at every other pixel (*i.e.* stride 2) for every input pixel. The spatial size of an output tensor is therefore determined by the spatial size of an input tensor, stride, and padding. In the decoder of U-Net, convolution-transpose layers are used to up-sample spatially compressed feature tensors back to the original image resolution. The

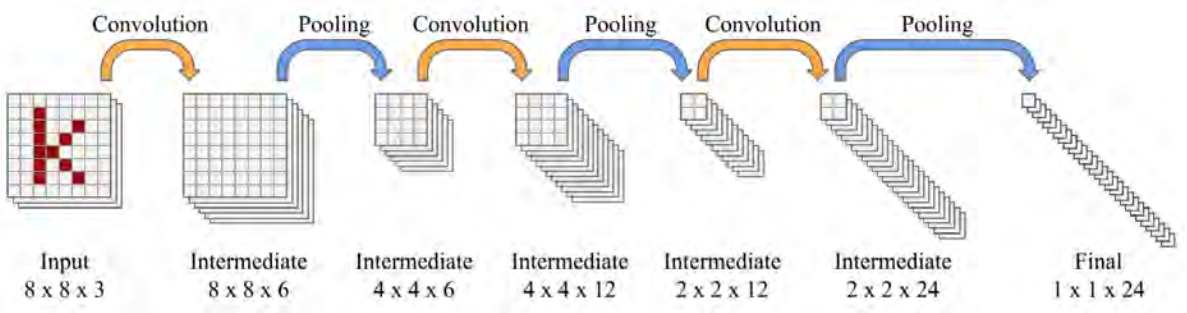

Figure 41.4: An example CNN architecture to extract a 1-dimensional array of features from an image via succession of convolution layers and pooling operations. The (square) kernel, stride, and padding size of a convolution operation are 3, 1, and 1 in respective order. The pooling operation uses a square kernel size of 2. The number of filters at the first convolution layer is 6, and is increased by a factor of 2 at subsequent convolution layers.

stride size of a convolution-transpose layer is almost always 2 in order to *slowly* transform the spatial size, and standard convolution layers (with stride 1) are placed in-between up-sampling operations. Because the output of the decoder has the same size as the input image, features for every pixel can be used for either a classification or a regression task at the pixel-level.

The idea behind encoder-decoder architecture is to extract features in the encoder, and the decoder interpolates those features back to the original spatial resolution. The down-sampling operation (*e.g.* max-pooling) in the encoder is, however, a lossy process where spatial information is permanently lost. This prevents a simple encoder-decoder architecture to perform a semantic segmentation task at the level of precision required for science research and industrial use. Interesting observation made by the U-Net authors is a symmetry in the encoder-decoder architecture in which there are tensors of corresponding (*i.e.* the same) spatial size between two parts of the model. This observation inspired them to concatenate the intermediate tensors in the encoder block to the intermediate tensors of the corresponding size in the decoder block before convolution layers are applied in the decoder, which dramatically improved the performance of semantic segmentation. This is a type of a *skip connection* discussed below.

41.5.3.8 *Residual networks and skip connections*

The representation power of a neural network increases as more hidden layers are added, but gradient-based optimization of deep models can be notoriously difficult due to vanishing gradients (see Sec. 41.6.5). One of powerful techniques to address this challenge is a *residual network* (ResNet), which is a modular architecture design that can be applied to neural network models [216]. Suppose a $f^*(x)$ as the target transformation to be learned by a few stacked layers where x is the input to the first layer. The authors of ResNet hypothesized that it may be easier for a model to learn a residual transformation $\tilde{f}x) \coloneqq f^*(x) - x$, thus the objective to learn is $\tilde{f}(x) + x$ where $\tilde{f}(x)$ denotes the output of stacked layers. This form assumes $\tilde{f}(x)$ and x share the same tensor dimension and size. If they differ in the feature dimension, equivalently the count of channels in an image tensor, one could use 1×1 convolutions to transform and match the dimension. The design is modular as it can be applied per a stack of convolution layers (e.g. U-ResNet introduced for LArTPC detectors uses ResNet modules within a U-Net architecture [112, 113]) widely in the present applications.

The authors of ResNet successfully demonstrated an improved performance of some models at the depth exceeding 1000 layers where the non-residual counter part could not improve the accuracy beyond a few dozens of layers. This remarkable success was due to the *skip connections* in ResNet, namely the element-wise addition of the input to the output at each block of convolution layers as shown in Figure 41.5. Without the presence of the skip connections, the gradients from the loss function is forced to go through all convolution layers (i.e. the reverse direction of orange allows in Figure 41.5), which results in the gradient being altered at every convolution layer. The layers closer to the input receive altered gradients by the continuously updated weights of deeper layers, making conversion difficult and slow. The skip connections provides the path for the gradient to flow directly to the preceding layers. As a result, the gradient can flow more directly to preceding layers and allows simultaneous optimization across layers. It is possible, however, that some convolution layers in ResNet may learn an identity mapping, thus contributing no effect to solving a given task despite consuming computing power.

Another type of skip connections is a concatenation of feature maps, in which case the input and the output of a block of convolution layers do not necessarily have to have the same number of features. This is shown to be very powerful in number of popular model architectures including U-Net [223] and DenseNet [224]. In this case, the input features are re-used: the next block of hidden layers can learn an optimal way to combine the input and the output of the preceding block (i.e. it could learn a simple addition operation, which makes it identical to ResNet). In DenseNet, input to a convolution layer is concatenated with the output of all preceding convolution layers of the same spatial dimension, thus $x_l = f_l([x_1, x_2, \cdots, x_{l-1}])$ where x_l is the output of l-th layer f_l and $[x_1, \cdots, x_{l-1}]$ denotes a concatenation of the inputs. In U-Net, tensors from the encoder block are concatenated with the tensors in the decoder block where they have the same size in spatial dimensions. This was critical for achieving a high spatial resolution for *semantic segmentation*, a class of tasks in Computer Vision to classify every pixel in an image among the predefined set of types (semantics), because the geometrical features at each spatial resolution is otherwise lost via pooling operation in the encoder block [223].

41.5.3.9 *Recurrent neural networks*

Recurrent Neural Networks (RNNs) [225] are a family of neural networks designed for sequential data (*e.g.* time series). Consider sequential data where x_t represents each step in a sequence with $t \in [1, n]$. A typical RNN takes the following form:

$$h_t = g_h(h_{t-1}, x_t, \theta) \tag{41.49}$$

where h_t and θ denote the *hidden state* of the system and parameters of g_h, the RNN model. The term *recurrent* refers the nature of the model operating on the previous state of the system (and hence the whole history). RNNs operate on three types of tasks:

- *One-to-many* takes a single input and generates a sequence (e.g. generates a sequence data, such as a sentence or waveform, given a category).
- *Many-to-one* takes a sequence and generates an output (e.g. sequence-labeling).
- *Many-to-many* takes a sequence and generates a sequence where the length of input and output sequence may be same (e.g. classification of individual element in a sequence) or different (e.g. sequence to sequence mapping).

Figure 41.6 shows an example for a many-to-many task, where $\{x_t\}_{t=1:n}$, $\{y_t\}_{t=1:n}$, and $\{h_t\}_{t=0:n}$ denote the inputs, outputs,

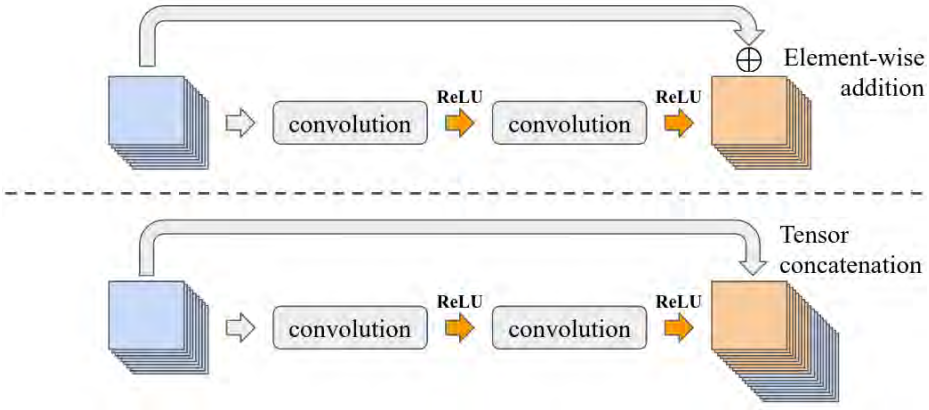

Figure 41.5: Two types of skip connections: the top is from ResNet where the input is element-wise added to the output tensor of a block of convolution layers while the bottom shows a concatenation of the input to the output tensor as employed in other models including U-Net and DenseNet.

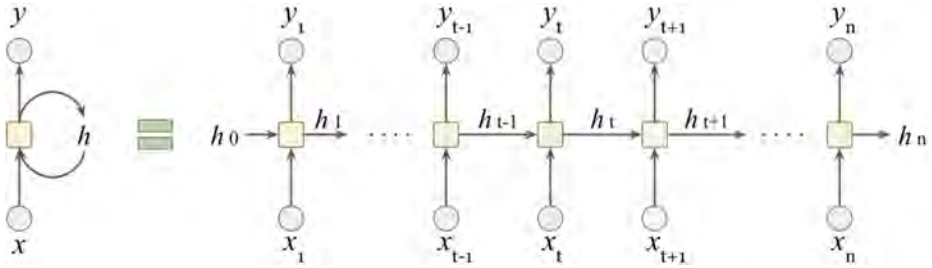

Figure 41.6: Pictorial description of a RNN (on the left) which takes an input and produces an output at every step with a hidden-to-hidden connection. The right diagram is unrolled over discrete steps. The yellow box represents a cell: a set of operations unique to each architecture.

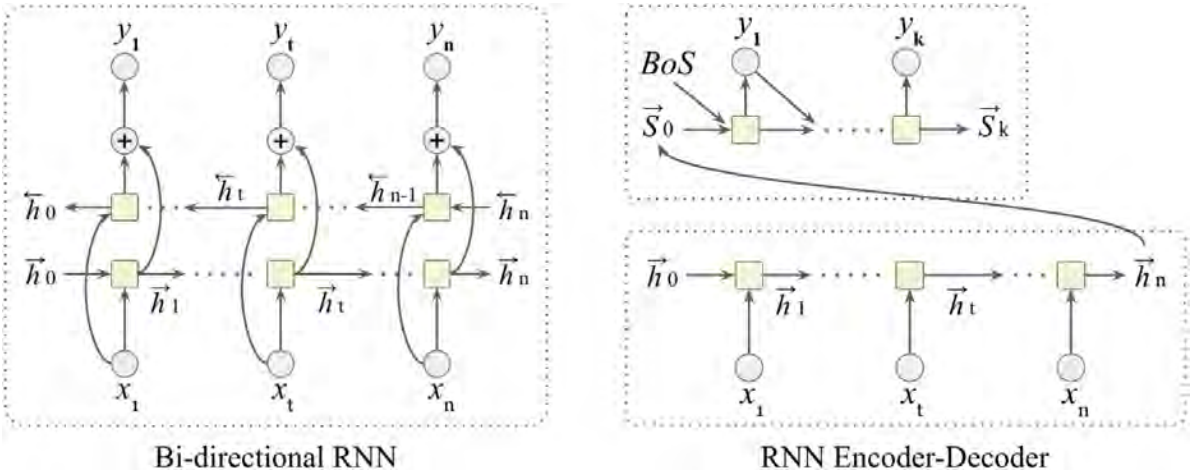

Figure 41.7: Bi-directional RNN (left) provides contexts in the preceding and subsequent parts of the input sequence. RNN encoder-decoder (right) can generate an output with a different sequence length from an input. Each cell in the decoder may take a previously generated element, starting from a special marker that signals the beginning of the sequence (BoS) and ending when the end of sequence is generated.

and hidden states respectively. A set of operations at each time step is called a *cell*. A simple RNN cell may look like:

$$\begin{aligned} h_t &= g_h(Wx_t + Vh_{t-1} + b) \\ y_t &= g_o(Uh_t) \end{aligned} \tag{41.50}$$

where $W \in \mathbb{R}^{d_h \times d_i}$, $V \in \mathbb{R}^{d_h \times d_h}$, $U \in \mathbb{R}^{d_o \times d_h}$ are matrices g_h and g_o represent functions. d_i, d_h, and d_o are the dimension of input, hidden state, and output. $b \in \mathbb{R}^{d_h}$ is a bias term. An example application is sequence-labeling where the goal is for y_t to classify each input x_t in the sequence. In that case, one might use g_h = tanh and g_o = softmax and use a loss function that averages clasification accuracy over the sequence.

Variations in RNN architectures result from the design of cells (described below) and flow of information across the cells. For instance, a bi-directional RNN (Figure 41.7 left) employs two set of RNNs, one processing the sequence in the forward direction and the other in the backward direction, and the hidden states from both directions are then combined to capture the context from both parts of the sequence. An RNN encoder-decoder (Figure 41.7 right) use one RNN to generate a context vector that encodes the whole input sequence, and use a separate RNN to generate another sequence from the encoded context. This can be used for machine translation.

41.5.3.10 *LSTM and GRU*

An RNN applies the same functions g_h and g_o in Eq. 41.50 repeatedly for each element of the sequence. This repeated component is similar to the shared weights for a convolutional filter in a CNN.

A hyperbolic tangent (tanh) is traditionally a popular choice for g_h as it regulates the magnitude of the hidden states and prevents it from diverging. Yet, this simple model is challenging to train for a long sequence of data [226, 227]. This is partially due to the fact that tanh contributes to the vanishing gradient problem and because repeated multiplication of the same weight matrices (i.e. V and W in Eq. 41.50) can lead to gradients that can either explode or vanish (see Sec. 41.6.5). Additionally, the way the signal accumulates means that changes early in the sequence have different impact from changes late in the sequence.

Long Short-Term Memory (LSTM) [228] is a model designed to address the issue of vanishing gradient for RNNs. In this model, a *context* is introduced as a way to enable the model to hold long-term memory while the hidden states remain to hold short-term memory. The context c_t and hidden state h_t at step t are computed as follows:

$$\begin{aligned} c_t &= f_t \bigodot c_{t-1} + i_t \bigodot \tilde{c}_t \\ h_t &= o_t \bigodot c_t \end{aligned} \quad \text{where} \quad \begin{aligned} f_t &= \sigma\left(W^f x_t + V^f h_{t-1} + b^f\right) \\ i_t &= \sigma\left(W^i x_t + V^i h_{t-1} + b^i\right) \\ o_t &= \sigma\left(W^o x_t + V^o h_{t-1} + b^o\right) \\ \tilde{c}_t &= \tanh\left(W^c x_t + V^c h_{t-1} + b^c\right) \end{aligned} \tag{41.51}$$

where σ and $\bigodot$ denote logistic function and an element-wise (i.e. Hadamard) product and f_t, i_t, and o_t are referred to as *gates*. Each gate outputs a value between 0 and 1, and is associated with unique weights, W and V, and a bias b. One can see c_t is a combination of the previous context vector c_{t-1} and a new context vector $\tilde{c}_t$. The *forget* gate f_t controls which and how much of the past context should be kept or forgotten. The *input* gate i_t controls how much of the present context $\tilde{c}_t$ should propagate to the current state c_t. The output gate o_t controls which and how much of the context vector should represent the present hidden state h_t. From Figure 41.8, one can see that the context vector c_t evolves with a gated addition operation. As such, it can be seen as an uninterrupted path for gradients to flow. This is similar to a residual connection (see ResNet in Sec. 41.5.3.8), which enabled training of CNNs with thousands of layers.

Another gated model to solve a vanishing gradient problem is the *Gated Recurrent Unit* (GRU) [182]. The GRU is similar to the LSTM with a few simplifications: the GRU merges the context vector and the hidden states and combines three gates into two. As a result, it requires less computational resources while retaining a similar level of performance for long sequences. The GRU operations are defined as follows:

$$h_t = z_t \bigodot h_{t-1} + (1 - z_t)\tilde{h}_t \quad \text{where} \quad \begin{aligned} r_t &= \sigma\left(W^r x_t + V^r h_{t-1} + b^r\right) \\ z_t &= \sigma\left(W^z x_t + V^z h_{t-1} + b^z\right) \\ \tilde{h}_t &= \tanh\left(W^h x_t + V^h \left(r_t \bigodot h_{t-1}\right) + b^h\right) \end{aligned} \tag{41.52}$$

where r_t and z_t are referred to as *reset* and *update* gate. As one can see in Figure 41.6, the reset gate in GRU performs the same task as the forget gate in LSTM by removing or reducing the elements of its memory (*i.e.* the hidden state). The update gate z_t determines the relative proportion of the previous hidden state h_{t-1} and the new context $\tilde{h}_t$ to be mixed in producing the new hidden state.

In addition to sequential data, the LSTM and GRU units can be used for data that has a tree-like structure. In this setting, the networks are often referred to as recursive neural networks or TreeRNN and they have found applications in natural language processing and jet physics [153, 154, 229–231].

41.5.3.11 *Attention*

Many tasks encountered in machine learning can be divided into subtasks. For example, classifying each pixel of an image or element of a sequence, predicting a target for each node in a graph, *etc.*. For each subtask the model may need to draw upon information from the entire input, but some parts of the input will be more relevant than others. At some point, the model will need to form a representation for the input as context for the subtask at hand. A fixed length vector c as a global context for this subtask is possible, but this approach scales poorly as the size of the input and number of subtasks grow. Either the size of the global context must grow or it will not have the capacity to represent all the relevant information, which would lead to a degredation in performance.

The idea behind *attention* is intuitive: one still forms a representation for the entire input, but different parts of the input are weighted differently according to the task at hand. By making the weights a learnable component, the network can learn to attend to the relevant parts of the input. A softmax function is a natural way to represent attention as it assigns a positive value to each component of the input and sums to one. Then for the i-th task, one can simply form a task-specific context c_i by computing the weighted average of the hidden state representations h_j for each component of the input. Let α_{ij} be the weights assigned to the j-th input for the i-th task, such that $\sum_j \alpha_{ij} = 1$. We can satisfy this naturally if for each i the α_{ij} are computed from the logits β_{ij} using a softmax function that normalizes by summing over j.

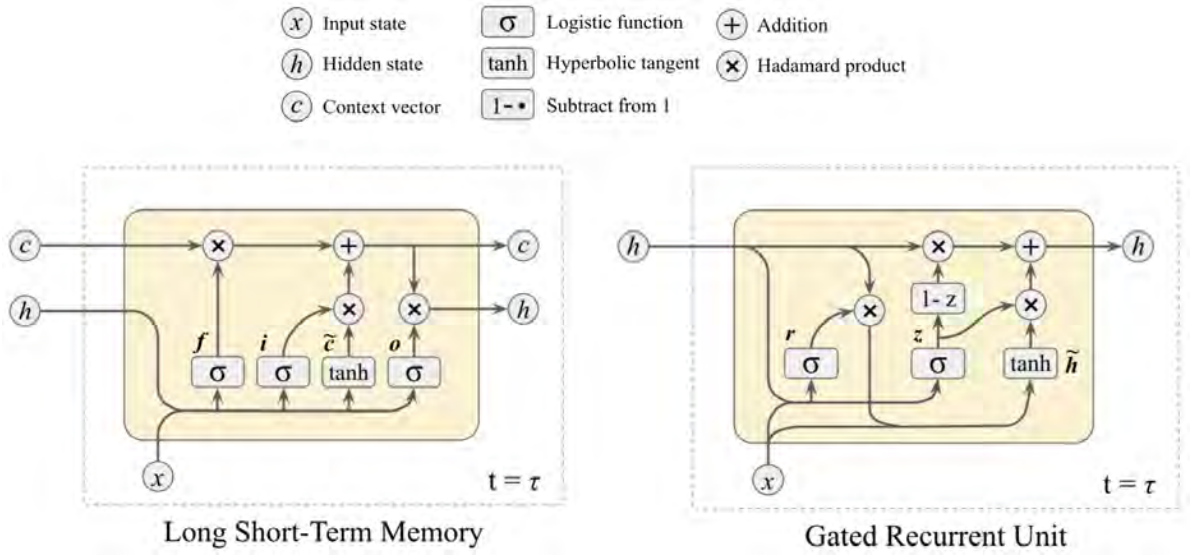

Figure 41.8: LSTM (left) and GRU (right) are both gated neural network designed to address a vanishing gradient problem for RNNs.

Putting these ingredients together, we have the *additive attention mechanism*

$$c_i = \sum_{j=1}^{n} \alpha_{ij} h_j \qquad \text{where} \qquad \alpha_{ij} = \text{softmax}\,(\beta_{ij})_{\text{over } j}\ . \tag{41.53}$$

As in the case of a multi-class classifier, the logits β_{ij} can be computed from a network component with learnable parameters. For instance, in the case of a cell of an RNN encoder-decoder network (see Fig. 41.7) that is decoding element i with an incoming input state s_{i-1}, the logits for the attention mechanism could be computed as follows

$$\beta_{ij} = U \tanh\left(W s_{i-1} + \tilde{W} h_j + b_i\right)\ , \tag{41.54}$$

where U, W, $\tilde{W}$ are the weights and b is the bias term of the model. Fig. 41.9 from Ref. [232] illustrates the full attention mechanism. The idea was implemented by a model called *RNNSearch* which made a breakthrough in machine translation by combining a bi-directional RNN with an additive attention mechanism [233].

We end this section by noting that the softmax α_{ij} can be used to visualize the influence of the j-th input element on the i-th output eleement, which improves interpretability of the model. An example of this from Ref. [232] is shown in Fig. 41.10.

41.5.3.12 *Scaled dot-product attention*

Shortly after the introduction of RNNSearch, the attention mechanism has been recognized as a powerful tool. One such variant is *scaled dot-product attention*, which is most widely recognized as the foundation of the *Transformer* architecture [234], which is described in more detail below.

In additive attention (Eq. 41.53) the hidden representations h_j were combined through a weighted average based on the coefficients α_{ij}, resulting in a task-specific context vector c_i. In the literature around scaled dot-product attention, multi-head attention, and transformers, the hidden states that will be combined are referred to as *values*, and they are often arranged in a matrix labeled $V \in \mathbb{R}^{m \times d_v}$, where the m rows of the matrix correspond to individual hidden state vectors of length d_v. The α_{ij} can also be represented as a $n \times m$ matrix α resulting from applying the softmax function to the $n \times m$ matrix β, normalized independently for each row. With this notation, Eq. 41.53 could be rewritten as $c = \text{softmax}(\beta)V$, where the softmax is normalized per row.

In scaled dot-product attention, the basic structure will be different, but instead of using an non-linear network component to compute the logits β as in Eq. 41.54, the logits will be computed

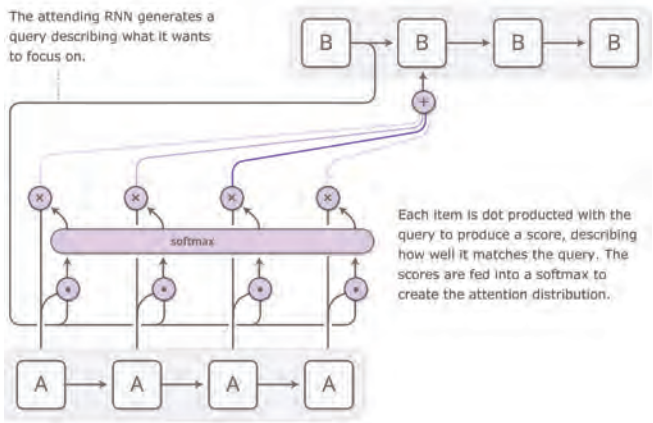

Figure 41.9: An illustration of the attention mechanism From Olah and Carter, "Attention and Augmented Recurrent Neural Networks". Lower boxes labeled `A` represent input elements in the sequence and upper boxes labeled `B` indicate output elements. The left-most line originating from the first `B` corresponds to the state s_{i-1} in the text.

by forming a dot product between a in incoming *query* and a *key*. The set of n query vectors can be arranged into the matrix $Q \in \mathbb{R}^{n \times d}$ and the set of d key vectors can be arranged into the matrix (transpose) $K^T \in \mathbb{R}^{d \times m}$. When the dot product between a particular query vector $q_i \in \mathbb{R}^d$ and key vector $k_j \in \mathbb{R}^d$ is large, then the resulting logit β_{ij} and attention weight α_{ij} will be large. One can interpret the keys as trying to detect certain types of queries and routing the attention to the relevant value. Typically, the dot-product is scalled by a factor of $1/\sqrt{d}$. The resulting task-dependent context is $c_i = \text{softmax}_j(q_i \cdot k_j/\sqrt{d})v_j$, where softmax_j indicates that normalizing sum runs over the index j. A common, though sometimes confusing, notation is simply

$$c = \text{Attention}\,(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d}}\right) V\ , \tag{41.55}$$

where c is a $n \times d_v$ matrix organizing the n context vectors of length d_v that are taylored summaries of the input vector for each of the n tasks.

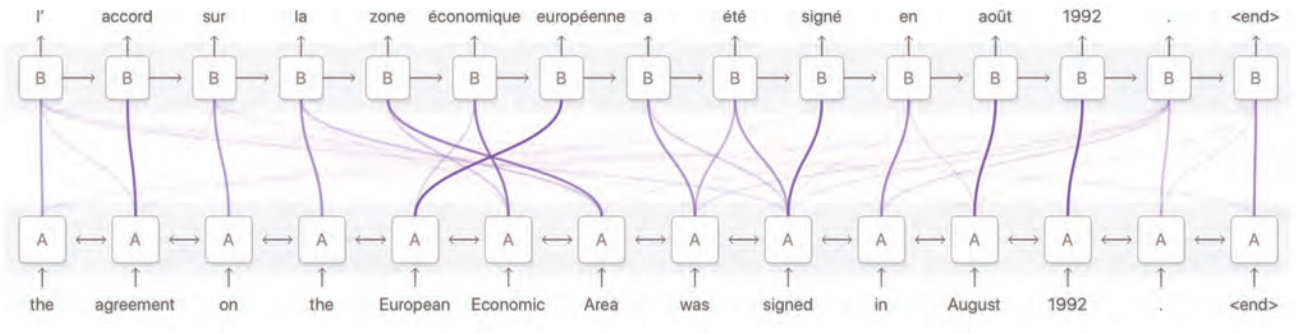

Figure 41.10: Visualization of the attention weights in a sequence-to-sequence problem taken from Olah & Carter, "Attention and Augmented Recurrent Neural Networks" The thickness of the lines is proportional to the attention weights α_{ij}..

41.5.3.13 *Transformer and multi-head attention*

The Transformer architecture is a powerful encoder-decoder model based on the scaled-dot product attention mechanism. It was originally designed for sequential data like RNNSearch, and subsequently used in other areas of research including computer vision. One advantage of scaled-dot product attention compared to the approach used in *RNNSearch* (Eq. 41.54) is that computing the logits β_{ij} (and thus the attention weights) does not involve any sequential processing. This allows the models to better leverage parallelism of the hardware to train much more expressive models than before. In place of the gated unites of an RNN that are key to avoiding the vanishing gradient problem, the Transformer architecture employs a residual connections at every attention module (*i.e.* the input tensor is added to the output as in Fig 41.5).

The second major ingredient in the Transformer architecture is the *multi-head attention* mechanism. A multi-head attention module executes multiple scaled dot-product attention in parallel. The query Q, key K, and value V matrices in each scaled dot-product attention module is obtained by applying a linear transformation (with learnable weights) to the common Q, K, and V input matrices. Each of them can be considered as a different (albeit rotated) *perspective* to derive attention.

For a sequence-to-sequence mapping task, the output of encoder is used to derive key K and value V matrices for the multi-head attention module in the decoder. The decoder is then responsible for mapping between the key-value features derived from the input (the encoder) and the queries from the decoder (which is still executed sequentially) in order to produce the final decoded output.

Finally, we note that the Transformer architecture does not just employ an attention mechanism in the decoder. By employing attention in the encoder as well the model has more capacity to "interpret" the input – a concept referred to as *self-attention*.

Models such as these have made breakthroughs in many areas of scientific and industrial research [235].

41.5.3.14 *Graph networks and geometric deep learning*

Graphs are a powerful data structure for representing structure data. A graph consists of *nodes* as elements and *edges* between between them. Graphs are sufficiently flexible to describe many types of structured data including images and sequences. Graph-based neural networks can also be seen as a generalization of many common types of machine learning models such as recurrent networks, convolutional neural networks, *etc.* [219]. The term *geometric deep learning* refers to this recent formulation that focuses largely on the symmetries of the data.

An earlier attempt to organize the variations on different flavors of graph-based neural networks can be found in Ref. [236]. In their formalism a Graph Network may be represented as $G(\mathbf{u}, V, E)$ where $\mathbf{u}$ represents an array of global features, $V = \{\mathbf{v}_i\}_{i=1:N^v}$ represents a set of N^v nodes with $\mathbf{v}_i$ as features for the i-th node (e.g. such as RGB channels if a node represents a pixel in image data), and $E = \{(\mathbf{e}_k, r_k, s_k)\}_{k=1:N^e}$ represents a set of N^e edges with $\mathbf{e}_k$ as features for the k-th edge. An edge may be (bi-)directional where r_k and s_k denotes the destination and origin nodes respectively. The features of a graph may evolve with three *update* functions ϕ and and three *aggregate* functions ρ:

$$
\begin{aligned}
\mathbf{e}'_k &= \phi^e(\mathbf{e}_k, \mathbf{v}_{r_k}, \mathbf{v}_{s_k}, \mathbf{u}) & \mathbf{e}'_i &= \rho^{e\to v}(E'_i) & \text{where} \quad E'_i &= \{(\mathbf{e}'_k, r_k, s_k)\}_{r_k=i, k=1:N^e} \\
\mathbf{v}'_i &= \phi^v(\bar{\mathbf{e}}_i, \mathbf{v}_i, \mathbf{u}) & \bar{\mathbf{e}}' &= \rho^{e\to u}(E') & \text{where} \quad E' &= \cup_i E'_i = \{(\mathbf{e}'_k, r_k, s_k)\}_{k=1:N^e} \\
\mathbf{u}' &= \phi^u(\bar{\mathbf{e}}', \bar{\mathbf{v}}', \mathbf{u}) & \bar{\mathbf{v}}' &= \rho^{v\to u}(V') & \text{where} \quad V' &= \{\mathbf{v}'_i\}_{i=1:N^v}
\end{aligned}
\tag{41.56}
$$

where $\mathbf{e}'$, $\mathbf{v}'$, and $\mathbf{u}'$ denote the updated node, edge, and graph features. In Graph Networks, three types of information are updated in the following order. The first step is ϕ^e to update every edge. The second step updates every node: for i-th node, compute $\rho^{e\to v}$ to aggregate updated attributes from the edges with $r_k = i$ then compute ϕ^v to update the node attributes. The third step updates the graph attributes through ϕ^u which takes the original state $\mathbf{u}$, aggregated node and edge attributes by $\rho^{v\to u}$ and $\rho^{e\to u}$ respectively.

Graph Neural Networks [237] (GNNs) are the class of neural networks that work on graph-structured data. A direct analog in Computer Vision and physics is the *point cloud* data type, which is an unordered set of points. Operations on point cloud need to be permutation invariant (e.g. *min, max*, $+$, $\cdot$), and analysis of 3-dimensional physical object represented by point cloud need to be rotation and translation invariant as in the case for an image. PointNet [238, 239], a GNN that performs an object classification on point cloud of 3-dimensional positions, treats each point as a node, applies MLPs as ϕ^v to update node features, and global max-pooling operation as $\rho^{v\to u}$. There is no explicit edge definition in PointNet (though the model applies affine transformation to all points using Spatial Transformer Network [240], which could be considered as a separate graph operation, to introduce rotation and translation invariance and to capture topological features). Deep Sets [241] follows the same manner except ϕ^v takes the global entities $\mathbf{u}$. This is same for PointNet when performing point cloud segmentation: ϕ^v takes a step of simply concatenating $\mathbf{u}$ to node entities to combine a local and global features. Dynamic Graph CNN [242] is a variant that (re)define edges dynamically using attention mechanism: $\rho^{e\to v}$ aggregates k neighbor nodes where the inter-node distance is defined as a Cartesian distance in the feature space. ϕ^v remains a MLP and, while edges are defined, there is no associated entity. A similar technique is used in Non-Local Neural Network [243] to efficiently propagate local

feature information to points that may be far in the 3D cartesian coordinate. Message Passing Neural Network [244] (MPNN) explicitly defines a feature vector as edge entities. In MPNN, $\rho^{e\to v}$ performs element-wise sum of features and feed into ϕ^e, explicitly passing features across nodes as the name suggests. While these are representative models that are frequently used in particle physics applications [117, 121, 132, 142, 156, 183, 245, 246], it is only a tiny fraction of GNN models developed over the past decade.

Graph-based models are particularly interesting for science applications because they often offer a natural way to organize the entities in the data and encode how those components should interact each other. This particular type of inductive bias is referred to as *relational inductive bias* in Ref. [237]. The structure of the graph is both an opportunity and a responsibility as one needs to define the graph structure including the edges to define the mode. A naive approach may be defining a fully-connected graph. However, for applications on hundreds of thousands of nodes (e.g. high resolution 3D point cloud), this may require a prohibitive amount of memory and computation. On the other hand, if the graph is too sparse, it may negatively impact the performance. One may need to compare the model performance among differently constructed graphs and balance against computational burden. Ideally the graph would be based on some knowledge of the interactions, but in the absence of such knowledge, popular graph construction methods include fully-connected, $k-$Nearest Neighbors, a Delaunay graph, and Minimum Spanning Tree.

Classification and regression tasks for graphs can be formulated such that the prediction is made for the entire graph or its individual nodes or edges. Graph-level prediction is like classifying an entire image, while node-level prediction is like semantic segmentation where individual pixels are classified. For clustering of points, GNNs can approximate a transformation function for nodes into the latent space where an optimal clustering of points can be performed. Alternatively, one can formulate clustering as an edge classification task. A comprehensive review on particle physics applications have been made available recently [247].

41.5.4 *Deep generative models*

Deep generative models are powerful machine learning models that can learn complex, high-dimensional distributions and generate samples from them. Because of their inherently probabilistic formulation, generative models are rapidly becoming an indispensable tool for scientific data analysis in a range of domains. Generative models can be contrasted against discriminative models that are primarily used for supervised learning tasks. Roughly, discriminative models are used for prediction and $f(x)$ provides a point estimate of the target y, and they are more closely connected to function approximation. In contrast, generative models describe the data distribution $p(x)$ (or the joint data distribuiton $p(x, y)$ in a supervised setting). An enlightening discussion of these two approaches can be found in Ref. [10].

There are a number of different types of deep generative models that have various pros and cons as they do not all have the same capabilities. We will focus on Variational Auto-Encoders (VAEs) [248,249] , Generative Adversarial Networks (GANs) [250, 251], and Normalizing Flows (NFs) [252–256], though there other approaches have been explored in this quickly developing area of research. Consider these three distinct types of functionality:

- **generation:** ability to sample or "generate" a data point $x_i \sim p(x)$.
- **likelihood for generated data:** ability to evaluate the probability density (likelihood) $p(x_i)$ for a data point x_i sampled from the model $x_i \sim p(x)$.
- **likelihood for arbitrary data:** ability to evaluate the probability density $p(x_i)$ for an arbitrary data point $x_i \in \mathcal{X}$.

Each of the models above can be used for generation; however, only normalizing flows provide all three capabilities. For reasons that we will describe below, GANs and VAEs do not provide a tractable likelihood function, and they are sometimes referred to as *implicit models*. This establishes a connection to simulation-based inference where most scientific simulators are also implicit models with an intractable likelihood. Because normalizing flows have a tractable likelihood, they can be trained via maximum likelihood (Eq. 41.18) as described in Sec. 41.3.2.1. GANs and VAEs, on the other hand, need to employ some other loss function to be trained. In the case of VAEs, training is based on the ELBO used in variational inference (see Sec. 41.3.1.3 and the discussion around the reverse KL divergence below Eq. 41.16). While GANs are also implicit models they data they can generate is typically restricted to a lower-dimensional manifold $\mathcal{M} \subset \mathcal{X}$, meaning that almost all real training dataset doesn't "live on" the subspace of possibilities that the model can produce. In this case, the liklelihood is for almost all data is zero, and so even ELBO-based training will not work. The breakthrough idea introduced in Ref. [250] was to use adversarial training where a classifier would be used to quantify how different the data generated from the model is from the data from the target distribution.

VAEs, GANs, and normalizing flows introduce a mapping $g(z, \theta)$ from a base random variable z to the space of the data $\mathcal{X}$. The map $g(z, \theta)$ is typically implemented with a neural network. The random variable z is sampled from some known base distribution $p(z)$ that is both easy to sample and has a density that is easy to evaluate. Typically, the base distribution is a multivariate normal.

In the literature on GANs and normalizing flows, this base random variable is often referred to as a latent variable and $p(z)$ is often referred to as a prior distribution, but this may cause confusion as the relationship between z and the observed x is deterministic. Typically, one would reserve the term latent variable for situations where one must marginalize (integrate) over z to obtain the marginal likelihood as in $p(x) = \int p(x, z)dz$. In this integral would involve a delta function imposing the deterministic relationship $x = g(z, \theta)$. A more natural interpretation of the relationship between x and z is through the change of variables formula, which is the essence of normalizing flows.

In the case of VAEs, the one additionally adds some normally-distributed (Gaussian) random noise ϵ to the output so that $x = g(z, \theta) + \epsilon$. In this case, x and z are not deterministically related and z is a legitimate latent variable in the model and $p(z)$ can be interpreted as the prior on that latent variable. In this case, the model can populate the full space of the data. Unfortunately, the marginal likelihood $p(x) = \int p(x, z)dz$ involves an intractable integral, thus maximum likelihood training is infeasible. However, the likelihood term $p(x|z)$ is tractable (*i.e.* the Gaussian noise), so training with the ELBO is possible.

Note that the dimensionality of of z need not be the same as that of x. If $z \in \mathbb{R}^q$ and $\mathcal{X} = \mathbb{R}^d$ with $q < d$, then all points $g(z, \theta)$ will lie on a d-dimensional surface in $\mathbb{R}^d$. In the case of a VAE, the Gaussian noise ϵ means that the genrerted data x will be distributed in a thin region around the surface defined by $g(z, \theta)$. The presence of a bottleneck (*i.e.* $q < d$) leads to advantages and disadvantages. The disadvantages for GANs is that the likelihood assigned to almost all real world data (*i.e.* data not generated by the model) will be zero, so training is more difficult and many tasks in probabilistic inference won't be applicable. However, often real world data is also effectively described by a low-dimensional subspace in the full space of the data – random images look like noise, while natural images are in some sense special. For this reason, images produced by GANs for instance often have better visual quality than those produced by other techniques. This points to the ambiguity encountered in quantifying how close two distributions are, and also motivates the use of distance measures such as the Earth Movers distance or Wasserstein distance [257, 258]. Conversely, the lack of a bottleneck (*i.e.* $q = d$) leads to very large models and scalability issues when the data is high dimensional.

Recent work has also focused on combining ideas from VAEs, GANs, and normalizing flows so that the generative model does involve a bottleneck but can still provide tractable likelihoods for density estimation restricted to that manifold [44,46,252,259,260]. Some of these models can also be used in the context of anomaly detection and out of distribution detection by identifying data that is off the manifold.

The parametrization of the mapping (the architecture of the neural network) should match the structure of the data and be

expressive enough. For problems with explicit symmetries it is beneficial to include them into the architecture of the network explicitly, which restricts the allowed space of the models and matches their inductive bias (implicit regularization inherently built into the choice of architecture of the network) to the data. Different architectures have been proposed [255, 261–263], and to achieve the best performance on a new dataset one needs extensive hyperparameter explorations [264].

41.5.4.1 *Variational auto-encoders*

The auto-encoder was described in Sec. 41.3.2.2 as model for compression and representation learning. The model is $f = g \circ e : \mathcal{X} \to \mathcal{X}$, where $e : \mathcal{X} \to \mathcal{Z}$ is referred to as the *encoder* and $g : \mathcal{Z} \to \mathcal{X}$ is referred to as the *generator* or *decoder*. The standard auto-encoder is not a probabilistic model, but additional probabilitic structure can be added.

One approach is VAE mentioned above [248, 249]. By equipping the latent space with a prior distribution $p(z)$, the decoder of the auto-encoder $g(z, \theta)$ implies a distribution on a manifold in the output space $\mathcal{X}$. VAEs additionally add some normally-distributed (Gaussian) random noise ϵ to the output so that $x = g(z, \theta) + \epsilon$. This implies that $p_\theta(x|z)$ is a tractable quantity, and it is interpreted as the likelihood in this context.

In a VAE one also elevates the encoder to have a probabilistic form. Instead of encoding $z = e(x)$ in a deterministic way, one seeks a distribution over z given x. A natural target for the probabilistic encoder would be to probabilistically invert the decoder. This inverse problem is solved by the posterior distribution $p(z|x)$ via Bayes theorem

$$p(z|x) = \frac{p(x|z)p(z)}{p(x)} \ . \tag{41.57}$$

While the likleihood and the prior may both be tractable, the normalizing constant $p(x) = \int p(x, z)dz$ involves an intractable integral (the same intractable integral that makes maximum likelihood training of the VAE infeasible).

One approach to Bayesian inference in these settings is variational inference (VI). In VI one approximates the posterior with some parametric family $q_\phi(z|x)$ in a parametric form, and then uses optimization to optimize the ELBO with respect to its parameters ϕ.

$$\begin{aligned} \text{ELBO} &= \mathbb{E}_{q(z)} \log p(x|z) - D_{KL}[q(z)||p(z)] \\ &\leq \log \mathbb{E}_{q(z)} \left[\frac{p(x, z)}{q(z)} \right] = \log p(x) \ , \end{aligned} \tag{41.58}$$

where we used Jensen's inequality for concave functions (log) and the reverse Kullback-Leibler (KL) divergence term is

$$D_{KL}[q(z)||p(z)] = \mathbb{E}_{q(z)}[\log q(z) - \log p(z)] \geq 0. \tag{41.59}$$

In a VAE, the variational model for the posterior $q_\phi(z|x)$ is often assumed to be an uncorrelated Gaussian (this is often called mean field approximation) defined by the mean μ and variance Σ. Instead of optimizing the mean and variance independently for each x, VAEs use neural networks to predict the mean $\mu_\phi(x)$ and the variance $\Sigma_\phi(x)$. This is called *amortized inference*, since after an up-front training cost the approximate posterior $q_\phi(z|x)$ can be evaluated effeciently with a single forward pass of the neural network. Note the standard auto-enocder is recovered if one only used the mean $\mu_\phi(x)$ for the encoder and did not add noise ϵ to the decoder.

Both the probabilistic encoder $q_\phi(z|x)$ and the probabilistic decoder $p_\theta(x|z)$ are trained jointly by optimizing the ELBO. Unlike the standard auto-encoder, which only minimizes the reconstruction error, ELBO optimization of Eq. 41.58 has a trade-off between minimizing the reconstruction error in the first term (averaged over the approximate posterior $q(z)$), which encourages high quality reconstructions, and minimizing the KL divergence term, which forces the posterior $q(z)$ to be as close to the chosen prior $p(z)$, and thus controls the sample quality by matching the aggregate posterior with a chosen prior distribution [265]. This term regularizes the VAE latent space, such that every sample drawn from the prior $p(z)$ correspond to a valid sample. Successful VAE training requires to find a delicate balance between the two contributing terms to the ELBO. Whether the VAE training process succeeds in striking this balance depends on a number of factors, including the network architectures, the chosen prior and the class of allowed posterior distributions. Once trained, the VAE can be used as a generative model by sampling from the prior $z_i \sim p(z)$ and then decoding according to $p_\theta(x|z) = g(z, \theta) + \epsilon$.

VAEs allow for expressive architectures, enjoy the benefits of regularization through data compression and have a firm theoretical foundation. Compared to GANs [250], VAEs are of particular interest to the scientific community as they provide a lower bound to the marginal likelihood (albeit potentially with a large gap) and a posterior distribution for the latent variables.

It is also interesting to consider a special case of the auto-encoder and VAE where the encoder and decoder are restricted to be linear transformations, which is effectively PCA. In PCA the (linear) decoder can be written $g(z) = Oz$, where O is a matrix. As in the case of the auto-encoder, PCA is not a probabilitic model, but probabilistic structure can be added. Probabilistic PCA [266] assumes that the latent variables follow a Gaussian distribution with mean zero and covariance Λ, where Λ is a diagonal matrix with the rank-ordered eigenvalues λ_i along its diagonal. The true distribution of the PCA components may be non-Gaussian, but a Gaussian is the maximum entropy approximation given their first two moments. Note that in Probabilistic PCA these moments are measured on training dataset (when finding the principal components).

One can generalize Probabilistic PCA to use non-linear encoder and decoder as in an auto-encoder. A Gaussian prior is a poor ansatz for the latent space distribution of data proceed by an auto-encoder. Instead one can learn the density of the training samples in latent space using a normalizing flow. This model was introduced in $\mathcal{M}$-flows [46] and in Probabilistic Auto-Encoder (PAE) [44], which achieves similar performance to a VAE in terms of sample quality without explicit ELBO optimization. In all these cases the dimensionality of the latent space is a hyperparameter to be chosen or optimized by the user. Unlike a standard VAE, these models do not add noise to the decoded output, thus the data is strictly restricted to the manifold defined by the decoder $g(z, \theta)$. However, unlike a GAN there is a well defined way to take an arbitrary data point x, project it onto the manifold, and calculate the density of the data point projected onto the manifold. Thus these models can also be used in the context of anomaly detection and out of distribution detection by identifying data that is off the manifold.

41.5.4.2 *Generative adversarial networks*

GANs [250] also typically choose a low dimensional latent space z with a known prior distribution $p(z)$, typically a normal (Gaussian) distribution with zero mean and unit variance. GANs do not add noise to the output $g(z, \theta)$, so the likelihood $p(x|z)$ (and marginal likleihood $p(x)$) for almost all of the data space is 0, which precludes training by maximum likelihood and the ELBO. Instead of training on ELBO, GANs train on a dissimilarity measure defined implicitly by a discriminator $D(x)$ (also referred to as the critic). Calculating the dissimilarity often involves it's own learning problem (*i.e.* adversarial training of the discriminator).

The training is usually framed as a mini-max game

$$\begin{aligned} &\min_g \max_D \mathcal{L}_{\text{GAN}} = \\ &\min_g \max_D \{\mathbb{E}_{x\sim p(x)} \log D(x) + \mathbb{E}_{z\sim p(z)} \log[1 - D[g(z)]]\}. \end{aligned} \tag{41.60}$$

The goal of the discriminator is to distinguish between true and generated data, hence we want to maximize this loss with respect to D, assigning 1 to true data and 0 to generated data. The goal of generator is to fool the discriminator such that it cannot distinguish between true and generated data, hence we want to minimize this loss with respect to g at fixed D. This can be viewed as a game theoretical setup in a zero sum game between generator and distriminator.

Instead of this game theory interpretation we can view the internal objective $\max_D \mathcal{L}_{\text{GAN}}$ as an implicit loss function that mea-

sures the dissimilarity between the target and generated distributions. The loss of Eq. 41.60 corresponds to the Jensen-Shannon (JS) divergence, which is a symmetrized form of KL divergence. However, JS divergence is hard to directly work with, and the adversarial training could bring many problems such as vanishing gradient, mode collapse (tendency of generator to cluster the samples around the training samples, with holes between them) and non-convergence [257, 258]. One of the core issues is that the distribution generated by the GAN is restricted to a manifold and the KL divergence isn't well defined in this case (because p is not absolutely continuous with respect to q). To address these issues Wasserstein GANs train on

$$\min_g \max_D \mathcal{L}_{WGAN} = \min_g \max_D \{\mathbb{E}_{x\sim p(x)} D(x) - \mathbb{E}_{z\sim p(z)} D[g(z)]\}. \tag{41.61}$$

Here again the goal of discriminator is to make the loss as large as possible between the true data and the generated data, while the goal of generator is to make it as small as possible, so that the discriminator cannot distinguish between the two. There is no requirement for $D(x)$ to be between 0 and 1, which helps with the above mentioned problems of JS divergence. Instead, this is replaced with a requirement that $D(x)$ is 1-Lipshitz, i.e. the absolute value of the norm of the gradient of the discriminator output with respect to the input has to be less or equal to 1.

Eq. 41.61 can be interpreted as the dual form of the 1-Wasserstein distance between the true and generated distribution [267]. Wasserstein distances are a measure of dissimilarity between two distributions used in the context of Optimal Transport, mathematical theory of how to optimally transport one distribution to another. Since the transport distance increases with the separation between the two distributions when they are non-overlapping, there is no gradient collapse that plagues other measures. In its primal form p-Wasserstein distance, $p \in [1, \infty)$, between two probability distributions p_1 and p_2, is defined as $W_p(p_1, p_2) = \inf_{\gamma\in\Pi(p_1,p_2)} \left(\mathbb{E}_{(x,y)\sim\gamma} [|x - y|^p]\right)^{\frac{1}{p}}$, where $\Pi(p_1, p_2)$ is the set of all possible joint distributions $\gamma(x, y)$ with marginalized distributions p_1 and p_2. In 1D the Wasserstein distance has a closed form solution via Cumulative Distribution Functions (CDFs), but this evaluation is intractable in high dimensions.

In the dual form of 1-Wasserstein distance, one instead maximizes Eq. 41.61 over all possible functions $D(x)$ that are 1-Lipschitz. One way to implement this is through weight clipping of the parameters of discriminator network, but a simpler solution is to add a gradient norm penalty term explicitly to the loss function [268].

Because of the discriminative nature of the dissimilarity measure defined in data space, GANs often generate more realistic samples than VAE or normalizing flows in high dimensions such as natural images. However, GANs do not provide an encoder from data to latent space, do not provide a tractable likelihood $p(x)$.

41.5.4.3 *Normalizing flows, autoregressive models, and score based models*

Normalizing Flows (NF) provide a powerful framework for density estimation and sampling [252–256, 269]. These models map the data x to latent variables z through a sequence of invertible transformations $f = f_1 \circ f_2 \circ \cdots \circ f_n$, such that $z = f(x)$ or $x = g(z) = f^{-1}(x)$. As in the VAE and GAN, z is modelled as a random number with a simple base distribution $p_Z(z)$, which is typically chosen to be a standard normal (Gaussian) distribution. The probability density of the model be evaluated using the change of variables formula:

$$p_X(x) = p_Z(f(x)) \left|\det\left(\frac{\partial f(x)}{\partial x}\right)\right| = p_Z(f(x)) \prod_{l=1}^{n} \left|\det\left(\frac{\partial f_l(x)}{\partial x}\right)\right|, \tag{41.62}$$

where we have added subscripts to $p_X(x)$ and $p_Z(z)$ for clarity. The Jacobian determinant $\det(\frac{\partial f_l(x)}{\partial x})$ must be efficient to compute for density estimation to be practical, and the transformation f_l should be easy to invert for sampling. In contrast to VAE and GANs, standard normalizing flows preserve the dimensionality of the data space as they are invertible (though there are normalizing flows that are defined on lower dimensional manifolds embeded in the data space [44,46,252,259,260]). As such, they do not have the problems of GANs and VAEs they can be trained via maximum likelihood (Eq. 41.18) as described in Sec. 41.3.2.1.

There are several popular architectures of NFs. A method used by NICE, RealNVP and Glow [253–255] is to split the space into two disjoint sets z_1 and z_2, and then use an identity forward map $z \to x$ for x_1, $x_1 = z_1$, and an affine transformation for x_2 of the form

$$x_2 = \exp(s(z_1)) \odot z_2 + m(z_1), \tag{41.63}$$

where $\odot$ is elementwise product and $m(z_1)$, $s(z_1)$ are neural networks. The Jacobian of this map is lower triangular, and its determinant is simply the product of elements along the diagonal, which is tractable, as is the inverse of the transformation. At the next layer one then performs a different split of dimensions into z_1 and z_2. The affine transformation can be further generalized to a nonlinear form using rational splines [270].

One can interpret the sequence of invertible transformations $f_1 \circ f_2 \circ \cdots \circ f_n$ as n discrete time steps in a continuous flow. In particular, one can think of a continuous-time flow described by an ordinary differential equation (ODE) and then interpret the discrete time steps as the result of a numerical integration of that ODE. This is the approach taken by the Ffjord algorithm [271] and other variants.

A different approach creating a deep generative model with a tractable likelihood is to model $p(x)$ autoregressively as

$$p(x) = \prod_{i=1}^{n} p(x_i|x_1, x_2, \ldots, x_{i-1}) \ . \tag{41.64}$$

This form describes each new dimension conditionally on all previous dimensions. It can model a general likelihood $p(x)$ as a sequence of conditional 1d distributions, whose conditional dependence on the parameters $x_1, x_2, \ldots, x_{i-1}$ can be modeled with neural networks. If x is a time series this form imposes a causal structure where x_i depends on all previous times x_j, $j < i$. WaveNet [272] and PixelCNN [273]) are two well known examples. Sampling from an autoregressive model is sequential, and can be slow in high dimensions. Inverse autoregressive flow reverses this process and makes sampling fast, but the likelihood evaluation is slow. Some normalizing flows have autoregressive coupling layers, such as Masked Autoregressive Flow (MAF) [269].

All of the methods above use maximum likelihood training of likelihood $p(x)$ against network parameters, so the training is to minimize KL divergence between the data distribution and a Gaussian in latent space. This can be overly sensitive to small variance directions that dominate the likelihood, without being sensitive to the global structure of the data. An alternative is to use Optimal Transport Wasserstein distance between the density of the generated samples and the data, which can be evaluated either in data space or in latent space. As Wasserstein distance is difficult to evaluate in high dimensions, one can instead use slices, 1d projections of the data along different directions in high dimensional space, to build the flow [45]. Along each slice direction one obtains the 1d marginal distribution that can be mapped to a Normal distribution using a cumulative distribution function method. In 1d the Jacobian and the inverse transformation are tractable. The projection directions are chosen to maximize the sliced 1d Wasserstein distance between the data and the distribution generated by the samples, or between the inverse flow from the data to the latent space and the target distribution (typically chosen as the Normal distribution). Because this training is less sensitive to small variance directions than maximum likelihood training it achieves better results on anomaly detection tasks [45].

One can reduce the architectural restrictions imposed by normalizing flows or autoregressive models by modeling the "score" $\nabla_x \log p(x)$ instead of $p(x)$. Note this usage of the term "score" is non-standard and goes back to Ref. [274]; the standard use of the term score is theta of Eq. 41.26. Score-based training avoids the normalization requirement. Score based models learn gradients of log probability density functions on a large number of

noise-perturbed data distributions, and then generate samples by Langevin-type sampling. The resulting generative models, called score-based generative models [275] or diffusion probabilistic models [276], have several advantages over existing model families. They achieve GAN-level sample quality without adversarial training, and enable exact log-likelihood computation through their connection to continuous-time flows, which can be represented as a probability flow ordinary differential equation [276]. The main advantage is that the distribution $p(x)$ can be specified solely by its gradient, which can subsequently be sampled from using Langevin dynamics. This is similar to the gradient based Monte Carlo Markov Chain methods (such as Langevin or Hamiltonian Monte Carlo) that sample from Bayesian posteriors without directly estimating the normalizing constant. This in turn enables more flexible model architectures than what can be used in normalizing flows or autoregressive models.

We end by noting that normalizing flows, autoregressive models, and other deep generative models that provide a tractable likelihood are incredibly powerful tools for simulation-based inference. They can provide surrogate models trained from large simulated datasets when the simulators have intractable likelihood functions, which is usually the case. As described in Sec. 41.3.5, one would like to work with models that can provide conditional density estimation in order to model either the likelihood $p(x|\theta)$ or the posterior $p(\theta|x)$ [56, 57]. These techniques are being actively explored and applied to a number of scientific problems.

41.6 Learning algorithms

41.6.1 *Gradient-based optimization*

Given a parameterized model $f(x, \theta)$ and a loss function $\mathcal{L}(x, \theta)$, where x and θ denotes data and model parameters, one way to optimize θ is to first apply an appropriate initialization, $\theta_{t=0}$ (e.g. Sec. 41.6.7 for neural networks), and perform an iterative update:

$$\theta_t = \theta_{t-1} - \lambda \nabla_\theta \mathcal{L}(x, \theta), \tag{41.65}$$

where λ is a small, real valued hyperparameter called *learning rate*. To see how this works, define $\delta\theta \equiv \theta_t - \theta_{t-1}$ and consider $\delta(\nabla_\theta \mathcal{L}(x, \theta))$:

$$\delta\left(\nabla_\theta \mathcal{L}(x, \theta)\right) \approx \delta\theta \cdot \nabla_\theta \mathcal{L}(x, \theta) = -\lambda |\nabla_\theta \mathcal{L}(x, \theta)|^2 \tag{41.66}$$

which would monotonically decrease the loss function, and locally move the parameter values in the desired direction of loss function minimization. This algorithm is called *Gradient Descent* . We note that λ needs to be sufficiently small for the approximation to hold. When λ is too large, this can be a cause of a gradient explosion discussed in Sec. 41.6.7.

41.6.2 *Stochastic gradient descent*

Stochastic Gradient Descent (SGD) follows GD but replaces the exact gradient term $\nabla_\theta \mathcal{L}(x, \theta)$ with a stochastic approximation, where we subsample the data in the loss function using N samples, where $N < n$,

$$\nabla_\theta \mathbb{E}_{\hat{p}(x)} \mathcal{L} \approx \frac{1}{N} \sum_i^N \nabla_\theta \mathcal{L}_i, \tag{41.67}$$

where $\mathcal{L}_i$ is the loss function for data sample i. It should be noted that N needs to be randomly and independently sampled for the approximation to hold. Implementation of SGD follows three steps: take new samples of size N, approximate the gradient, then update the parameters θ.

In the case of optimizing the loss using a static database (*i.e.* one cannot take new N samples for every update), *mini-batch learning* is often employed. This replaces the first step with a randomly sampled *batch* of data, which is a subset of all the samples in the database. In this case, however, since a batch of data used for each parameter update is not entirely independent, a model may overfit. In practice, a part of the whole dataset is reserved as a *validation* sample, and the model performance is carefully monitored during the optimization process to avoid overfitting via an early stopping criterion (see Sec. 41.6.6 and Fig. 41.11).

SGD with slowly decreasing learning rate can be shown to converge to a local minimum almost surely under mild conditions, and to a global minimum for unimodal loss functions. SGD may also prevent getting stuck in shallow local minima of the loss function, thereby reaching a better local minimum for multi-modal loss functions. The noise in SGD with a constant learning rate can be viewed as a form of Langevin dynamics, which under proper conditions on the learning rate and mini-batch size converges to the stationary posterior distribution of the weights [277]. Thus SGD at a constant learning rate can be viewed as a sampler bouncing around and exploring the posterior surface for better solutions, descending onto the best found solution as the learning rate is decreased, a process related to temperature annealing in global optimization.

Another advantage of SGD is simply the computational cost: rather than evaluating the loss over all the data samples at each update, we use a small subset of data instead at each update. Furthermore, mini-batching can take advantage of vectorization libraries and GPU architectures. Large batch training requires specialized methods of training, such as Layer-wise Adaptivee Rate Scaling (LARS).

41.6.3 *Optimization algorithms*

GD and SGD are the basic building blocks for more advanced optimization algorithms. One can improve the convergence rate of gradient based optimization by considering the learning rate λ to depend on individual θ_i. Second order algorithms such as Newton's method take into account second order derivatives (Hessian) to find the minimum, and give an exact solution in a single update when the loss is quadratic around the peak. However, this requires a matrix inversion of the Hessian, which is exceedingly expensive in ML applications, where the number of network parameters is very large. As a consequence, second order optimization is rarely used in ML.

There are several improvements to the basic SGD even in the absence of Hessian information. Momentum based optimization takes a physics perspective of a viscous fluid in an external potential, where one updates current velocity with the potential gradient (force), followed by an update in position based on velocity. This approach therefore uses previous gradients in addition to the current one to compute a running average of the gradient, with a forgetting factor that controls how far back the averaging goes. This helps move faster towards the minimum in ravines, where gradient descent is usually inefficient due to the high condition number of the Hessian.

One way to make the learning rate dependent on θ_i is to consider the gradient norm squared $(\nabla_{\theta_i} \mathcal{L})^2$. RMSprop learns its running average and then reduces the learning rate in directions with a large average gradient norm squared, thereby reducing the oscillations along that direction. ADAM (Adaptive Moment Estimation) combines the momentum and gradient norm ideas, computing running averages of both the gradient and the gradient norm squared, each with its own forgetting factor [278].

41.6.4 *Automatic differentiation and back propagation*

In practice, $f(x, \theta)$ might take a complex form and may include a large set of parameters. The term $\nabla_\theta \mathcal{L} = \nabla_\theta \mathcal{L}(f(x, \theta))$ requires computing partial derivatives with respect to individual parameter θ_i. If f is a composite model (i.e. $f = f_n(f_{n-1}(\cdots, \theta_{n-1}), \theta_n)$), and if all of $f_{i:1,n}$ are differentiable, a chain rule can be applied:

$$\nabla_{\theta_i} \mathcal{L} = \frac{\partial \mathcal{L}(f(x, \theta))}{\partial \theta_i} = \frac{\partial \mathcal{L}}{\partial x_n} \cdot \frac{\partial x_n}{\partial x_{n-1}} \cdots \frac{\partial x_i}{\partial \theta_i} \tag{41.68}$$

where x_n denotes the output of n-th composite function f_n. In order to compute $\nabla_{\theta_i} \mathcal{L}$ for f_i, it needs computation of a gradient at all preceeding (or subsequent if seen in the forward context) functions. As the gradients accumulate across differentiable functions in the reverse order of the model composition, this technique is called *back propagation* [225]. An example of f that satisfies conditions to apply back propagation is a neural network, which consists of repeating blocks of a (differentiable) activation function and an affine transformation.

When the model $f(x, \theta)$ is implemented as a computer program in practice, *automatic differentiation* (AD), also called *algorithmic differentiation*, is used to compute the derivatives. AD ex-

ploits the fact that any computer program consists of a sequence of elementary arithmetic operations (i.e. addition, subtraction, multiplication, division) and functions (e.g. log, exp, sin, cos) and apply chain rules to compute the target derivative. AD has advantages over traditional approaches including symbolic and numerical differentiation. The symbolic differentiation faces a serious difficulty of converting a program into a single expression, and the numerical differentiation suffers from round-off errors. Finally, both methods scale poorly in speed of computation for calculating partial derivatives with a large number of inputs. AD delivers much faster speed and does not suffer from increasing errors for calculating higher derivatives.

There are two modes of AD: the *forward* and *backward* mode. Consider a composite function $f(x,\theta) = f_n(f_{n-1}(\cdots f_1(x,\theta_1)\cdots),\theta_{n-1}),\theta_n)$. The forward mode applies the chain rule in the same order of the forward evaluation of f by computing $\partial f_1/\partial x$ first, then $\partial f_2/\partial f_1$, and continue to $\partial f_n/\partial f_{n-1}$. The backward mode traverses the reverse direction: starting from the last (outer-most) function $\partial f_n/\partial f_{n-1}$, next $\partial f_{n-1}/\partial f_{n-2}$, and continue to $\partial f_1/\partial x$. Therefore, the back propagation of gradients can be implemented using the backward AD, in which the target variable to be differentiated is fixed and the derivative is computed with respect to each sub-expression recursively as shown in Eq. 41.68. The forward mode is simpler to implement as the order of gradient calculation follows the order of composite functions to be executed. The reverse mode typically requires less amount of computation than the forward mode, but more memory is required to store intermediate function output values to calculate derivatives efficiently. Another consideration is the mapping of dimensionality $f : \mathbb{R}^k \to \mathbb{R}^\ell$ as it concerns the number of variables to sweep from each end. The forward mode is efficient when $k << \ell$ while the reverse mode takes an advantage if $\ell << k$. For instance, in the case of an image classification where $(k,\ell) = (\text{pixel count}, 1)$, the reverse AD is more efficient.

41.6.5 *The vanishing and exploding gradient problems*

Gradient based optimization crucially depends on the size of gradient with respect to each model parameter. If the magnitude of gradient is too large with respect to the distance to an optimal parameter value, it may repeatedly overshoot the target and cause an oscillation preventing convergence. If the gradient is too small, it may take an impractically long time to converge. As shown in Eq. 41.68, the gradient of i-th function f_i is a product of gradients from the subsequent functions. If those gradients are too large or too small, the magnitude can can either increase or decrease exponentially in the number of layers. These are called *exploding* and *vanishing* gradient problem respectively.

Modern deep neural networks consist with many composite functions (i.e. layers) and are particularly prone to this effect. Let us consider a simple RNN. From Eq. 41.50, we can write the back-propagating gradient:

$$\frac{\partial h_t}{\partial h_{t-1}} = \text{diagonal}\left(f'\left(Wx_t + Vh_{t-1} + b1\right)\right) W \tag{41.69}$$

where f' denotes the derivative of an activation function. The gradient of the contribution to the loss $\mathcal{L}_i$ from the i-th element in the sequence with respect to the j-th hidden state h_j is therefore:

$$\frac{\partial \mathcal{L}_i}{\partial h_j} = \frac{\partial \mathcal{L}_i}{\partial h_i} V^{i-j} \prod_{j<t\leq i} \text{diagonal}\left(f'\left(Wx_t + Vh_{t-1} + b1\right)\right) \tag{41.70}$$

where we can see that V contributes multiplicatively with $i-j$ powers when $i-j>1$. This example is explored in depth for recurrent models [226, 227] but is common for all types of deep neural networks.

In practice, one may explicitly inspect the magnitude of gradients propagating across layers to ensure an effective optimization. One way to mitigate an exploding gradient is to set the maximum gradient value $\delta_{\max}$ as a model hyperparameter and *clip* any larger gradients δ where it appears in the back propagation:

$$\delta = \frac{\delta_{\max}}{\|\delta\|}\delta \text{if} \|\delta\| > \delta_{\max}. \tag{41.71}$$

This is called *gradient clipping* [227].

Alternatively, there are many architecture designs that are motivated by the vanishing and exploding gradient problem or which aim to help propagate gradients across many layers. These considerations drove the design of gated models like the LSTM and GRU for sequential data and also motivated the ReLU non-linearity. Other example architectural designs or components motivated by these considerations include identity mapping and skip connections used in ResNet, U-Net, and DenseNet, which allow gradients to flow across many layers.

Other factors contributing to vanishing and exploding gradient include initialization of model parameters and normalization of input data. These factors contribute in keeping the magnitude of activation, which also concerns the magnitude of gradient, within a reasonable range. A recommended practice for a gradient-based optimization of a neural network is to maintain the input values centered around zero and a similar level of covariance across the inputs (and the outputs that are the inputs to the next layer) [279]. These factors are discussed in the following.

41.6.6 *Early stopping*

Early stopping is a form of regularization used to avoid overfitting when an iterative method, such as gradient descent, is used as a learning algorithm. Imagine a plot of the training loss and test loss as a function of iterations (*i.e.* parameter updates). As learning proceeds, the training loss will generally decrease. However, the test loss will often decrease initially and then start to increase, which is the classic sign of overfitting as shown in Fig. 41.11. The basic idea of early stopping is simply to stop training before overfitting takes place. In some approaches to early stopping theoretical analysis of the learning problem provides a prescription for when to stop the training [280]; however, the most straight forward approaches use a held-out validation dataset to monitor the generalization performance [281].

41.6.7 *Initialization of model parameters*

An improper initialization can slow down the optimization process or even result in a loss of convergence. While $b^{(l)}$ is typically initialized to zero, $W^{(l)}$ values need to be stochastic to avoid identical updates during optimization. One way is to sample $W^{(l)}$ from a zero-centered Gaussian distribution with a small variance (e.g. 0.01) [282]. However, this method does not guarantee the same variance in the input to each layer, which depends on the size of the input layer, and makes it difficult to train a deep neural network [220]. The *Xavier* initialization takes this into account and sets the variance of a Gaussian distribution to be $\sigma^2 = 1/d^{(l-1)}$ assuming a symmetric activation function around zero, such as a logistic function or hyperbolic tangent [283]. The *He* initialization uses the variance $\sigma^2 = 0.5/d^{(l-1)}$, and is a simple extension of Xavier initialization for leaky, parametric, and standard ReLU activation [208].

41.6.8 *Input normalization*

Input data to a neural network is often pre-processed for the same goals discussed previously: values are shift to have the mean of zero and scaled to keep a similar covariance across features. Furthermore, a data may be transformed using techniques including PCA and whitening (sphering) to keep input features independent and uncorrelated from each other [279].

41.6.9 *Batch normalization*

Even with careful normalization of the input data and initialization of model parameters, the mean and covariance of the data representations in hidden layers will evolve during training and may pose challenges for learning for downstream layers. This is called an *internal covariate shift* [284] and may cause negative effects to an optimization process. Accordingly, techniques to explicitly normalize features in between hidden layers are often employed for a deep neural network. One of them is *Batch Normalization*, which shifts and scales the input to a hidden layer:

$$\tilde{u}^{(l)} = \gamma \frac{u^{(l)} - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}} + \beta \tag{41.72}$$

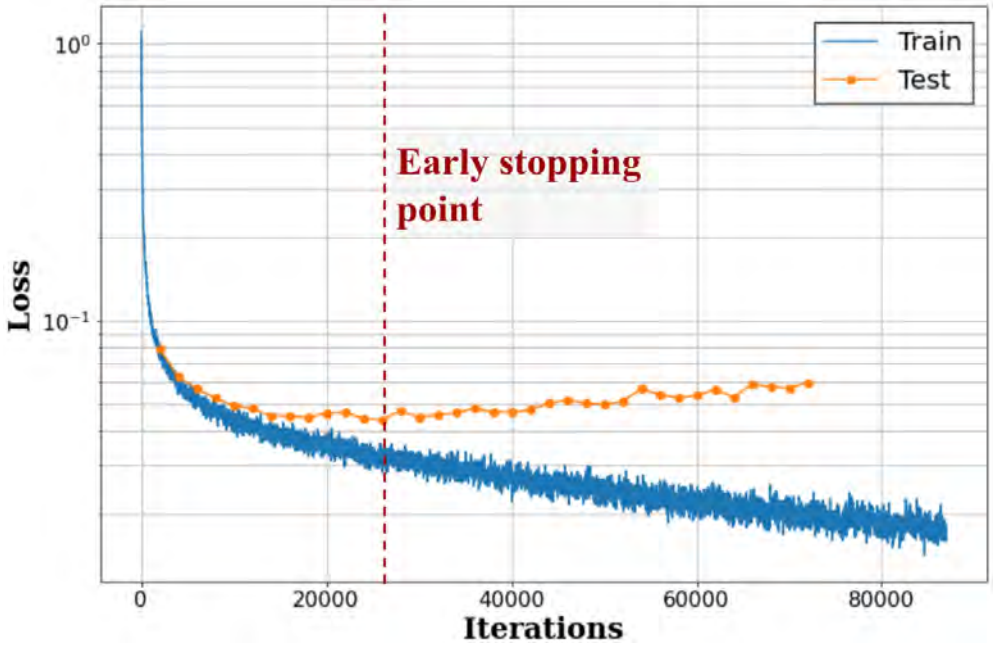

Figure 41.11: An example instance of overfitting. The training loss (vertical axis) shown in blue decreasing over iterations (horizontal axis) while the loss values evaluated on test samples shown in orange start to increase at around 26,000 iterations as indicated by the vertical line.

where $u^{(l)}$ and $\tilde{u}^{(l)}$ refer to the raw and normalized input to the l-th layer, μ_B and σ_B represent the mean and mean-squared-error of $u^{(l)}$ calculated using a *batch* of input data used to update the network parameters. γ and β are part of model parameters that are updated during the optimization. After optimization is complete, these parameters are fixed for model evaluation during production. ϵ is a small, fixed constant value to ensure numerical stability. While it is popular (especially in Computer Vision), a downside of BN is its dependency on the batch size. In situations where the batch size is limited to be a small number (e.g. memory limitation for a large data or a model), the performance using BN could degrade since β and γ values may not be generalized for the dataset during training.

There are several variants to batch normalization with considerations on how to group a subset of values in u^l. For instance, an image naturally has three groupings: a set of pixels across spatial axis, features within one pixel (i.e. image *channels*), alongside with a grouping across multiple images (i.e. batch). Different groupings have been studied and found and some are found effective to particular type of applications: Layer Normalization groups values along the channel and spatial dimensions [285], Instance Normalization groups along the spatial dimension but not along the batch nor channel [286], and Group Normalization is similar to Layer Normalization but forms multiple sub-groups of channels [287]. These variants does not apply normalization across samples within a batch, and thus agnostic to the batch size.

41.6.10 *Transfer learning: pre-training and fine-tuning*

Transfer learning is a technique to improve performance and accelerate optimization process by reusing a pre-trained machine learning model for a new task. Two tasks and data sets for each task may be different: the idea is that fundamental features may be reusable across different data and tasks. Transfer learning typically takes two steps: the first is to alter the model or data if necessary, then train (*fine-tuning*) the model. The first step is required, for example, when solving a different task that requires a different architecture (e.g. regression v.s. classification), or when input data format requires a change (e.g. original model trained on three channel image, such as RGB images, while new data has a single channel). Transfer learning has been widely practiced in the field of Computer Vision where large, labeled data sets are available [288–291]: a CNN trained for classifying images of an animal can be largely reused for object detection, or even for analyzing image data in science (e.g. particle trajectories recorded by an imaging detector). It is a critical aspect for the development of generic AI as well as interdisciplinary sharing of models across research fields.

For sequential models, transfer learning had been challenging before the appearance of Transformer. While Transformer was initially introduced for machine translation, Generative Pre-trained Transformer (GPT-1) showed that the model can be generalized to multiple NLP tasks by achieving the state-of-the-art in several seemingly different tasks including a sentence classification, semantic similarity, question answering and commonsense reasoning [292].

41.6.11 *Zero, one, and a few shot learning*

Fine-tuning (and thus transfer learning) may not be necessary if model is well generalized: humans can picture an imaginary animal in mind just from descriptions, or perform a task that he or she has never done before. One-shot learning is an extreme case of transfer learning where only one example is presented at the fine-tuning stage [293]. A similar variant is called a few-shot learning (fine-tuning using a few examples). This is possible only if the model has already learned the solution during the pre-training and the example is used to map the solution to the task. Zero-shot [294–296] learning is even more extreme where the model is given a new task without any example. This is only possible if the task is already learned during the pre-training in an implicit or unsupervised manner since zero-shot training implies that the model was never trained for the task.

41.7 Incorporating uncertainty

A fundamental aspect of data analysis is the quantification of uncertainty. This broad topic includes the traditional distinction between statistical and systematic uncertainty, procedures for propagation of errors, and the incorporation of uncertainty in to the statistical models (*e.g.* with nuisance parameters) that are used in Bayesian or frequentist statistical procedures (see Sec. 40). Accounting for systematic uncertainty can be seen as a requirement, but ideally systematic uncertainties are also taken into account in the design of the analysis so as to mitigate their effect. The introduction of machine learning into the analysis pipeline

requires revisiting the techniques used for uncertainty quantification and exposes many fundamental issues that have nothing to do with the use of machine learning per se. See Ref. [297] for a recent review on this topic.

In machine learning research and industrial settings, the mismatch between the data distribution $p_{\text{train}}(x, y)$ used for training and the data distribution $p_{\text{prod}}(x, y)$ that the model will be applied to in production is referred to as *covariate shift* or *domain shift*. For example, one might train a classifier to identify cats and dogs with images from a well lit studio and then apply the classifier on images taken in doors with poor lighting conditions and a scratched lens. Not surprisingly, the mis-classification rate of the classifier will be different between the two settings.

Physicists are keenly aware that the simulations that we use to describe the data are not perfect, and this mismodelling corresponds to a large fraction of the of systematic uncertainties accounted for in published works. Since simulated data is often used to train machine learning models (*i.e.* $p_{\text{train}}(x, y)$), it is important to understand and account for how this mismodelling will influence results when applied to real data (*i.e.* $p_{\text{prod}}(x, y)$).

One of the primary approaches to incorporating this type uncertainty is to introduce nuisance parameters ν corresponding to the uncertain inputs to the simulation and to parameterize various types of perturbations (*e.g.* corrections to efficiencies, energy scales, *etc.*) in hopes that the resulting family of distributions $p(x|y, \nu)$ is flexible enough to encompass the true data distribution for class y. In this approach one does not have just two "domains" for the data (*i.e.* p_{train} and p_{prod}), but a continuous family of domains parameterized by the nuisance parameters ν.

With this framing in mind, there are several approaches to incorporating uncertainty into an analysis that includes ML-based components:

- **propagation of errors:** one works with a model $f(x)$ and simply characterizes how uncertainty in the data distribution propagate through the function to the down-stream task irrespective of how it was trained.
- **domain adaptation:** one incorporates knowledge of the distribution for domains (or the parameterized family of distributions $p(x|y, \nu)$) into the training procedure so that the performance of $f(x)$ for the down-stream task is robust or insensitive to the uncertainty in ν.
- **parameterized models:** instead of learning a single function of the data $f(x)$, one learns a family of functions $f(x; \nu)$ that is explicitly parameterized in terms of nuisance parameters and then accounts for the dependence on the nuisance parameters in the down-stream task.
- **data augmentation:** one trains a model $f(x)$ in the usual way using training dataset from multiple domains by sampling from some distribution over ν.

In this setting it is best to consider the trained model $f(x)$ or $f(x; \nu)$ to be a fixed function and decouple the variability associated to training or the choice of architecture. The fact that one could have chosen a different architecture or learning algorithm should be treated in the same way as other choices that are made in the data analysis pipeline. While it is reasonable to want down-stream inference and decisions to be robust to these choices, they are of a different nature than the uncertainty in the modelling of the data distribution. We return to this point in Sections 41.7.5 and 41.7.6.

41.7.1 *Propagation of errors*

In this Section we consider the common scenario in which one has used some machine learning technique to train a model $f(x)$ for classification or regression and wants to assess the sensitivity of the output of $f(x)$ to uncertainty in the input x. We regard the function $f(x)$ as fixed and we are not concerned with how the model was trained.

Propagating uncertainty through a ML-based model $f(x)$ is not fundamentally different than for any other function, and one can use the standard propagation of errors formula of Sec. 39.2.1. As always, it is important to recognize the limitations of the propagation of errors formula, which is accurate when the uncertainty on x is Gaussian and the function $f(x)$ is approximately linear within the region set by the uncertainty on x.

Similarly, classifiers are often used for particle identification or event selection. In that case, one is primarily interested in the efficiency ϵ to satisfy a cut on the classifier output. The efficiency depends on the distribution $p(x|y)$ through the equation $\epsilon_y = P(f(x) > f_{\text{cut}}|y) = \int H(f(x) - f_{\text{cut}})p(x|y)dx$, where H is the Heaviside step function and y is an index or label for the category of data that is being considered (*e.g.* signal or background, electron or jet, *etc.*). Thus, the question in this context is what is the uncertainty on the efficiency ϵ_y due to uncertainty in the distribution $p(x|y)$. In practice, the quantification of the uncertainty in the efficiency ϵ_y is usually based on either a calibration measurement on real data or estimated with simulated data. These procedures typically treat the classifier as a black-box, and thus nothing precludes using those procedures on a ML-based classifier. An early example of this approach for b-tagging can be found in Ref. [298].

In the case where simulation is used to estimate the efficiency ϵ_y and its uncertainty, one usually varies nuisance parameters ν associated to the simulation. One then uses simulated samples to approximate $\epsilon_y(\nu) = P(f(x) > f_{\text{cut}}|y, \nu) = \int H(f(x) - f_{\text{cut}})p(x|y, \nu)dx$. Again, the procedure for incorporating uncertainty isn't fundamentally different if the classifier $f(x)$ is based on machine learning or a hand-crafted observable.

41.7.2 *Domain adaptation*

While estimating the uncertainty for a ML-based model is not fundamentally different than any other hand-crafted observable used for regression or classification, the worry of many physicists is that by working with a high-dimensional set of features x that one is more susceptible to mismodelling of subtle correlations. This is a valid concern, and it should be appreciated that a great deal of prior knowledge and physical insight goes into the construction of hand-crafted observables so that they will be robust to the most uncertain aspects of data. However, much of this craft is based on heuristics that are difficult to systematize. Furthermore, one can only validate that such an observable is robust if one can explicitly evaluate the performance for a perturbed distribution. Thus in the settings where one can validate the robustness to a perturbed scenario ν_0, one must have access to $p(x|y, \nu_0)$.

One approach to formalize this type of robustness is to consider the dependence on the distribution of the output of the model $f(x)$ to the nuisance parameters. In statistics, if the distribution of f is independent of the nuisance parameters, then f is referred to as a *pivotal quantity*. This is a property that we can incorporate directly into the training procedure to target a particular notion of robustness. The authors of Ref. [299] introduced an adversarial approach (similar to what is used in the generative adversarial network of Sec. 41.5.4.2) to penalize a model during training if the distribution of the output varies with the nuisance parameters. To construct the training dataset $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$, one must sample y and ν according to some proposal distribution (similar to a prior, but only used for the creation of training dataset, not necessarily for statistical inference), corresponding to a joint distribution $p(x, y, \nu)$. Instead of minimizing the target loss $\mathcal{L}_f$ (*e.g.* cross-entropy, squared-error, *etc.*) with respect to the parameters ϕ_f that parameterize the model f, one trains with a minimax strategy that also includes an adversary q with parameters ϕ_r. The trained model is characterized by the saddle point

$$\hat{\phi}_f, \hat{\phi}_r = \arg\min_{\phi_f} \arg\max_{\phi_r} E_\lambda(\phi_f, \phi_r) \,, \tag{41.73}$$

where the value function E_λ includes the target loss as well as a regularization term associated to the adversary

$$E_\lambda(\phi_f, \phi_r) = \mathcal{L}_f(\phi_f) - \lambda \mathcal{L}_r(\phi_f, \phi_r) \,. \tag{41.74}$$

The constant λ is a hyperparameter, since generally there is a tradeoff between the two terms and only in special cases can the model that minimizes $\mathcal{L}_f$ also be a pivotal quantity. The regularization term

$$\mathcal{L}_r(\phi_f, \phi_r) = \mathbb{E}_{p(x,y,\nu)}[-\log q_{\phi_r}(\nu|f_{\phi_f}(x))] \tag{41.75}$$

is an example of conditional density estimation (see Sec. 41.3.2.1), where the model $q_{\phi_r}(\nu|f)$ is trying to predict the distribution of the nuisance parameter ν given the output of the model $f(x)$. This term is maximized when f is independent of ν. Earlier work had also used an adversarial technique for domain adaptation, but was limited to just two domains [300–302], while here ν parameterizes a continuous family of distributions and can have multiple components corresponding to different sources of uncertainty. Furthermore, the previous work aimed to make the distribution for a high-dimensional, intermediate representation of the data be invariant to the domain shift as opposed to just the final output $f(x)$.

One way of interpreting Eq. 41.73 is that the goal is to minimize a regularized loss function $\tilde{\mathcal{L}}(\phi_f) = \arg\max_{\phi_r} E_\lambda(\phi_f, \phi_r)$, where the optimization with respect to ϕ_r is not exposed. This motivates another approach in which the regularization is not achieved through a learned adversary, but by a measure of discrepancy between distributions that can be computed directly from samples. In particular, the authors of Ref. [303] proposed the use of *distance correlation* to avoid what can be a challenging min-max optimization problem.

In either case, the optimization of the hyperparameter λ is based on the downstream task. For example, in Ref. [299] considered the case where f was a signal vs. background binary classifier where the nuisance parameter ν was associated to uncertainty in the background model. The hyperparameter λ was then optimized to maximize the approximate median significance (AMS). Similarly, the authors of Refs. [304] and [303] considered new physics searches in the context of boosted jet tagging, where the hyperparameter controls the sculpting of the side-bands used for background estimation.

While these strategies modify the training procedure so that the sensitivity to the nuisance parameters is reduced, it does not typically eliminate it. As a result, one still needs to propagate the uncertainty in the data distribution through the learned model as described in the preceding section.

Note, this adversarial technique has also been employed in other settings where one would like to decorrelate the output of the classifier with an observed quantity so that it can be used for background estimation [304]. Widely used alternative approaches to decorrelation include uboost [305] and DDT [306]. Other examples of the domain adaptation and decorrelation use cases from the Living Review include [299, 303–318].

41.7.3 *Parameterized models*

An alternative to learning a model $f(x)$ that is pivotal — *i.e.* whose distribution is independent of the nuisance parameter ν — is to learn a family of models $f(x;\nu)$ that is parameterized in terms of the nuisance parameters. In general, there is a tradeoff between the two terms of Eq. 41.74 for a single model $f(x)$. In a parameterized model, $f(x;\nu)$ optimizes the performance of the model for every value of ν. Parameterized classifiers were first advocated in Ref. [58] in the context of simulation-based inference (see Sec. 41.7.7) and in Ref. [319] for new physics searches. It has also been applied to simulation-based inference for effective field theory parameters in Ref. [19] and Ref. [320] provides additional pedagogical examples.

The training of a parameterized model is similar to the standard procedure. For example, if one originally wanted to minimize the squared loss function $\mathcal{L}(y, f(x)) = (y - f(x))^2$ with training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$, then the corresponding training procedure for the parameterized model would be as follows. One would need to construct a training set $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$ as described in the preceeding section, construct a parameterized model $f(x;\nu)$ that takes as input the original feature vector x as well as the nuisance parameters ν, and then train using the same loss $\mathcal{L}(y, f(x;\nu)) = (y - f(x;\nu))^2$.

One complication of the parameterized approach is that it is no longer possible to evaluate the model on a dataset $\{x_i\}$ and pass on only $\{f_i\}$ for downstream analysis tasks since $f(x_i;\nu)$ still depends on ν. Instead, one delay evaluating the model to some down-stream stage when the dependence on ν would accounted for. For example, in the context of a likelihood based analysis where one is testing a hypothesis where the nuisance parameters take on a particular value ν_{test}, then one will consider the data distribution $p(x|\nu_{\text{test}})$, and at that point one would evaluate the model at the corresponding nuisance parameter value, *i.e.* $f(x;\nu_{\text{test}})$. Explicit examples are given in Refs. [19, 58, 297, 320]. While this may seem complicated, it actually corresponds to what is done in a typical likelihood-based fit when the statistical model has nuisance parameters; *i.e.* the likelihood-ratio corresponds to the model $f(x;\nu)$ as in Eq. 41.12.

41.7.4 *Data augmentation*

An intuitive approach to building in robustness to systematic effects that can lead to domain shift, is simply to augment the training dataset so that it includes examples corresponding to several values of the nuisance parameter or systematic variations. As before one can construct a dataset $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$, but instead of leveraging the information about ν_i, one simply discards this information. This corresponds to sampling from the marginal distribution $x_i, y_i \sim p(x,y) = \int d\nu p(x,y|\nu)p(\nu)$, and is often referred to as *smearing*. One can then use this smeared dataset for supervised learning in the traditional way. While it is possible that this approach will lead to improved robustness to systematic variations (*i.e.* generalization for ν other than the nominal value) than if systematic uncertainty weren't considered at all), this intuitive approach has several shortcomings. The approach does not yield a pivotal quantity as in the adversarial approach, so propagation of uncertainty through the network is still required. Moreover, there is no direct way to control the trade-off between independence from the nuisance parameter and the original target loss as in the adversarial approach. Finally, it can lead to significant performance loss compared to what is possible with the parameterized approach. These trade-offs were studied in Refs. [319, 320] with both pedagogical and physically-motivated examples.

41.7.5 *Aleatoric and epistemic uncertainty*

In the machine learning and risk assessment literature, uncertainty is often characterized in terms of *aleatoric* and *epistemic* uncertainty [321–324]. Familiarity with these terms is useful, but the distinction between the two can be ambiguous, the terms are not always consistently used, and they do not clearly map onto the concepts used physics.

For example, Ref. [323], states that "roughly speaking, aleatoric (aka statistical) uncertainty refers to the notion of randomness, that is, the variability in the outcome of an experiment which is due to inherently random effects", while "epistemic (aka systematic) uncertainty refers to uncertainty caused by a lack of knowledge (about the best model)". This seems clear enough, but in that same reference (and in Ref. [325]) the aleatoric uncertainty is considered irreducible, while the epistemic uncertainty could be reduced with additional information. This may seem backwards for many physicists since often in particle physics, we think of how uncertainties scale as we collect more data but keep the experimental design fixed. In that case, the statistical uncertainty will be reduced with time while the systematic uncertainty will remain constant[6]. There is no paradox here, it is simply a different point of view. The emphasis of the risk assessment community is not on collecting more data with the same experimental design, but collecting different types of data that will inform the models themselves. Clearly even for physicists, data from new experiments or calibration measurements could also reduce our systematic uncertainties. While there are exceptions in the literature, the bulk of it associates aleatoric uncertainty with the randomness of classical probability (*i.e.* the statistical uncertainty associated to repeating the same experiment many times) and epistemic uncertainty with our state of knowledge.

Perhaps a more important distinction between the perspective of physicists and machine learning researchers has to do with the use of the term "model" and what exactly is uncertain. In physics, the systematic and epistemic uncertainty is typically associated to our understanding of the underlying physics and "the model" usually refers to the physics model, detector model encapsulated

[6] Further complicating the relationship between the terms is that many experimental uncertainties that are characterized as systematic are actually statistical in nature as auxiliary measurements and control regions are used to constrain the corresponding nuisance parameters.

in a simulation. In contrast, for machine learning research, "the model" usually refers to the trained model $\hat{f} \in \mathcal{F}$ used as described in Section 41.2.1 (or the class of functions $\mathcal{F}$ itself). This makes sense if we recall that in the bulk of machine learning research, one has little insight into the process that generated the data (*e.g.* images of cats and dogs, natural language, *etc.*). In that sense, the epistemic uncertainty in machine learning is usually associated to uncertainty in the model parameters ϕ after training, which would be reduced if one could collect more training dataset (see Ref. [324] for this point of view).

In the literature on Uncertainty Quantification (UQ), which is more closely connected to physics given the role of computer simulations, the terminology is more fine grained and less ambiguous. That community uses the terms parameter uncertainty (*i.e.* nuisance parameters), structural uncertainty (*i.e.* mismodelling), algorithmic uncertainty (*i.e.* numerical uncertainty), experimental uncertainty (*i.e.* uncertainty from experimental resolution and statistical fluctuations), and interpolation uncertainty (*i.e.* uncertainty due to interpolating between different parameter values due to lack of computational resources).

41.7.6 *Model averaging and Bayesian machine learning*

The core of Bayesian machine learning is the model averaging view. Here one often takes a more ambitious view of learning than described in Sec. 41.2.1, which is framed mainly as function approximation. While in Sec. 41.2.1, the goal is to find a function that minimizes the risk, in Bayesian machine learning one explicitly builds a probability model $q_\phi(x, y)$ for the training dataset $\mathcal{D} = \{x_i, y_i\}_{i=1,\ldots,n}$. It is the same change in perspective that one has when one views the squared error loss function $\mathcal{L}_{MSE} = (y - f_\phi(x))^2$ as the log-likelihood for a probability model $y \sim N(f(x), \sigma)$. In addition, one assumes some prior on the model parameters $p(\phi)$, which is often a Gaussian distribution, and is analogous to Tikhonov regularization (see Sec. 41.3.1.2). With this view in mind, a single trained model $\hat{f} = f_{\hat{\phi}}$ is the MAP point estimate and the more complete Bayesian solution is the entire posterior distribution over the model parameters $p(\phi|\mathcal{D})$. With this view, it is clear how increasing the number of training examples n will lead to a reduction in uncertainty on ϕ. However, this notion of epistemic uncertainty has little to do with the notion of systematic uncertainty as the term is used by particle physicists.

Bayesian methods can be applied to non-probabilistic regression problems, in which case they can provide uncertainty quantification. Consider the case of regression in traditional (non-Bayesian) machine learning. The trained model $f_{\hat{\phi}}(x)$ is used to predict the target label y. For a fixed x, the model does not provide any notion of uncertainty on the prediction. One could propagate uncertainty on x through $f(x)$, but that is also not the desired quantity to characterize the intrinsic spread $p(y|x)$ in the data, which may exist even if x has negligible uncertainty. In contrast, Gaussian process regression (a Bayesian method) does provide a natural way to communicate the uncertainty on the prediction, which is possible because one first had to specify a prior on the mean and covariance of the Gaussian process.

In the context of Bayesian deep learning and Bayesian Neural Networks, one would place a prior on the weights and biases of the neural network $p(\phi)$ and then use one of the many emerging techniques to calculate the approximate posterior $p(\phi|\mathcal{D})$. However, we should recognize that we have little-to-no insight into the parameters of a deep neural network, so the prior on ϕ is hardly well-justified. Furthermore, just as in all Bayesian approaches, the prior is not invariant to reparametrizing the model: $\phi \to \eta(\phi)$. While it is difficult to justify the choice of the prior on the parameters (and, thus, the resulting posterior), the resulting model may perform well empirically. In such high-dimensional parameter spaces, the bias-variance tradeoff can be dramatic.

Bayesian model averaging (BMA) performs Bayesian average over the posterior $p(\phi|\mathcal{D})$. This can be applied to any quantity f_ϕ, such as a regression or classification prediction y. Suppose we can draw from the posterior $\phi \sim p(\phi|\mathcal{D})$. For each draw we can evaluate the predicted regression variable $y = f_\phi(x) + \epsilon$, where ϵ is some noise to account for uncertainty in the predictions. We can denote this process as a draw from $p(y|x, \phi)$, $y \sim p(y|x, \phi) = N(f_\phi(x), \sigma_\epsilon^2)$, where σ_ϵ^2 is the noise variance. The BMA then performs

$$p(y|x, \mathcal{D}) = \int d\phi p(\phi|\mathcal{D}) p(y|x, \phi). \tag{41.76}$$

In practice $p(y|x, \phi)$ is evaluated by drawing samples of y and ϕ, so the posterior is defined implicitly by the samples. For example, the mean prediction is obtained by averaging $f_\phi(x)$ over the samples of ϕ, and the covariance matrix is similarly evaluated by averaging the second moments over the samples of ϕ.

Ref. [326] provides a different perspective on BMA analyzed in what are referred to as the $\mathcal{M}$-open and $\mathcal{M}$-closed settings [326]. The $\mathcal{M}$-closed setting refers to the situation where the true data generating process is in the space of models, even if it is unknown to us. In contrast, the $\mathcal{M}$-open setting refers to when the true data generating process is not in model space (*i.e.* the model is mis-specified). Interestingly, in the $\mathcal{M}$-open case one can potentially do better than any one model in the model class by considering an average over the models, since averaging can create a new model that is not in the model class. BMA provides one such averaging, but other averages, which are not weighted by $p(\phi|\mathcal{D})$, can be a better choice. When the weights of each model are optimized against appropriate loss the resulting procedure is called stacking, which has been shown to be superior to BMA in the $\mathcal{M}$-open setting [326]. Ref. [327] performed experiments indicating that in some cases model averaging can also improve predictive uncertainty estimates under domain shifts.

Neural network model averaging beyond BMA comes in several different flavors. Two successful model averaging procedures are Monte Carlo dropout [328], which uses dropout ensembling, and deep ensembles [329], which use random initialization ensembling. These methods may not only be superior to BMA, they are also often significantly faster than BMA. Whether these model averages are an approximation to BMA, or an alternative to it, remains a debated topic, and both views have been advocated. BMA itself can be accelerated using approximate methods, such as stochastic Variational Inference with reparametrization trick [330].

41.7.7 *Connection to probabilistic machine learning*

We end this Section by reinforcing the connection between uncertainty quantification in traditional machine learning and the more probabilistic approaches to machine learning exemplified by simulation-based inference (see Sec 41.3.5) and deep generative models (see Sec. 41.5.4). In the standard approach to supervised learning (*e.g.* classification and regression) the model $f(x)$ provides a point estimate for y. Estimating an uncertainty on y goes a step further, but the complete picture would be to model the posterior distribution $p(y|x)$. Gaussian processes (see Sec. 41.5.1) are an example, but the form of the models is limited to Gaussian posteriors. In Sec 41.3.5 we discussed approaches to model $p(y|x)$ using conditional density estimation [51, 56, 57]. If we extend this task to include a family of distributions parameterized by some nuisance parameters ν, then the task is to model $p(y|x, \nu)$, which is structurally similar.

In the context of classification, the output is already probabilistic, and the interpretation of the resulting classifier is $\hat{f}_{MSE}(x) \approx p(y = 1|x)$ (see Eq. 41.10). Incorporating the dependence on the nuisance parameter, then connects to the likelihood-ratio trick (see Eq. 41.12), approaches to simulation-based inference that involve learning the likelihood-ratio, and the parameterized approaches described in Sec. 41.7.3.

If one pairs the training procedure for classification, regression, or density estimation used in the approaches above with model averaging techniques such as BMA, then it would be possible to incorporate both uncertainty associated to finite training dataset and the uncertainty associated to systematic uncertainties. However, as described in Sec. 41.7.5 and Sec. 41.7.1, it is not clear that in physics applications it is desirable to account for the variability associated to training when the more common practice is to regard the trained model $\hat{f}(x)$ as fixed.

While these probabilistic approaches to machine learning are attractive conceptually, it is known in the machine learning community that classifiers often are poorly calibrated and often overly

confident in their predictions. This is a problem even if one regards the trained model $\hat{f}(x)$ as fixed. Various approaches, including model averaging, are being pursued to improve the calibration of trained models, but the problem is unlikely to be eliminated entirely. Miscalibration can be verified by evaluating the true positive and false positive rates on held out data. This is common practice in experimental particle physics, where the output of a binary classifier is rarely taken at face value. Instead, the true and false positive rates are estimated with simulated data or control samples as described in Sec. 41.7.1. Furthermore, the true and false positives can be characterized as a function of the nuisance parameters. These procedures can be used to help calibrate parameterized models based on the likelihood-ratio trick (see Refs. [58, 320]). Unfortunately, calibration in the context of density estimation is more challenging. This connects to topics and challenges in anomaly detection (see Sec. 41.3.4).

41.8 Infrastructure for deployment in experiments

The software and computing needs of training a machine learning model are different than those encountered when it deployed for use. In machine learning jargon, the two stages are often referred to as *training* and *inference*, where inference might refer to making a prediction for y given x in a classification or regression problem. Sometimes this transition also involves using different programming languages for implementing the trained model from the ones used for training them. Modern machine learning frameworks support various serialization formats to exchange trained models. For instance, `ONNX` provides an open source format for many types of models and is is widely supported and can be found in many frameworks, tools, and hardware. This is important when integrating a trained model into the large software frameworks used by the large experiments.

While hardware acceleration with GPUs is important for efficiently training modern machine learning techniques, there are also advantages of hardware acceleration at inference time. This may include GPUs or Field Programmable Gate Arrays (FPGAs), and the Living Review includes many example works focusing on efficient inference for a given hardware architecture [81, 108, 331–340]. For applications where latency is a key concern (eg triggering at collider experiments), various accelerators have been investigated [167, 171, 341–355]. In addition, some solutions for deployment of ML models involve deployment in the cloud [356, 357].

42. Monte Carlo Techniques

Revised September 2021 by G. Cowan (RHUL).

Monte Carlo techniques are often the only practical way to evaluate difficult integrals or to sample random variables governed by complicated probability density functions. Here we describe an assortment of methods for sampling some commonly occurring probability density functions.

42.1 Sampling the uniform distribution

Most Monte Carlo sampling or integration techniques assume a "random number generator," which generates uniform statistically independent values on the half open interval $[0, 1)$; for reviews see, *e.g.*, Refs. [1, 2].

Uniform random number generators are available in software libraries such as CLHEP [3], and ROOT [4]. For example, in addition to a basic congruential generator `TRandom` (see below), ROOT provides three more sophisticated routines: `TRandom1` implements the RANLUX generator [5] based on the method by Lüscher, and allows the user to select different quality levels, trading off quality with speed; `TRandom2` is based on the maximally equidistributed combined Tausworthe generator by L'Ecuyer [6]; the `TRandom3` generator implements the Mersenne twister algorithm of Matsumoto and Nishimura [7]. All of the algorithms produce a periodic sequence of numbers, and to obtain effectively random values, one must not use more than a small subset of a single period. The Mersenne twister algorithm has an extremely long period of $2^{19937} - 1$. A recent review of high-quality random number generators can be found in Ref. [8].

The performance of the generators can be investigated with tests such as DIEHARD [9] or TestU01 [10]. Many commonly available congruential generators fail these tests and often have sequences (typically with periods less than 2^{32}), which can be easily exhausted on modern computers. A short period is a problem for the `TRandom` generator in ROOT, which, however, has the advantage that its state is stored in a single 32-bit word. The generators `TRandom1`, `TRandom2`, or `TRandom3` have much longer periods, with `TRandom3` being recommended by the ROOT authors as providing the best combination of speed and good random properties. For further information see, *e.g.*, Ref. [11].

42.2 Inverse transform method

If the desired probability density function is $f(x)$ on the range $-\infty < x < \infty$, its cumulative distribution function (expressing the probability that $x \leq a$) is given by Eq. (39.6). If a is chosen with probability density $f(a)$, then the integrated probability up to point a, $F(a)$, is itself a random variable which will occur with uniform probability density on $[0, 1]$. Suppose u is generated according to a uniformly distributed in $(0, 1)$. If x can take on any value, and ignoring the endpoints, we can then find a unique x chosen from the p.d.f. $f(x)$ for a given u if we set

$$u = F(x) \ , \tag{42.1}$$

provided we can find an inverse of F, defined by

$$x = F^{-1}(u) \ . \tag{42.2}$$

This method is shown in Fig. 42.1a. It is most convenient when one can calculate by hand the inverse function of the indefinite integral of f. This is the case for some common functions $f(x)$ such as $\exp(x)$, $(1 - x)^n$, and $1/(1 + x^2)$ (Cauchy or Breit-Wigner), although it does not necessarily produce the fastest generator. Standard libraries contain software to implement this method numerically, working from functions or histograms in one or more dimensions, *e.g.*, the UNU.RAN package [12], available in ROOT. For a discrete distribution, $F(x)$ will have a discontinuous jump of size $f(x_k)$ at each allowed $x_k, k = 1, 2, \cdots$. Choose u from a uniform distribution on (0,1) as before. Find x_k such that

$$F(x_{k-1}) < u \leq F(x_k) \equiv \text{Prob}\,(x \leq x_k) = \sum_{i=1}^{k} f(x_i) \ ; \tag{42.3}$$

then x_k is the value we seek (note: $F(x_0) \equiv 0$). This algorithm is illustrated in Fig. 42.1b.

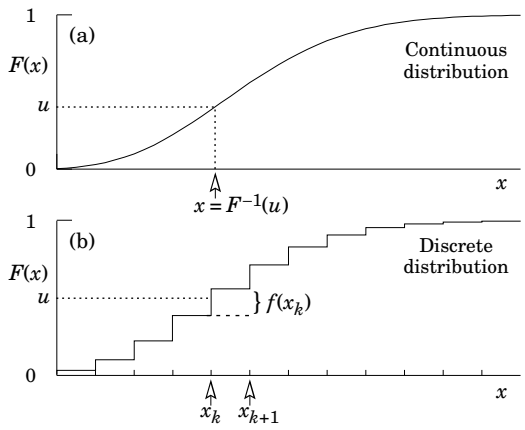

Figure 42.1: Use of a random number u chosen from a uniform distribution (0,1) to find a random number x from a distribution with cumulative distribution function $F(x)$.

42.3 Acceptance-rejection method (Von Neumann)

Very commonly an analytic form for $F(x)$ is unknown or too complex to work with, so that obtaining an inverse as in Eq. (42.2) is impractical. We suppose that for any given value of x, the probability density function $f(x)$ can be computed, and further that enough is known about $f(x)$ that we can enclose it entirely inside a shape which is C times an easily generated distribution $h(x)$, as illustrated in Fig. 42.2. That is, $Ch(x) \geq f(x)$ must hold for all x. Frequently $h(x)$ is uniform or is a normalized sum of uniform distributions. Note that both $f(x)$ and $h(x)$ must be normalized to unit area, and therefore, the proportionality constant $C > 1$. To generate $f(x)$, first generate a candidate x according to $h(x)$. Calculate $f(x)$ and the height of the envelope $C\,h(x)$; generate u and test if $uC\,h(x) \leq f(x)$. If so, accept x; if not reject x and try again. If we regard x and $uC\,h(x)$ as the abscissa and ordinate of a point in a two-dimensional plot, these points will populate the entire area $C\,h(x)$ in a smooth manner; then we accept those which fall under $f(x)$. The efficiency is the ratio of areas, which must equal $1/C$; therefore we must keep C as close as possible to 1.0. Therefore, we try to choose $C\,h(x)$ to be as close to $f(x)$ as convenience dictates, as in the lower part of Fig. 42.2.

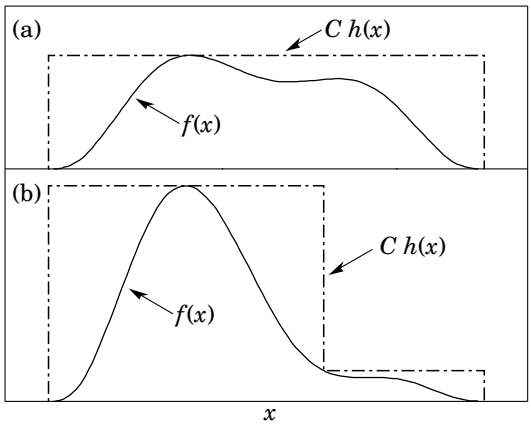

Figure 42.2: Illustration of the acceptance-rejection method. Random points are chosen inside the upper bounding figure, and rejected if the ordinate exceeds $f(x)$. The lower figure illustrates a method to increase the efficiency (see text).

42.4 Algorithms

Algorithms for generating random numbers belonging to many different distributions are given for example by Press [13], Ahrens and Dieter [14], Rubinstein [15], Devroye [16], Walck [17] and Gentle [18]. For many distributions, alternative algorithms exist, varying in complexity, speed, and accuracy. For time-critical applications, these algorithms may be coded in-line to remove the significant overhead often encountered in making function calls.

In the examples given below, we use the notation for the variables and parameters given in Table 39.1. Variables named "u" are assumed to be independent and uniform on [0,1). Denominators must be verified to be non-zero where relevant.

42.4.1 *Exponential decay*

This is a common application of the inverse transform method, and uses the fact that if u is uniformly distributed in $[0,1]$, then $(1-u)$ is as well. Consider an exponential p.d.f. $f(t) = (1/\tau)\exp(-t/\tau)$ that is truncated so as to lie between two values, a and b, and renormalized to unit area. To generate decay times t according to this p.d.f., first let $\alpha = \exp(-a/\tau)$ and $\beta = \exp(-b/\tau)$; then generate u and let

$$t = -\tau \ln(\beta + u(\alpha - \beta)). \tag{42.4}$$

For $(a,b) = (0,\infty)$, we have simply $t = -\tau \ln u$. (See also Sec. 42.4.6.)

42.4.2 *Isotropic direction in 3D*

Isotropy means the density is proportional to solid angle, the differential element of which is $d\Omega = d(\cos\theta)d\phi$. Hence $\cos\theta$ is uniform $(2u_1 - 1)$ and ϕ is uniform $(2\pi u_2)$. For alternative generation of $\sin\phi$ and $\cos\phi$, see the next subsection.

42.4.3 *Sine and cosine of random angle in 2D*

Generate u_1 and u_2. Then $v_1 = 2u_1 - 1$ is uniform on $(-1,1)$, and $v_2 = u_2$ is uniform on (0,1). Calculate $r^2 = v_1^2 + v_2^2$. If $r^2 > 1$, start over. Otherwise, the sine (S) and cosine (C) of a random angle (*i.e.*, uniformly distributed between zero and 2π) are given by

$$S = 2v_1v_2/r^2 \quad \text{and} \quad C = (v_1^2 - v_2^2)/r^2 \ . \tag{42.5}$$

42.4.4 *Gaussian distribution*

If u_1 and u_2 are uniform on (0,1), then

$$z_1 = \sin(2\pi u_1)\sqrt{-2\ln u_2} \quad \text{and} \quad z_2 = \cos(2\pi u_1)\sqrt{-2\ln u_2} \tag{42.6}$$

are independent and Gaussian distributed with mean 0 and $\sigma = 1$.

There are many variants of this basic algorithm, which may be faster. For example, construct $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$, which are uniform on $(-1,1)$. Calculate $r^2 = v_1^2 + v_2^2$, and if $r^2 > 1$ start over. If $r^2 < 1$, it is uniform on (0,1). Then

$$z_1 = v_1\sqrt{\frac{-2\ln r^2}{r^2}} \quad \text{and} \quad z_2 = v_2\sqrt{\frac{-2\ln r^2}{r^2}} \tag{42.7}$$

are independent numbers chosen from a normal distribution with mean 0 and variance 1. $z_i' = \mu + \sigma z_i$ distributes with mean μ and variance σ^2.

For a multivariate Gaussian with an $n \times n$ covariance matrix V, one can start by generating n independent Gaussian variables, $\{\eta_j\}$, with mean 0 and variance 1 as above. Then the new set $\{x_i\}$ is obtained as $x_i = \mu_i + \sum_j L_{ij}\eta_j$, where μ_i is the mean of x_i, and L_{ij} are the components of L, the unique lower triangular matrix that fulfils $V = LL^T$. The matrix L can be easily computed by the following recursive relation (Cholesky's method):

$$L_{jj} = \left(V_{jj} - \sum_{k=1}^{j-1} L_{jk}^2 \right)^{1/2} \ , \tag{42.8a}$$

$$L_{ij} = \frac{V_{ij} - \sum_{k=1}^{j-1} L_{ik}L_{jk}}{L_{jj}} \ , \ j = 1, ..., n \, ; \ i = j+1, ..., n, \tag{42.8b}$$

where $V_{ij} = \rho_{ij}\sigma_i\sigma_j$ are the components of V. For $n = 2$ one has

$$L = \begin{pmatrix} \sigma_1 & 0 \\ \rho\sigma_2 & \sqrt{1-\rho^2}\,\sigma_2 \end{pmatrix} \ , \tag{42.9}$$

and therefore the correlated Gaussian variables are generated as $x_1 = \mu_1 + \sigma_1\eta_1$, $x_2 = \mu_2 + \rho\sigma_2\eta_1 + \sqrt{1-\rho^2}\,\sigma_2\eta_2$.

42.4.5 $\chi^2(n)$ distribution

To generate a variable following the χ^2 distribution for n degrees of freedom, use the Gamma distribution with $k = n/2$ and $\lambda = 1/2$ using the method of Sec. 42.4.6.

42.4.6 *Gamma distribution*

All of the following algorithms are given for $\lambda = 1$. For $\lambda \neq 1$, divide the resulting random number x by λ.

- If $k = 1$ (the *exponential* distribution), accept $x = -\ln u$. (See also Sec. 42.4.1.)

- If $0 < k < 1$, initialize with $v_1 = (e+k)/e$ (with $e = 2.71828...$ being the natural log base). Generate u_1, u_2. Define $v_2 = v_1u_1$.

  Case 1: $v_2 \leq 1$. Define $x = v_2^{1/k}$. If $u_2 \leq e^{-x}$, accept x and stop, else restart by generating new u_1, u_2.

  Case 2: $v_2 > 1$. Define $x = -\ln([v_1 - v_2]/k)$. If $u_2 \leq x^{k-1}$, accept x and stop, else restart by generating new u_1, u_2. Note that, for $k < 1$, the probability density has a pole at $x = 0$, so that return values of zero due to underflow must be accepted or otherwise dealt with.

- Otherwise, if $k > 1$, initialize with $c = 3k - 0.75$. Generate u_1 and compute $v_1 = u_1(1-u_1)$ and $v_2 = (u_1 - 0.5)\sqrt{c/v_1}$. If $x = k + v_2 - 1 \leq 0$, go back and generate new u_1; otherwise generate u_2 and compute $v_3 = 64v_1^3u_2^2$. If $v_3 \leq 1 - 2v_2^2/x$ **or** if $\ln v_3 \leq 2\{[k-1]\ln[x/(k-1)] - v_2\}$, accept x and stop; otherwise go back and generate new u_1.

42.4.7 *Binomial distribution*

Begin with $k = 0$ and generate u uniform in $[0,1)$. Compute $P_k = (1-p)^n$ and store P_k into B. If $u \leq B$ accept $r_k = k$ and stop. Otherwise, increment k by one; compute the next P_k as $P_k \cdot (p/(1-p)) \cdot (n-k)/(k+1)$; add this to B. Again, if $u \leq B$, accept $r_k = k$ and stop, otherwise iterate until a value is accepted. If $p > 1/2$, it will be more efficient to generate r from $f(r; n, q)$, *i.e.*, with p and q interchanged, and then set $r_k = n - r$.

42.4.8 *Poisson distribution*

Iterate until a successful choice is made: Begin with $k = 1$ and set $A = 1$ to start. Generate u. Replace A with uA; if now $A < \exp(-\mu)$, where μ is the Poisson parameter, accept $n_k = k - 1$ and stop. Otherwise increment k by 1, generate a new u and repeat, always starting with the value of A left from the previous try.

Note that the Poisson generator used in ROOT's `TRandom` classes before version 5.12 (including the derived classes `TRandom1, TRandom2, TRandom3`) uses a Gaussian approximation when μ exceeds a given threshold. This may be satisfactory (and much faster) for some applications. To do this, generate z from a Gaussian with zero mean and unit standard deviation; then use $x = \max(0, [\mu + z\sqrt{\mu} + 0.5])$ where $[\,]$ signifies the greatest integer $\leq$ the expression. The routines from Numerical Recipes [13] and CLHEP's routine `RandPoisson` do not make this approximation (see, *e.g.*, Ref. [11]).

42.4.9 *Student's t distribution*

Generate u_1 and u_2 uniform in $(0,1)$; then $t = \sin(2\pi u_1)[n(u_2^{-2/n} - 1)]^{1/2}$ follows the Student's t distribution for $n > 0$ degrees of freedom (n not necessarily an integer).

Alternatively, generate x from a Gaussian with mean 0 and $\sigma^2 = 1$ according to the method of 42.4.4. Next generate y,

an independent gamma random variate, according to 42.4.6 with $\lambda = 1/2$ and $k = n/2$. Then $z = x/\sqrt{y/n}$ is distributed as a t with n degrees of freedom.

For the special case $n = 1$, the Breit-Wigner distribution, generate u_1 and u_2; set $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$. If $v_1^2 + v_2^2 \leq 1$ accept $z = v_1/v_2$ as a Breit-Wigner distribution with unit area, center at 0.0, and FWHM 2.0. Otherwise start over. For center M_0 and FWHM Γ, use $W = z\Gamma/2 + M_0$.

42.4.10 *Beta distribution*

The choice of an appropriate algorithm for generation of beta distributed random numbers depends on the values of the parameters α and β. For, *e.g.*, $\alpha = 1$, one can use the transformation method to find $x = 1 - u^{1/\beta}$, and similarly if $\beta = 1$ one has $x = u^{1/\alpha}$. For more general cases see, *e.g.*, Refs. [17, 18] and references therein.

42.5 Importance sampling and weighted Monte Carlo

Often the goal of a Monte Carlo calculation is to determine an expectation value of a function $h(x)$, where x is a (single or vector) random variable that follows a pdf $f(x)$,

$$E_f[h(x)] = \int h(x) f(x)\, dx \equiv \mu \,. \tag{42.10}$$

A Monte-Carlo estimator $\hat{\mu}_{\rm MC}$ for μ is the average of N values of $h(x)$ where x is sampled (generated) from $f(x)$, i.e., $\hat{\mu}_{\rm MC} = \frac{1}{N}\sum_{i=1}^{N} h(x_i)$. This has a variance

$$V[\hat{\mu}_{\rm MC}] = \frac{1}{N} V_f[h(x)] = \frac{1}{N}\left(E_f[h^2(x)] - \mu^2\right) \,. \tag{42.11}$$

By using the method of *importance sampling*, one can achieve a reduction in this variance and thus a more accurate determination of the expectation value for a given number of random values generated. The key idea is to rewrite the expectation value in Eq. (42.10) as

$$\mu = \int h(x) f(x)\, dx = \int \frac{h(x) f(x)}{g(x)}\, g(x)\, dx = E_g\left[\frac{h(x) f(x)}{g(x)}\right] \,, \tag{42.12}$$

where $g(x)$ is any other pdf of x with the same support as $f(x)$ (i.e., nonzero for the same region of x). Thus the desired quantity μ is the expectation value with respect to g of $h(x)f(x)/g(x)$. It can be estimated by generating N values of x sampled from g and computing

$$\hat{\mu}_{\rm IS} = \frac{1}{N}\sum_{i=1}^{N} \frac{h(x_i) f(x_i)}{g(x_i)} \,. \tag{42.13}$$

The variance of $\hat{\mu}_{\rm IS}$ is given by

$$V[\hat{\mu}_{\rm IS}] = \frac{1}{N} V_g\left[\frac{h(x) f(x)}{g(x)}\right] = \frac{1}{N}\left(E_g\left[\frac{h^2(x) f^2(x)}{g^2(x)}\right] - \mu^2\right) \,, \tag{42.14}$$

By choosing $g(x)$ such that $h(x)f(x)/g(x)$ is as constant as possible, the variance of $\hat{\mu}_{\rm IS}$ can be substantially reduced. One can show (see, e.g., Refs. [19,20]) that the variance is minimized when $g(x) \propto |h(x)|f(x)$.

An alternative importance sampling estimator can be constructed by replacing the number of generated values N in Eq. (42.13) by the sum $\sum_{i=1}^{N} f(x_i)/g(x_i)$. This can given an even smaller variance at the price of a small bias. It can be of further advantage in problems where the pdf $f(x)$ is known only up to a normalization constant, which then cancels (see Refs. [19, 20]).

A closely related application of importance sampling is the use of weighted Monte Carlo to compute the probability $P_f(x \in A)$ for x to be in a specified region A:

$$P_f(x \in A) = \int_A f(x)\, dx \,. \tag{42.15}$$

It may be, however, that one does not have an MC model capable of generating $x \sim f(x)$, but rather one can generate x according to a different density $g(x)$. The probability $P_f(x \in A)$ can be written

$$\begin{aligned} P_f(x \in A) &= \frac{\int_A \frac{f(x)}{g(x)}\, g(x)\, dx}{\int_A g(x)\, dx} \int_A g(x)\, dx \\ &= E_g[w(x) | x \in A]\, P_g(x \in A) \,, \end{aligned} \tag{42.16}$$

where $w(x) = f(x)/g(x)$ is the *weight function* and $P_g(x \in A) = \int_A g(x)\, dx$ is the probability to find $x \in A$ assuming $x \sim g(x)$. That is, $P_f(x \in A)$ is the conditional expectation value of $w(x)$ with respect to $g(x)$ given $x \in A$ multiplied by the probability to find $x \in A$ under assumption of $g(x)$.

Suppose N values of x are generated according to $g(x)$ and m of them are found in the region A. Then the probability to be in A for $x \sim g(x)$ can be estimated by m/N, and the expectation value above can be obtained from the average of the weights in A. Therefore the desired probability $P_f(x \in A)$ can be estimated using

$$\hat{P}_f(x \in A) = \frac{1}{m}\sum_{i=1}^{m} w_i \times \frac{m}{N} = \frac{1}{N}\sum_{i=1}^{m} w_i \,, \tag{42.17}$$

where $w_i = w(x_i)$ and the sum includes only the m values of x found in A. That is, when generating the x values according to $g(x)$ instead of $f(x)$, the number of events m found in A is replaced by the corresponding sum of weights. The variance of $\hat{P}_f(x \in A)$ can be found from

$$\widehat{V}[\hat{P}_f(x \in A)] = \frac{1}{N^2}\sum_{i=1}^{m} w_i^2 \,. \tag{42.18}$$

By choosing $g(x)$ so that a larger fraction of x values are sampled in the "important" region A, one can reduce the variance of the estimated probability for a given total number of generated values.

42.6 Markov Chain Monte Carlo

In applications involving generation of random numbers following a multivariate distribution with a high number of dimensions, the transformation method may not be possible and the acceptance-rejection technique may have too low of an efficiency to be practical. If it is not required to have independent random values, but only that they follow a certain distribution, then Markov Chain Monte Carlo (MCMC) methods can be used. In depth treatments of MCMC can be found, *e.g.*, in the texts by Robert and Casella [19], Liu [20], and the review by Neal [21]. HEP-oriented software for MCMC is available from the Bayesian Analysis Toolkit (BAT) [22, 23].

MCMC is particularly useful in connection with Bayesian statistics, where a p.d.f. $p(\boldsymbol{\theta})$ for an n-dimensional vector of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_n)$ is obtained, and one needs the marginal distribution of a subset of the components. Here one samples $\boldsymbol{\theta}$ from $p(\boldsymbol{\theta})$ and simply records the marginal distribution for the components of interest.

A simple and broadly applicable MCMC method is the Metropolis-Hastings algorithm, which allows one to generate multidimensional points $\boldsymbol{\theta}$ distributed according to a target p.d.f. that is proportional to a given function $p(\boldsymbol{\theta})$. It is not necessary to have

$p(\boldsymbol{\theta})$ normalized to unit area, which is useful in Bayesian statistics, as posterior probability densities are often determined only up to an unknown normalization constant.

To generate points that follow $p(\boldsymbol{\theta})$, one first needs a proposal p.d.f. $q(\boldsymbol{\theta};\boldsymbol{\theta}_0)$, which can be (almost) any p.d.f. from which independent random values $\boldsymbol{\theta}$ can be generated, and which contains as a parameter another point in the same space $\boldsymbol{\theta}_0$. For example, a multivariate Gaussian centered about $\boldsymbol{\theta}_0$ can be used. Beginning at an arbitrary starting point $\boldsymbol{\theta}_0$, the Hastings algorithm iterates the following steps:

1. Generate a value $\boldsymbol{\theta}$ using the proposal density $q(\boldsymbol{\theta};\boldsymbol{\theta}_0)$;
2. Form the Hastings test ratio, $\alpha = \min\left[1, \frac{p(\boldsymbol{\theta})q(\boldsymbol{\theta}_0;\boldsymbol{\theta})}{p(\boldsymbol{\theta}_0)q(\boldsymbol{\theta};\boldsymbol{\theta}_0)}\right]$;
3. Generate a value u uniformly distributed in $[0,1]$;
4. If $u \leq \alpha$, take $\boldsymbol{\theta}_1 = \boldsymbol{\theta}$. Otherwise, repeat the old point, *i.e.*, $\boldsymbol{\theta}_1 = \boldsymbol{\theta}_0$.
5. Set $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_1$ and return to step 1.

If one takes the proposal density to be symmetric in $\boldsymbol{\theta}$ and $\boldsymbol{\theta}_0$, then this is the *Metropolis*-Hastings algorithm, and the test ratio becomes $\alpha = \min[1, p(\boldsymbol{\theta})/p(\boldsymbol{\theta}_0)]$. That is, if the proposed $\boldsymbol{\theta}$ is at a value of probability higher than $\boldsymbol{\theta}_0$, the step is taken. If the proposed step is rejected, the old point is repeated.

Methods for assessing and optimizing the performance of the algorithm are discussed in, *e.g.*, Refs. [19–21]. One can, for example, examine the autocorrelation as a function of the lag k, *i.e.*, the correlation of a sampled point with that k steps removed. This should decrease as quickly as possible for increasing k.

Generally one chooses the proposal density so as to optimize some quality measure such as the autocorrelation. For certain problems it has been shown that one achieves optimal performance when the acceptance fraction, that is, the fraction of points with $u \leq \alpha$, is around 40%. This can be adjusted by varying the width of the proposal density. For example, one can use for the proposal p.d.f. a multivariate Gaussian with the same covariance matrix as that of the target p.d.f., but scaled by a constant.

43. Monte Carlo Event Generators

Revised July 2021 by P. Nason (INFN, Milano-Bicocca; Milano-Bicocca U.) and P. Skands (Monash U.).

General-purpose Monte Carlo (GPMC) generators like HERWIG [1–3], PYTHIA [4,5], and SHERPA [6], provide detailed simulations of high-energy collisions. They play an essential role in QCD modeling (in particular for aspects beyond fixed-order perturbative QCD) and in data analysis and the planning of new experiments, where they are used together with detector simulation to estimate signals and backgrounds in high-energy processes. They are built from several components, that describe the physics starting from very short distance scales, up to the typical scale of hadron formation and decay. Since QCD is weakly interacting at short distances (below a femtometer), the components of the GPMC dealing with short-distance physics are based upon perturbation theory. At larger distances, all soft hadronic phenomena, like hadronization and the formation of the underlying event in hadron collisions, cannot be computed from first principles at present, and one must rely upon QCD-inspired models.

The purpose of this review is to illustrate the main components of these generators. It is divided into four sections. The first one deals with short-distance, perturbative phenomena. The basic concepts leading to the simulations of the dominant QCD processes are illustrated here. In the second section, the nonperturbative transition from partons to hadrons ("hadronization") is treated. The two most popular hadronization models, the string and cluster models, are illustrated. The basics of the implementation of decay chains of unstable "primary" hadrons into stable "secondaries" is also illustrated here. In the third section, models for soft hadron physics are discussed. These include models for the underlying event and for low-$p_\perp$ ("minimum-bias") interactions. Issues of collective effects, such as Bose-Einstein and color-reconnection effects, are also discussed here. The fourth section briefly introduces the challenges of MC uncertainty estimates and tuning.

We use natural units throughout, such that $c = 1$ and $\hbar = 1$, with energies, momenta and masses measured in GeV, and times and distances measured in GeV^{-1}.

43.1 Short-distance physics in GPMC generators

The short-distance components of a GPMC generator deal with the computation of the primary process at hand, with decays of short-lived particles, and with the generation of QCD and QED radiation. QCD radiation is computable in perturbation theory as long as the time scales involved are well below $1/\Lambda$, where Λ is a typical hadronic scale of few hundred MeV. Because of the presence of logarithmic enhancements due to both collinear and soft emissions, this description involves an indefinite number of final-state particles that are emitted at time scales below $1/\Lambda$. In e^+e^- annihilation into hadrons, for example, the time scale of the primary process is of the order of the inverse of the annihilation energy Q. Collinear and soft emissions take place at all time scales between $1/Q$ and $1/\Lambda$, Technically, the computation of the dominant collinear and soft radiation is carried out by the so called shower algorithms. Historically, "Parton Shower" algorithms were first developed for resummation of collinear singularities. We will briefly describe this approach in this section. We stress, however, that many modern generators adopt approaches that focus initially upon soft singularities, leading to "Dipole Showers", discussed in Sec. 43.1.3.

Collinear singularities arise when the angle between two emitted light partons becomes small. For example, in a process in which a quark and a gluon are emitted, if the angle θ among them is very small (and is smaller than the angles among all other pairs of light partons in the process) the squared amplitude factorizes as follows

$$|M_{qg}|^2 \mathrm{d}\Phi_{qg} \approx |M_q|^2 \,\mathrm{d}\Phi_q \frac{\alpha_s}{2\pi} P_{q,qg}(z)\mathrm{d}z \frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}\theta^2}{\theta^2} \tag{43.1}$$

where M_{qg}, $\mathrm{d}\Phi_{qg}$ are the amplitude and phase space when both the gluon and the quark are emitted; M_q, $\mathrm{d}\Phi_q$ are the amplitude and phase space when only the quark is emitted; $z = E_q/(E_q+E_g)$ is the fraction of energy carried by the quark; ϕ is the azimuth of the splitting plane, and $P_{q,qg}(z) = C_F(1+z^2)/(1-z)$ is the Altarelli-Parisi splitting kernel for gluon emission from a quark line, with color factor $C_F = 4/3$. The factorized form of Eq. (43.1) is due to the fact that for small angle the process is dominated by a single amplitude in which the splitting quark is almost on shell and hence propagates for long distances. We define the energy scale corresponding to the inverse of this distance as the *hardness* of the splitting process, so that larger hardness corresponds to shorter distance. We can define the hardness t as the product $E^2\theta^2$, or as the virtuality of the splitting parton p^2, or as a measure of the relative transverse momentum in the splitting such as the k_t of an emitted parton relative to its parent, defined by

$$\begin{aligned} p^2 &= 2E^2 z(1-z)(1-\cos\theta) \approx z(1-z)E^2\theta^2\,, \\ k_t^2 &= z^2(1-z)^2E^2\theta^2\,. \end{aligned} \tag{43.2}$$

If the region of small values of z and $1-z$ was not important, these definitions would be equivalent. In QCD we also have soft divergences, arising when soft gluons are emitted. In Eq. (43.1) they appear as $z \to 1$, because of the $1/(1-z)$ singularity of $P_{q,qg}(z)$. Thus, we expect that the choice of the appropriate ordering variable will be relevant when dealing with soft divergences (see Sec. 43.3). The $\mathrm{d}\theta^2/\theta^2$ factor in Eq. (43.1) can be equivalently written in terms of the hardness $\mathrm{d}t/t$. After integration, it gives rise to a logarithmic factor $\log(Q^2/\Lambda^2)$. We can have many subsequent splittings, that we can describe by applying Eq. (43.1) recursively, as long as the splittings are strongly ordered in decreasing hardness. This means that, from a typical final-state configuration, by clustering together final-state parton pairs with the smallest hardness recursively, we can reconstruct a branching tree, that may be viewed as the splitting history of the event. We stress that all hardness values between the hardness of the primary process and the cutoff scale Λ are equally involved here. The collinear approximation is applied recursively to splitting processes that have much smaller hardness with respect to all previous ones.

By integrating over the phase space, a process with n collinear splittings will be of order $(\alpha_S(Q^2)\log(Q^2/\Lambda^2))^n$ with respect to the primary process. Since $\alpha_S(Q^2) \propto 1/\log(Q^2/\Lambda^2)$ [7], these corrections are not small. The so-called KLN theorem [8,9] guarantees that large logarithmic enhancements arising from final-state collinear splitting cancel against the virtual corrections in inclusive cross sections, order by order in perturbation theory. Furthermore, the factorization theorem guarantees that initial-state collinear singularities can be factorized into the parton density functions (PDFs) [7]. Therefore, the cross section for the basic process remains accurate up to corrections of higher orders in $\alpha_S(Q)$, provided it is interpreted as an inclusive cross section, rather than as a bare partonic cross section. For example, the leading order (LO) cross section for $e^+e^- \to q\bar{q}$ is a good LO estimate of the e^+e^- cross section for the production of a pair of quarks accompanied by an arbitrary number of collinear and soft gluons, but is not a good estimate of the cross section for the production of a $q\bar{q}$ pair with no extra radiation. In summary, perturbation theory at fixed order can yield increasingly accurate predictions for inclusive observables, but cannot be used to describe the indefinite sequence of collinear and soft radiations that accompany the hard partons.

Parton-Shower algorithms are used to compute the cross section for generic hard processes including all dominant collinear radiation. These algorithms begin with the generation of the kinematics of the basic process, performed with a probability proportional to its LO partonic cross section. This is interpreted physically as the inclusive cross section for the basic process, followed by an arbitrary sequence of shower splittings. The algorithm then assigns a probability to each splitting sequence, so that the initial LO cross section is partitioned into the cross sections for a multitude of final states of arbitrary multiplicity, with their sum equal to the cross section of the primary process. This property of the GPMCs reflects the KLN cancellation mentioned earlier, and it is often called "unitarity of the shower process", a name that reminds us that the KLN cancellation itself is a consequence

of unitarity. The fact that a quantum mechanical process can be described in terms of composition of probabilities, rather than amplitudes, follows from the collinear approximation. In fact, because of strong ordering, a radiated parton cannot be collinear to more than one parton in the amplitude, and this suppresses interference effects.

We now illustrate the basic parton-shower algorithm, as first introduced in Ref. [10]. (For more pedagogical introductions see Ref. [11] and references therein.) For simplicity, we consider the example of e^+e^- annihilation into $q\bar{q}$ pairs, where we only have to deal with final state radiation (FSR). We consider all final states that can be built by dressing the q and $\bar{q}$ partons with an indefinite number of splitting processes. By recursively clustering together final state parton pairs with the smallest relative hardness, from each final state configuration we can construct two trees rooted at the q and $\bar{q}$ partons. The momenta of all intermediate lines of the tree diagrams are then uniquely determined from the final-state momenta. Hardnesses in the trees are ordered. One assigns to each splitting vertex the hardness t, the energy fractions z and $1-z$ of the two generated partons, and the azimuth ϕ of the splitting process with respect to the momentum of the incoming parton. For definiteness, we assume that z and ϕ are defined in the center-of-mass (CM) frame of the e^+e^- collision. The differential cross section for a given final state is given by the product of the differential cross section for the initial $e^+e^- \to q\bar{q}$ process, multiplied by a factor

$$\Delta_i(t_m,t_n)\frac{\alpha_S(t)}{2\pi}P_{i,jk}(z)\frac{dt_m}{t_m}dz\frac{d\phi}{2\pi} \tag{43.3}$$

for each intermediate line arising from the n^{th} and ending in the m^{th} splitting vertex. $\Delta(t_m,t_n)$ is the so-called Sudakov form factor

$$\Delta_i(t_m,t_n)=\exp\left[-\int_{t_m}^{t_n}\frac{dq^2}{q^2}\,\frac{\alpha_S(q^2)}{2\pi}\sum_{jk}P_{i,jk}(z)dz\frac{d\phi}{2\pi}\right]. \tag{43.4}$$

The suffixes i and jk represent the parton species of the incoming and final partons, respectively, and $P_{i,jk}(z)$ are the Altarelli-Parisi [12] splitting kernels. Notice that the endpoints on the z integration depend upon the definition of hardness. For example, in case of virtuality or transverse momentum ordering, the z integration is automatically cut-off near the extremes, see eq. (1.2). When this is not the case (as, for example, for angular ordering) an explicit cut-off on z must be introduced, corresponding to the requirement that an emission must have some minimum energy to be distinguishable from no emission. For lines originating at the primary vertex, the scale t_n is replaced by the typical scale of the primary process and for lines ending without any further splitting the scale t_m is replaced by t_0, an infrared cutoff defined by the shower hadronization scale (at which the charges are screened by hadronization) or, for an unstable particle, its width (a source cannot emit radiation with a period exceeding its lifetime).

Eq. (43.3) can be obtained by iterating formula Eq. (43.1) recursively, with two important corrections: a) the strong coupling is evaluated at a scale corresponding to the hardness of the splitting process; b) the presence of the Sudakov form factor. Both these modifications arise from the inclusion of all collinear-dominant virtual corrections.

Notice that the Sudakov form factor for a small hardness interval $\Delta_i(t,t+\delta t)$ is equal to one minus the integrated emission probability of Eq. (43.3), i.e. it can be interpreted as the probability of no emission in the interval $t,t+\delta t$. From this, it immediately follows that $\Delta_i(t_m,t_n)$ can be interpreted as the no-emission probability in the full t_m,t_n interval. This interpretation allows to formulate the shower process as a probabilistic algorithm. We first notice that $0<\Delta_i(t_m,t_n)\leq 1$, where the upper extreme is reached for $t_m=t_n$, and the lower extreme is approached for $t_m=t_0$. Starting from each of the partons in the primary process (e.g., $e^+e^-\to q\bar{q}$), event generation then proceeds recursively as follows. Given a parton exiting a vertex with hardness t_n, (taken to be of order the annihilation scale Q^2 for the first branching) one seeks a solution of the equation $r=\Delta_i(t_m,t_n)$, with $r\in[0,1]$ a uniform random number, and solves it for the hardness of the next branching t_m. If $t_m\leq t_0$, no splitting is generated and the line is interpreted as a final parton. If $t_m>t_0$, a branching is generated at the scale t_m. Its z value and the final parton species jk are generated with a probability proportional to $P_{i,jk}(z)$. The azimuth is generated uniformly, neglecting angular correlations (see Sec. 43.1.1). This procedure is started with each of the primary process partons, and is applied recursively to all generated partons. It may generate an arbitrary number of partons, and it stops when no final-state partons undergo further splitting.

The four-momenta of the final-state partons are reconstructed from the momenta of the initial ones, and from the whole sequence of splitting variables, subject to overall momentum conservation. Different algorithms employ different strategies to treat recoil effects due to momentum conservation, which may be applied either locally for each splitting, or globally for the entire set of partons (a procedure called *momentum reshuffling*.) This has a subleading effect with respect to the collinear approximation.

We emphasize that the shower cross sections described above can be derived from perturbative QCD by keeping only the collinear-dominant real and virtual contributions to the cross section. As such it is unpredictive for large-angle radiation. It is thus unsafe to rely upon Parton Shower Monte Carlo alone to compute backgrounds to new physics signals that are characterized by several widely separated jets.

A Shower Monte Carlo builds its final state as if it developed from an iterative process, often with each intermediate stage made available to the user. It should be remarked that the meaning of these intermediate stages is only relevant within the approximation adopted by the generator, and could also differ in different implementations.

43.1.1 *Angular correlations*

In gluon-splitting processes ($g\to q\bar{q},\ g\to gg$) in the collinear approximation, the distribution of the split pair is not uniform in azimuth, and the Altarelli-Parisi splitting functions are recovered only after azimuthal averaging. This dependence is due to the interference of positive and negative helicity states for the gluon that undergoes splitting. Spin correlations propagate through the splitting process, and determine acausal correlations of the EPR kind [13]. A method to partially account for these effects was introduced in Ref. [14], in which the azimuthal correlation between two successive splittings is computed by averaging over polarizations. This can then be applied at each branching step. Acausal correlations are argued to be small, and are discarded with this method, that is still used in `PYTHIA` [4]. A method that fully includes spin correlation effects was later proposed [15], and has been implemented in `HERWIG` [3,16].

43.1.2 *Initial-state radiation*

Initial-state radiation (ISR) arises because incoming particles may undergo collinear radiation before entering the hard-scattering process. In doing so, they acquire a non-vanishing transverse momentum, and their virtuality becomes negative (spacelike). It turns out to be convenient to develop the ISR shower starting with the highest hardness (i.e. with the hard process) and ending with the smallest (i.e. with the incoming parton in the hadron). Unlike the case of FSR, however, hardness ordering is opposite to time ordering in the ISR case. A corresponding backwards-evolution algorithm was formulated by Sjöstrand [17], and was basically adopted in all shower models. It can be illustrated by considering a primary interaction initiated by a quark where no collinear emission of hardness $\geq t$ have taken place, and the same process where the quark also emits a collinear gluon of hardness t. The respective cross sections are proportional to

$$\begin{aligned}&|M_q(x)|^2\mathrm{d}x f_q(x,t),\quad\text{and}\\&|M_q(x)|^2\,\mathrm{d}x\frac{\alpha_s(t)}{2\pi}f_q(x/z,t)P_{q,qg}(z)\mathrm{d}z\frac{\mathrm{d}\mathrm{Œ}}{2\pi}\frac{\mathrm{d}t}{t}\,.\end{aligned} \tag{43.5}$$

Here f_q is the quark PDF in the incoming hadron, x is the fraction of momentum of the incoming quark that enters the basic process, while x/z is the fraction of momentum of the incoming quark *before* it emits the collinear gluon. The elementary *emission probability* is the ratio of the second over the first expression

in Eq. (43.5). In analogy with the final state radiation case, this ratio will appear in the exponent of the Sudakov form factor, that (after the inclusion of all splitting subprocesses) is given by

$$\Delta_i^{\mathrm{ISR}}(t,t') = \exp\left[-\int_{t'}^{t}\frac{dt''}{t''}\frac{\alpha_{\mathrm{S}}(t'')}{2\pi}\int_x^1\frac{dz}{z}\sum_{jk}P_{j,ik}(z)\frac{f_j(t'',x/z)}{f_i(t'',x)}\right]. \tag{43.6}$$

Notice that there are two uses of the PDFs: they are used to compute the cross section for the basic hard process, and they control ISR via backward evolution. Since the evolution is generated with leading-logarithmic accuracy, it is acceptable to use two different PDF sets for these two tasks, provided they agree at the LO level.

In the context of GPMC evolution, each ISR emission generates a finite amount of transverse momentum. Details on how the recoils generated by these transverse "kicks" are distributed among other partons in the event, in particular the ones involved in the hard process, constitute one of the main areas of difference between existing algorithms, see Ref. [11]. An additional $\mathcal{O}(1\,\mathrm{GeV})$ of "primordial k_T" is typically added, to represent the sum of unresolved and/or non-perturbative motion below the shower cutoff scale.

43.1.3 *Soft emissions and QCD coherence*

Soft singularities arise in QCD due to the real or virtual emission of soft gluons. For example, the cross section for the emission of a soft gluon in e^+e^- annihilation into hadrons is given by

$$\begin{aligned}\mathrm{d}\sigma_{q\bar{q}g} &\approx \mathrm{d}\sigma_{q\bar{q}}\frac{4}{3}(4\pi\alpha_s)\left[\frac{2\,p_q\cdot p_{\bar{q}}}{p_q\cdot l\;p_{\bar{q}}\cdot l}\right]\frac{\mathrm{d}^3 l}{2l^0(2\pi)^3}\\ &= \mathrm{d}\sigma_{q\bar{q}}\frac{\alpha_s}{2\pi}\frac{4}{3}\frac{\mathrm{d}l^0}{l^0}\frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}\cos\theta}{1-\cos^2\theta},\end{aligned} \tag{43.7}$$

where p_q, $p_{\bar{q}}$ and l are the quark, antiquark and gluon momentum, and θ and ϕ are the polar and azimuthal angle of the gluon momentum with respect to the quark direction. Since the gluon is soft, we may assume that p_q and $p_{\bar{q}}$ are unaffected by the gluon emission. The soft singularity is manifest in the $\mathrm{d}l^0/l^0$ factor. Notice that also collinear singularities are present at the same time when $\theta\to 0$ and $\theta\to\pi$, corresponding to the gluon becoming collinear to either the quark or the antiquark. It is easy to check that in the collinear limits Eq. (43.7) becomes equivalent to Eq. (43.1) with $P_{q,qg}(z) = (4/3)2/(1-z)$, i.e. the limiting form of $P_{q,qg}(z)$ when z approaches 1. Thus, soft singularities coexist with collinear ones, so that two potentially large logarithms can arise simultaneously due to gluon emission.

Unlike the case of collinear emission, soft emission is not tied to a single emitting particle. The amplitude for the emission of a soft gluon from an external (incoming or outgoing) line with momentum p is proportional to $p\cdot\epsilon/p\cdot l$. When squaring the amplitude, products like the one appearing in the square bracket of Eq. (43.1) arise for all pairs of external particles, with the product of a single emission amplitude with itself appearing only if $p^2>0$, i.e. for massive colored particles. Thus, interference plays here a crucial role. This is unlike the case of collinear singularities, where because of strong ordering a radiated parton cannot be collinear to more than one other parton.

It was shown in a set of publications (see Ref. [18]) that, within the conventional parton-shower formalism based on collinear factorization, the region of collinear and soft emissions can be correctly described by using the angle of the emissions as the ordering variable, rather than the virtuality, and by setting the argument of α_{S} at the splitting vertex equal to the relative parton transverse momentum after the splitting. Physically, the ordering in angle approximates the coherent interference arising from large-angle soft emission from a bunch of collinear partons. Without this effect, the particle multiplicity would grow too rapidly with energy, in conflict with e^+e^- data. For this reason, angular ordering is used as the default evolution variable in all versions of `HERWIG` (see Ref. [19]). To partially account for soft interference effects, an angular veto is imposed on the virtuality-ordered evolution in `PYTHIA` 6 [20].

A radical alternative formulation of QCD cascades first proposed in Ref. [21] focuses upon soft emission, rather than collinear emission, as the basic splitting mechanism. It then becomes natural to consider a branching process where it is a parton pair (i.e. a dipole) rather than a single parton, that emits a soft parton. Adding a suitable correction for non-soft, collinear partons, one can simultaneously achieve the correct logarithmic structure for both the collinear and soft emissions in the so called leading color approximation, i.e. when terms suppressed by a power of the number of colors are neglected. The `ARIADNE` [22] and `VINCIA` [23] programs are based on this approach. Dipole-type showers [24] are also used by default in `SHERPA` [25] and exist as an option in `HERWIG` [26]. An alternative dipole-based model is available in `PYTHIA` and `SHERPA` via the `DIRE` [27] plugin. The $p_\perp$-ordered showers in `PYTHIA` 6 and 8 represent a hybrid, combining collinear splitting kernels with dipole kinematics [28].

43.1.4 *Resummation*

Shower Monte Carlo generators perform resummation of all-order collinear- and/or soft-enhanced perturbative contributions, and it is thus natural to compare them to QCD resummation calculations [7]. The latter start from the definition of specific infrared-safe observables, that develop towers of large logarithms in certain regions of phase space, typically organized as

$$A(\alpha_{\mathrm{S}})\exp[Lg_0(\alpha_{\mathrm{S}}L)+g_1(\alpha_{\mathrm{S}}L)+g_2(\alpha_{\mathrm{S}}L)+\ldots] \tag{43.8}$$

where L is the large logarithm, α_{S} is the strong coupling constant evaluated at some hard scale, and the functions A and g_i have an all-order expansion in their arguments. We talk about $\mathrm{N}^n\mathrm{LL}$ accuracy if all g_i functions for $i\le n$ have been computed correctly in the resummation formula. In particular we talk about LL accuracy if the function g_0 is given correctly, NLL accuracy if g_2 is correct, and so on.

In general, a dedicated resummation calculation must be performed for each new observable. The predictions of shower MCs, on the other hand, are cast in terms of complete sets of final-state momenta, on which one can evaluate any observable; i.e., the shower algorithm itself is normally independent of the specific observable(s) under study. Because of this, it is not easy to qualifying the accuracy of a shower MC using the same criteria adopted in resummation calculation. In spite of this fact, shower MCs perform generally quite well in the description of observables that require resummation. This is related to their inclusion of several universal but formally subleading aspects. There is no guarantee, however, that the shower MC should perform to a certain level of accuracy for all distributions that require resummation. Thus, a more systematic treatment of subleading effects is quite desirable.

Several studies have appeared in the literature, aiming at either improving the current shower algorithms or formulate totally new ones, in such a way that the theoretical accuracy can be discussed in more precise terms [29–34]. In particular, in refs [29–31] (the PanScales collaboration), it was shown that criteria for defining the accuracy of Shower Generators can indeed be given on a quite general ground. They identified two such criteria: the first one regards the multi-parton real matrix-elements generated by the shower algorithm, that are required to be accurate in the region of phase space that are relevant for $\mathrm{N}^n\mathrm{LL}$ accuracy. The second one regards the implementation of the virtual corrections, and it requires that for a large class of shape variables the shower MC must agree with the resummed calculation at the $\mathrm{N}^n\mathrm{LL}$ level. The PanScale collaboration has also constructed shower algorithms that, at least in the leading color approximation, are NLL accurate according to these criteria.

43.1.5 *Massive quarks*

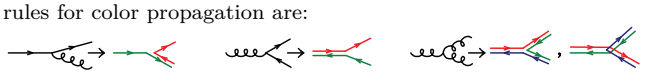
Quark masses act as a cut-off on collinear singularities. If the mass of a quark is below, or of the order of Λ, its effect in the shower is small. For larger quark masses, like in c, b, or t production, it is the mass, rather than the typical hadronic scale, that cuts off collinear radiation. For a quark with energy E and mass m_Q, the divergent behavior $d\theta/\theta$ of the collinear splitting process

is regulated for $\theta \leq \theta_0 = m_Q/E$. We thus expect less collinear activity for heavy quarks than for light ones, which in turn is the reason why heavy quarks carry a larger fraction of the momentum acquired in the hard production process.

This feature can be implemented with different levels of sophistication. Using the fact that soft emission exhibits a zero at zero emission angle, older parton shower algorithms simply limited the shower emission to be not smaller than the angle θ_0. More modern approaches are used in both `PYTHIA`, where mass effects are included using a kind of matrix-element correction method [35], and in `HERWIG++` and `SHERPA`, where a generalization of the Altarelli-Parisi splitting kernel is used for massive quarks [36].

43.1.6 *Color information*

In event generators, quarks and antiquarks are represented by color lines, with arrows indicating the direction of color flow. In the limit of infinitely many colors (called the leading color approximation), each such line can be associated with a unique label; the probability for two quarks (or antiquarks) to have the same color (anticolor) vanishes. Moreover, in the same limit gluons can be represented by a pair of color lines with opposite arrows, as can be realized e.g. from the SU(3) group relation $8 = 3 \otimes \bar{3} \ominus 1$. The rules for color propagation are:



During the shower development, partons are connected by color lines. We can have a quark directly connected by a color line to an antiquark, or via an arbitrary number of intermediate gluons, as shown in Fig. 43.1. It is also possible for a set of gluons to be connected cyclically in color, as e.g. in the decay $\Upsilon \to ggg$. The

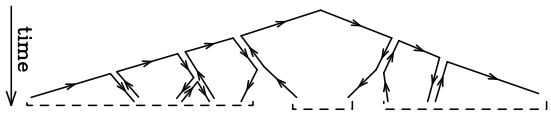


Figure 43.1: Color development of a shower in e^+e^- annihilation. Color-neutral clusters of partons are indicated by the dashed under-brackets.

color information is used in angular-ordered showers, where the angle of color-connected partons (i.e. partons connected by the same color line) determines the initial angle for the shower development, and in dipole showers, where dipoles are always color-connected partons. It is also used in hadronization models, where the initial strings or clusters used for hadronization are formed by color-neutral clusters of partons.

43.1.7 *Electromagnetic (and weak) corrections*

The physics of photon emission from charged particles, and of photon splittings to pairs of charged fermions, can also be treated with a shower MC algorithm. High-energy electrons and quarks, for example, are accompanied by bremsstrahlung photons. Also here, similarly to the QCD case, electromagnetic corrections are of order $\alpha_{\rm em} \ln(Q/m)$, where m is the mass of the radiating particle, or even of order $\alpha_{\rm em} \ln(Q/m) \ln(E_\gamma/E)$ for soft γ emissions, so that, especially for the case of electrons, their inclusion in the simulation process is mandatory. This is done in most GPMCs (for a comparative study see [37]), which typically agree in collinear (DGLAP) limits but differ in whether and how soft (multipole) QED interference effects are handled. The specialized generator PHOTOS [38] is sometimes used as an afterburner for an improved treatment of QED radiation in non-hadronic resonance decays.

For photon emissions off leptons, the shower can be continued down to virtualities arbitrarily close to the lepton mass shell (unlike the case in QCD). In practice, an infrared cutoff is still required for the shower algorithm to terminate. Therefore, there is always an energy cut-off for emitted photons that depends upon the implementations [37]. In the case of electrons, this energy is typically of the order of its mass. Electromagnetic radiation below this scale is not enhanced by collinear singularities, and is thus bound to be soft, so that the electron momentum is not affected by it.

For photons emitted from quarks, we have instead the obvious limitation that the photon wavelength cannot exceed the typical hadronic size. Longer-wavelength photons are in fact emitted by hadrons, rather than quarks. This last effect is in practice never modeled by existing shower MC implementations. Thus, electromagnetic radiation from quarks is cut off at a typical hadronic scale. Finally, hadron (and τ) decays involving charged particles can produce additional soft bremsstrahlung. This is implemented in a general way in `HERWIG++/HERWIG 7` [39] and `SHERPA` [40].

At energies significantly above the electroweak (EW) scale, showers involving emissions (and splittings) of weak gauge and Higgs bosons can also be relevant, with recent implementations based on collinear limits ranging from weak-boson emissions from fermions in `PYTHIA 8` [41], to triple-boson couplings in `HERWIG 7` [42], to the full set of EW branching processes in `VINCIA` [43].

43.1.8 *Beyond-the-Standard-Model Physics*

The inclusion of processes for physics beyond the Standard Model (BSM) in event generators is to some extent only a matter of implementing the relevant hard processes and (chains of) decays, with the level of difficulty depending on the complexity of the model and the degree of automation [44, 45]. Notable exceptions are long-lived colored particles [46], particles in exotic color representations, and particles showering under new gauge symmetries, with a growing set of implementations documented in the individual GPMC manuals. Further complications that may be relevant are finite-width effects (discussed in Sec. 43.1.9) and the assumed threshold behavior.

In addition to code-specific implementations [11], there are a few commonly adopted standards that are useful for transferring information and events between codes. Currently, the most important of these is the Les Houches Event File (LHEF) standard [47], normally used to transfer parton-level events from a hard-process generator to a shower generator. Another important standard is the Supersymmetry Les Houches Accord (SLHA) format [48], originally used to transfer information on supersymmetric particle spectra and couplings, but by now extended to apply also to more general BSM frameworks and incorporated within the LHEF standard [49].

43.1.9 *Decay Chains and Particle Widths*

In most BSM processes and some SM ones, an important aspect of the event simulation is how decays of short-lived particles, such as top quarks, EW and Higgs bosons, and new BSM resonances, are handled. We here briefly summarize the spectrum of possibilities, but emphasize that there is no universal standard. Users are advised to check whether the treatment of a given code is adequate for the physics study at hand.

The appearance of an unstable resonance as a physical particle at an intermediate stage of the event generation implies that its production and decay processes are treated as being factorized. This is valid up to corrections of order Γ/m_0, with Γ the width and m_0 the pole mass. States whose widths are a substantial fraction of their mass should instead be treated as intrinsically off-shell internal propagator lines.

For states treated as physical particles, two aspects are relevant: the mass distribution of the decaying particle itself and the distributions of its decay products. For the former, matrix-element generators often use a simple δ function at m_0. The next level up, typically used in GPMCs, is to use a Breit-Wigner distribution, which formally resums higher-order virtual corrections to the mass distribution. Note, however, that this still only generates an improved picture for *moderate* fluctuations away from m_0. Similarly to above, particles that are significantly off-shell (in units of Γ) should not be treated as resonant, but rather as internal off-shell propagator lines. In most GPMCs, further refinements are included, for instance by letting Γ be a function of m ("running widths") and by limiting the magnitude of the allowed fluctuations away from m_0. We finally point out that NLO+PS generators have appeared that can deal with resonances including off-shell effects, non-resonance contributions and interference of radiation generated in resonance decay and production, see [50] and references therein. A new "interleaved" shower treatment also allows for interference between production and decay in the Vincia model [43].

For the distributions of the decay products, the simplest treatment is again to assign them their respective m_0 values, with a uniform phase-space distribution. A more sophisticated treatment distributes the decay products according to the differential decay matrix elements, capturing at least the internal dynamics and helicity structure of the decay process, including EPR-like correlations. Further refinements include polarizations of the external states [51] and assigning the decay products their own Breit-Wigner distributions, the latter of which opens the possibility to include also intrinsically off-shell decay channels, like $H \to WW^*$.

GPMC manuals often give instructions on how to include new decay modes, at varying levels of sophistications ranging from simple uniform phase-space sampling (which the user can reweight a posteriori) and step-function thresholds, to fully matrix-element weighted decay implementations including potential off-shell / threshold effects.

During subsequent showering of the decay products, most parton-shower models will preserve the total invariant mass of the decayed resonance, so as not to skew the original resonance shape. In the context of passing externally generated LHEF files [47] to a GPMC for showering, note that this is only possible if the intermediate resonances are present (with status code 2) in the LHEF event record [52].

43.1.10 *Matching and Merging with Fixed-Order Matrix Elements*

Shower algorithms are based upon a combination of the collinear (small-angle) and soft (small-energy) approximations and are thus normally inaccurate for hard, wide-angle emissions (i.e., additional well-resolved jets). They also contain only the leading singular pieces of next-to-leading order (NLO) and higher corrections to the basic process.

Traditional GPMCs, like `HERWIG` and `PYTHIA`, have included for a long time the so called Matrix Element Corrections (MEC), first formulated in Ref. [53] with later developments summarized in Ref. [11]. They are typically available for $2 \to 1$ or $1 \to 2$ processes, like DIS, vector boson and Higgs production and decays, and top decays. The MEC corrects the emission of the hardest jet at large angles, so that it becomes exact at LO. A generalization of the method to multiple emissions was formulated in [54].

Aside from MECs implemented directly in the GPMCs, the improvements on the parton-shower description of hard collisions have been made in two main directions: the so called Matrix Elements and Parton Shower matching (ME+PS from now on), and the matching of NLO calculations and Parton Showers (NLO+PS). We now discuss each of these, and then briefly summarize techniques becoming available for combining them.

The ME+PS method allows one to use tree-level matrix elements for hard, large-angle emissions. It was first formulated in the so-called CKKW paper [55], and several variants have appeared, including the CKKW-L, MLM, pseudoshower and MESS methods, see Refs. [11, 56, 57] and references therein. So called "Truncated Showers" are required [58] to maintain color coherence when interfacing to angular-ordered parton showers, and care must be taken to use consistent α_S choices for the real (ME-driven) and virtual (PS-driven) corrections [59].

In the ME+PS method one typically starts by generating LO matrix elements for the production of the basic process plus a certain number $\leq n$ of other partons. A minimum separation is imposed on the produced partons, requiring, for example, that the relative transverse momentum in any pair of partons is above a given cut $Q_{\rm cut}$. One then reweights these amplitudes in such a way that, in the strongly ordered region, the virtual effects that are included in the shower algorithm (i.e. running couplings and Sudakov form factors) are also accounted for. At this stage, before parton showers are added, the generated configurations are tree-level accurate at large angle, and at small angle they match the results of the shower algorithm, except that there are no emissions below the scale $Q_{\rm cut}$, and no final states with more than n partons. These kinematic configurations are thus fed into a GPMC, that must generate all splittings with relative transverse momentum below the scale $Q_{\rm cut}$, for initial events with less than n partons, or below the scale of the smallest pair transverse momentum, for events with n partons. The matching parameter $Q_{\rm cut}$ must be chosen to be large enough for fixed-order perturbation theory to hold, but small enough so that the shower is accurate for emissions below it. Notice that the accuracy achieved with MEC is equivalent to that of ME+PS with $n = 1$, where MEC has the advantage of not having a matching parameter $Q_{\rm cut}$.

The popularity of the ME+PS method is due to the fact that processes with many jets often appear as backgrounds to new-physics searches. These jets are typically required to be well separated, and to have large transverse momenta. These kinematic configurations are exactly those for which pure shower algorithms are unreliable, hence it is mandatory to describe them using at least LO matrix elements.

Several ME+PS implementations use existing LO generators, like `ALPGEN` [60], `MADGRAPH` [61], and others summarized in Ref. [56], for the calculation of the matrix elements, and feed the partonic events to a GPMC like `PYTHIA` or `HERWIG` using the Les Houches Interface for User Processes (LHI/LHEF) [47, 52]. `SHERPA` and `HERWIG 7` also include their own matrix-element generators.

The NLO+PS methods promote the accuracy of the generation of the basic process from LO to NLO in QCD. They must thus include the radiation of one extra parton with tree-level accuracy, since this radiation constitutes a NLO correction to the basic process. They must also include NLO virtual corrections. They can be viewed as an extension of the MEC methods with the inclusion of NLO virtual corrections. They are however more general, since they are applicable to processes of arbitrary complexity. Two of these methods are now widely used: MC@NLO [62] and POWHEG [58,63], with several alternative methods now also being pursued, see Ref. [11] and references therein.

NLO+PS generators produce NLO accurate distributions for inclusive quantities, and generate the hardest jet with tree-level accuracy. It should be recalled, though, that in $2 \to 1$ processes like Z/W production, GPMCs including MEC and weighted by a constant K factor may perform nearly as well, and, if suitably tuned, may even yield a better description of data. In this context, note also that the optimal tuning of an NLO+PS generator may well be different from that of the pure PS.

Several NLO+PS processes are implemented in the MC@NLO program [62], together with the `AMC@NLO` development [64], and in the POWHEG-BOX framework [63]. `HERWIG 7` supports its own variants of POWHEG and MC@NLO for several processes. `SHERPA` instead implements a variant of the MC@NLO method.

For applications that require an accurate description of more than one hard, large-angle jet associated with the primary process, ME+PS schemes are still superior to NLO+PS ones. Ideally, one would like to improve NLO generators in such a way that also the production of associated jets achieves NLO accuracy. The FXFX [65], UNLOPS [66], MiNLO [67] and `MEPS@NLO` [68] methods address this problem. The solution of this problem is also a prerequisite for the construction of NNLO+PS generators, i.e. generators that, besides being NLO accurate for the production of an associated jet, are also NNLO accurate for fully inclusive observables. Three different approaches have appeared in the literature for dealing with this problem: the UN^{2}NLOPS, based upon UNLOPS method [69]; methods extending the MiNLO approach by reweigthting [70] and by the so called MiNNLO$_{\rm PS}$ technique [71]; and the GENEVA method [72]. Several processes have been implemented with the MiNLO related and GENEVA methods, mostly for the production of color singlet systems, with the exception of the recent MiNNLO$_{\rm PS}$ implementation of $t\bar{t}$ production (see refs. [73, 74] for an extensive list of references).

43.2 Hadronization Models

In the context of GPMCs, *hadronization* denotes the process by which a set of colored partons (*after* showering) is transformed into a set of "primary hadrons", which may then subsequently decay further (to "secondary hadrons"). This non-perturbative transition takes place at the *hadronization scale* $Q_{\rm had}$, which by construction is equal to the infrared cutoff of the parton shower. In the absence of a first-principles solution to the relevant dynamics, GPMCs use QCD-inspired phenomenological models to describe this transition.

An important result in "quenched" lattice QCD (see Chap. 17

of PDG book) is that the potential energy between two partons with opposite color charges grows linearly with their separation, at distances greater than about a femtometer. This is known as "linear confinement", and it forms the starting point for the *string model of hadronization*, discussed below in Sec. 43.2.1. Alternatively, a property of perturbative QCD called "preconfinement" is the basis of the *cluster model of hadronization*, discussed in Sec. 43.2.2.

A key difference between MC hadronization models and the fragmentation-function (FF) formalism used to describe inclusive hadron spectra in perturbative QCD (see Chap. 9 and Chap. 19 of PDG book) is that FFs can be defined at an arbitrary perturbative scale Q while MC hadronization models are intrinsically defined at the scale $Q_{\rm had}$. Direct comparisons are therefore only meaningful if the perturbative evolution between Q and $Q_{\rm had}$ is taken into account. FFs are calculable in pQCD, given a non-perturbative initial condition obtained by fits to hadron spectra. In the MC context, one can prove that the correct QCD evolution of the FFs arises from the shower formalism, with the hadronization model providing an explicit parameterization of the non-perturbative component. However, the MC modeling of shower and hadronization includes much more information on the final state since it is fully exclusive (i.e., it addresses all particles in the final state explicitly), while FFs only describe inclusive spectra. This exclusivity also enables MC models to make use of the color-flow information coming from the perturbative shower evolution (see Sec. 43.1.6) to determine between which partons confining potentials should arise. E.g., in the string picture, the nonperturbative limit of a QCD dipole is a string piece [75].

Given an exact hadronization model, its dependence on the scale $Q_{\rm had}$ should in principle be compensated by the corresponding scale dependence of the shower algorithm, which stops generating branchings at the scale $Q_{\rm had}$. However, due to their complicated and fully exclusive nature, it is generally not possible to enforce this compensation automatically in MC models. One must therefore be aware that the nonperturbative model parameters must be "retuned" by hand if the infrared cutoff is modified. Any other changes to the perturbative part of the calculation, such as matching to further (fixed-order or resummed) coefficients, may also necessitate a retuning. Tuning is discussed briefly in Sec. 43.4.

Finally, it should be emphasized that the so-called "parton level" that can be obtained by switching off hadronization in a GPMC, is not a universal concept, since each model defines $Q_{\rm had}$ differently (e.g. via a cutoff in $p_\perp$, invariant mass, etc., with different tunes using different values for the cutoff). Comparisons to distributions at this level may therefore be used to provide an idea of the overall impact of hadronization corrections within a given model, but should be avoided in the context of physical observables.

43.2.1 *The String Model*

Starting from early concepts [76], several hadronization models based on strings have been proposed [11]. Of these, the most widely used today is the so-called Lund model [77, 78], implemented in `PYTHIA` [4, 5]. We concentrate on that particular model here, though many of the overall concepts would be shared by any string-inspired method.

Consider a quark and an antiquark that have a large relative momentum and which are in an overall color-singlet state, such as the $\bar{q}q$ pair produced at the end of the shower in the center of Fig. 43.1). As the charges move apart, linear confinement implies that a potential $V(r) = \kappa\, r$ is reached for large distances r. (At short distances, there is a Coulomb term $\propto 1/r$ as well, but this is neglected in the Lund string.) This potential describes a string with tension $\kappa \sim 1\,\text{GeV/fm} \sim 0.2\,\text{GeV}^2$. The physical picture is that of a color flux tube being stretched between the q and the $\bar{q}$. As the string grows, the nonperturbative creation of quark-antiquark pairs can break the string, via the process illustrated in Fig. 43.2. If either of the resulting string pieces after the break still has a large invariant mass, new breaks will then continue to occur until every piece has a mass of order a typical hadron. In nature, quantum mechanics ensures that these masses are (Breit-Wigner-distributed around) those of the physical hadron states in QCD, while in an algorithmic implementation, this is less trivial

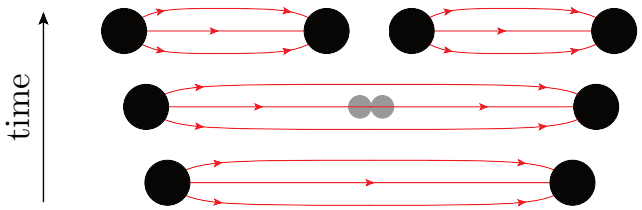

Figure 43.2: Illustration of string breaking by quark pair-creation in the string field.

to impose. Within the Lund model, the constraint that each final string piece must have a mass consistent with that of physical hadron is addressed by first noting that each breakup vertex is spacelike separated from all others (the string cannot break again in the forward lightcone of a point where it has already broken); since the breakups are therefore causally disconnected, they do not have to be considered in any particular order. The Lund model exploits this to perform the fragmentation in an outwards-in manner [78], splitting off one physical hadron at a time from either the left or right endpoint (chosen randomly in each step).

The first hadron to be generated (starting either from the left or right) is thus the "outermost" one (sometimes called the "first-rank" hadron), formed by combining the original hadronizing endpoint quark (or antiquark) q_0 with an antiquark (or quark) $\bar{q}_1$ produced by the first breakup. The new leftover quark (or antiquark) q_1 becomes the string endpoint for the next iteration, in a Markov chain which continues, alternating randomly between the left and right ends of the string, until finally a small last bit of string is decayed directly to two hadrons, with no energy left over.

Not only does this allow for the hadron that is split off in each step to be assigned a physical mass, the fact that the fragmentation spectrum should be independent of whether one performs the fragmentation from left to right or vice versa places a strong constraint on the form of the nonperturbative *fragmentation function*, $f(z)$, which governs the probability for the hadron produced in a given step to take a fraction $z \in [0, 1]$ of the remaining energy. Thus, in the Lund model, causality dictates that the fragmentation function should be of the form,

$$f(z) \propto \frac{1}{z}(1-z)^a \exp\left(-\frac{b\,(m_h^2 + p_{\rm T} h^2)}{z}\right) . \qquad (43.9)$$

This is known as the Lund symmetric fragmentation function (normalized to unit integral). The dimensionless parameter a dampens the hard tail of the fragmentation function, towards $z \to 1$, and may in principle be flavor-dependent, while b, with dimension GeV^{-2}, is a universal constant related to the string tension [78] which determines the behavior in the soft limit, $z \to 0$. Note that the dependence on the hadron mass, m_h, in $f(z)$ implies that heavier hadrons have higher $\langle z \rangle$. We return to the transverse momentum $p_{\rm T} h$ below.

The model is Lorentz invariant, so considerations involving boosted string systems are straightforward, involving the usual Lorentz effects.

As a by-product, the probability distribution in invariant time τ of $q'\bar{q}$ breakup vertices, or equivalently $\Gamma = (\kappa\tau)^2$, is also obtained, with $dP/d\Gamma \propto \Gamma^a \exp(-b\Gamma)$ implying an area law for the color flux, and the average breakup time lying along a hyperbola of constant invariant time $\tau_0 \sim 10^{-23}$s [78].

For massive endpoints (e.g. c and b quarks), which do not move along straight lightcone sections, the exponential suppression with string area leads to modifications of the form $f(z) \to f(z)/z^{b\,m_Q^2}$, with m_Q the mass of the heavy quark [79]. Although different forms, such as the Peterson formula [80], can also be used to describe inclusive heavy-meson spectra (see Sec 19.8 of PDG book), such choices are not strictly consistent with causality in the string framework.

43.2.1.1 *Strings with Gluons*

In the string model, energetic gluons lead to transverse "kinks" on strings, illustrated in Fig. 43.3. The order of these kinks follows from the color ordering produced by the parton shower, cf. the $\bar{q}gggq$ and $\bar{q}gq$ systems on the left and right part of Fig. 43.1. (Modifications to this order, by possible color reconnection/rearrangement effects, are discussed in Sec. 43.3.2.) Thus gluons

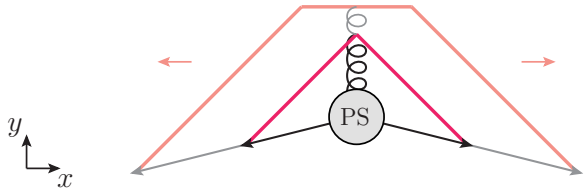

Figure 43.3: Schematic illustration of an $e^+e^- \to qg\bar{q}$ configuration emerging from the parton shower (PS). Snapshots of string positions are shown at two different times (full and shaded lines respectively). The gluon forms a transverse kink which grows in the y direction until all the gluon's kinetic energy has been used up.

effectively build up a transverse structure in the originally one-dimensional object, with infinitely soft ones smoothly absorbed into the string. Note: cyclic topologies made entirely of gluons (closed strings) are also possible, e.g. in decays such as $H \to gg$ or $\Upsilon \to ggg$. The space-time evolution is more involved when kinks are taken into account [78], but no additional free parameters need to be introduced. The main difference between quark and gluon hadronization stems from the fact that gluons are connected to two string pieces (one on either side), while quarks are only connected to a single string piece. Hence, the relative rate of energy loss per unit invariant time — and consequently also the rate of hadron production — is larger by a factor of 2 for gluons (analogously to the ratio of gluon to quark color charges $C_A/C_F = 2.25$).

43.2.1.2 *Transverse Momentum and Flavors*

For each breakup vertex, quantum mechanical tunneling is assumed to control the masses and p_{T} kicks (transverse to the string axis, in a frame in which the string itself has no transverse motion) that can be produced, leading to a Gaussian suppression

$$\mathrm{Prob}(m_q^2, p_{\mathrm{T}}q^2) \;\propto\; \exp\left(\frac{-\pi m_q^2}{\kappa}\right) \exp\left(\frac{-\pi p_{\mathrm{T}}q^2}{\kappa}\right) \;, \quad (43.10)$$

where m_q is the mass of the produced quark flavor and p_{T} is the nonperturbative transverse momentum imparted to it by the breakup process, with a universal average value of $\left\langle p_{\mathrm{T}}q^2 \right\rangle = \kappa/\pi \sim (250\,\mathrm{MeV})^2$. The antiquark has the same mass and opposite p_{T}.

In an MC model with a fixed shower cutoff t_0, the effective amount of p_{T} in string breaks may be larger than the purely nonperturbative κ/π above, to account for effects of additional (unresolved) radiation below t_0.

From the mass term in Eq. (43.10), one concludes that charm and bottom quarks are too heavy to be produced in string breaks, while strange quarks will be suppressed relative to up and down ones. Lacking unambiguous and precise mass definitions for light quarks, however, the effective amount of strangeness suppression is normally extracted from experimental data, using observables such as K/π, K^*/ρ, and ϕ/K^* ratios.

Baryon production can also be incorporated, at various levels of sophistication. The simplest option is to allow string breaks to produce pairs of *diquarks*, loosely bound states of two quarks in an overall $\bar{3}$ representation. Again, the relative rate of such pairs is extracted from data, e.g. using p/π or Λ/K ratios. Since the perturbative shower splittings do not produce diquarks, the optimal value for this parameter is mildly correlated with the amount of $g \to q\bar{q}$ splittings in the shower. More sophisticated options, including the so-called "popcorn" mechanism, are discussed in Ref. [78]. Finally, the PYTHIA framework also allows for baryon string junctions [81]. These represent epsilon tensors in color space (analogously to how color dipoles represent Kronecker deltas), and are used, e.g., to model the fragmentation of baryon beam remnants. They can also be created (in pairs of junctions and antijunctions) in some color-reconnection scenarios [82], making the effective baryon-to-meson ratios in such models dependent on the amount and type of color reconnections that occur in each event.

The next step of the algorithm is the assignment of the produced quarks within hadron multiplets. Using a nonrelativistic classification of spin states, the hadronizing q may combine with the $\bar{q}'$ from a newly created breakup to produce a hadron of a given spin S and angular momentum L. The lowest-lying pseudoscalar and vector meson multiplets, and spin-1/2 and -3/2 baryons, are assumed to dominate in a string framework[1], but individual rates are not predicted by the model, and hence the ratios of spin-1 to spin-0 mesons and diquarks are free parameters (modulo a factor 3 from spin counting) which must be constrained by data. In that context, it is often advisable to begin with the heaviest states, since so-called feed-down from the decays of higher-lying hadron states complicates the extraction for lighter particles, see Sec. 43.2.3.

43.2.2 *The Cluster Model*

The cluster hadronization model is based on *preconfinement*, i.e., on the observation [83, 84] that the color structure of a perturbative QCD shower evolution at any scale Q_0 is such that color-singlet subsystems of partons (labeled "clusters") occur with a universal invariant mass distribution which is power suppressed at large masses. For any starting scale $Q \gg Q_0 \gg \Lambda_{\mathrm{QCD}}$, only the number of such clusters depends on Q, while the shape of their mass distribution only depends on Q_0 and on Λ_{QCD}.

Following early models based on this universality [10, 85], the cluster model developed by Webber [86] has for many years been a hallmark of the HERWIG generators, with an alternative implementation [87] now available in the SHERPA generator. The key idea, in addition to preconfinement, is to force "by hand" all gluons to split into quark-antiquark pairs at the end of the parton shower. Compared with the string description, this effectively amounts to viewing gluons as "seeds" for string breaks, rather than as kinks in a continuous object. After the splittings, a new set of low-mass color-singlet clusters is obtained, formed only by quark-antiquark pairs. These can be decayed to on-shell hadrons in a simple manner, with the relative yields of different hadron species mainly governed by their masses and the size of the phase space.

The algorithm starts by generating the forced $g \to q\bar{q}$ breakups, and by assigning flavors and momenta to the produced quark pairs. For a typical shower cutoff corresponding to a gluon virtuality of $Q_{\mathrm{had}} \sim 1\,\mathrm{GeV}$, the p_{T} generated by the splittings can be neglected. The constituent light-quark masses, $m_{u,d} \sim 300\,\mathrm{MeV}$ and $m_s \sim 450\,\mathrm{MeV}$, imply a suppression (typically even an absence) of strangeness production. In principle, the model also allows for diquarks to be produced at this stage, but due to the larger constituent masses this would only become relevant for shower cutoffs larger than 1 GeV.

If a cluster formed in this way has an invariant mass above some cutoff value, typically 3–4 GeV, it is forced to undergo sequential $1 \to 2$ cluster breakups, along an axis defined by the constituent partons of the original cluster, until all sub-cluster masses fall below the cutoff value. Due to the preservation of the original axis in these breakups, this treatment has some resemblance to the string-like picture, though the nonperturbative $p_\perp$ kicks generated in this way are generally larger, up to half the allowed cluster mass.

Next, on the low-mass side of the spectrum, some clusters are allowed to decay directly to a single hadron, with nearby clusters absorbing any excess momentum. This improves the description of the high-z part of the spectrum — where the hadron carries almost

[1] In PYTHIA, the four $L = 1$ meson multiplets (scalar, tensor, and 2 pseudovectors) are also available but are disabled by default, since many states (and their decays) are poorly known.

all the momentum of its parent jet — at the cost of introducing one additional parameter, controlling the probability for single-hadron cluster decay.

Having obtained a final distribution of small-mass clusters, now with a strict cutoff at 3–4 GeV and with the component destined to decay to single hadrons already removed, the remaining clusters are interpreted as a smoothed-out spectrum of excited mesons, each of which decays isotropically to two hadrons, with relative probabilities proportional to the available phase space for each possible two-hadron combination that is consistent with the cluster's internal flavors, including spin degeneracy. It is important that all the light members (containing only *uds*) of each hadron multiplet be included, as the absence of members can lead to unphysical isospin or SU(3) flavor violation. Typically, the lightest pseudoscalar, vector, scalar, even and odd charge conjugation pseudovector, and tensor multiplets of light mesons are included. In addition, some excited vector multiplets of light mesons may be available. For baryons, usually only the lightest flavor-octet, -decuplet and -singlet baryons are present, although both the `HERWIG++` and `SHERPA` implementations now include some heavier baryon multiplets as well.

Differently from the string model, the mechanism of phase-space suppression employed here leads to a natural enhancement of the lighter pseudoscalars, and no parameters beyond the spectrum of hadron masses need to be introduced at this point. The phase space also limits the transverse momenta of the produced hadrons relative to the jet axis.

Note that, since the masses and decays of excited heavy-flavor hadrons in particular are not well known, there is some freedom in the model to adjust these, which in turn will affect their relative phase-space populations.

43.2.3 *Hadron and τ Decays*

Of the so-called primary hadrons, originating directly from string breaks and/or cluster decays (see above), many are unstable and so decay further, until a set of particles is obtained that can be considered stable on time scales relevant to the given measurement. (A typical hadron-collider definition of a "stable particle" $c\tau \geq 10\,\text{mm}$ includes weakly-decaying strange hadrons K, Λ, $\Sigma^{\pm}$, $\bar{\Sigma}^{\pm}$, Ξ, Ω.) The decay modeling can therefore have a significant impact on final particle yields and spectra, especially for the lowest-lying hadronic states, which receive the largest relative contributions from decays (feed-down). This interplay also implies that hadronization parameters may need to be retuned if significant changes to the decay treatment are made.

Particle summary tables, such as those given elsewhere in this *Review*, represent a condensed summary of the available experimental measurements and hence may be incomplete and/or exhibit inconsistencies within the experimental precision. In an MC decay package, on the other hand, all information must be quantified and consistent, with all branching ratios summing to unity. When adapting particle summary information for use in a decay package, a number of choices must therefore be made. The amount of ambiguity increases as more excited hadron multiplets are added to the simulation, about which less and less is known from experiment, with each GPMC making its own choices.

A related choice is how to distribute the decay products differentially in phase space, in particular which matrix elements to use. Historically, MC generators contained matrix elements only for selected (generator-specific) classes of hadron and τ decays, coupled with a Breit-Wigner smearing of the masses, truncated at the edges of the physical decay phase space (the treatment of decay thresholds can be important for certain modes [11]). A more sophisticated treatment can then be obtained by reweighting the generated events using the obtained particle four-momenta and/or by using specialized external packages such as `EVTGEN` [88] for hadron decays and `TAUOLA` [89] for τ decays.

More recently, `HERWIG++` and `SHERPA` include helicity-dependence in τ decays [6, 90], with a more limited treatment available in `PYTHIA` 8 [5]. The `HERWIG++` and `SHERPA` generators have also included significantly improved internal simulations of hadronic decays, which include spin correlations between those decays for which matrix elements are used. Photon-bremsstrahlung effects are discussed in Sec. 43.1.7.

`HERWIG++` and `PYTHIA` include the probability for B mesons to oscillate into $\bar{B}$ ones before decay. `SHERPA` and `EVTGEN` also include CP-violating effects and, for common decay modes of the neutral meson and its antiparticle, the interference between the direct decay and oscillation followed by decay.

We end on a note of warning on double counting. This may occur if a particle can decay via an intermediate on-shell resonance. An example is $a_1 \to \pi\pi\pi$ which may proceed via $a_1 \to \rho\pi$, $\rho \to \pi\pi$. If these decay channels of the a_1 are both included, each with their full partial width, a double counting of the on-shell $a_1 \to \rho\pi$ contribution would result. Such cases are normally dealt with consistently in the default MC generator packages, so this warning is mostly for users that wish to edit decay tables on their own.

43.3 Models for Soft Hadron-Hadron Physics

43.3.1 *Underlying Event*

In the GPMC context, "underlying event" (UE) denotes any additional activity *beyond* the basic process and its associated ISR and FSR activity. The UE is thus only defined in the context of events selected with a "hard" (i.e., high-$p_\perp$) trigger which defines the basic process at hand. The dominant contribution to the UE is believed to come from additional color exchanges between the colliding hadronic states. These multiple exchanges can be modeled either as additional perturbative (mainly t-channel gluon) exchanges, called multiple parton-parton interactions (MPI), or nonperturbatively using so-called cut pomerons (roughly equivalent to exchange of gluons with $p_\perp \to 0$). The experimental observation that events with a hard trigger are accompanied by a higher-than-average level of associated activity is called the "jet pedestal" effect.

The most clearly identifiable consequence of MPI is arguably the possibility of observing several hard parton-parton interactions in one and the same hadron-hadron event. Typically, these are QCD $2 \to 2$ interactions, which produce additional back-to-back jet pairs, with each pair having a small value of sum($\vec{p}_\perp$). The fraction of MPI that give rise to additional reconstructible jets is, however, small. Soft interactions, that exchange color and a small amount of momentum without giving rise to observable jets, are much more plentiful, and can give significant corrections to the color flow and total scattered energy of the event. This affects the final-state activity in a more global way, increasing hadron-multiplicity and summed E_T distributions, and contributing to the break-up of the beam remnants in the forward direction.

The first detailed Monte Carlo model for perturbative MPI was proposed in Ref. [91], and with some variation this still forms the basis for most modern implementations. Some useful additional references can be found in Ref. [11]. The first crucial observation is that the t-channel propagators appearing in perturbative QCD $2 \to 2$ scattering almost go on shell at low $p_{\rm T}$, causing the differential cross sections to behave roughly as

$$d\sigma_{2\to 2} \propto \frac{dt}{t^2} \sim \frac{dp_{\rm T}{}^2}{p_{\rm T}{}^4} \,. \tag{43.11}$$

This cross section represents the inclusive scattering of partons against partons in perturbative QCD, summed over all partons. Thus, if a single hadron-hadron scattering contains *two* parton-parton interactions, that event will contribute twice to the parton-parton cross section $\sigma_{2\to 2}$ but only once to the hadron-hadron one $\sigma_{\rm tot}$, and so on. In the limit that all the parton-parton interactions are independent and equivalent, one has

$$\sigma_{2\to 2} = \langle n \rangle \, \sigma_{\rm tot} \,, \tag{43.12}$$

with $\langle n \rangle$ the average number of parton-parton interactions, typically defined with some minimal $p_{\rm T} > p_{\perp \rm min}$ to render the parton-parton cross section finite. The probability for n parton-parton scatterings then follows a Poisson distribution,

$$\mathcal{P}_n = \langle n \rangle^n \frac{\exp\left(-\langle n \rangle\right)}{n!} \,. \tag{43.13}$$

This simple argument expresses unitarity; instead of the total hadron-hadron interaction cross section diverging as the parton-parton $p_{\rm T} \to 0$ (which would violate unitarity), we have restated

the problem so that it is now the *number of parton-parton interactions per hadron-hadron collision* that diverges, with the total hadron-hadron cross section remaining finite. At LHC energies, the parton-parton scattering cross sections computed using the LO QCD cross section folded with modern PDFs become larger than the total pp one for $p_{\perp\min}$ values of order 4–5 GeV (see e.g. [92, 93]). One therefore expects the average number of perturbative MPI to exceed unity at around that scale.

Two ingredients remain to fully regulate the remaining divergence. Firstly, the interactions cannot use up more momentum than is available in the parent hadron. This suppresses the large-n tail of the estimate above. In `PYTHIA`-based models, the MPI are ordered in $p_{\rm T}$, and the parton densities for each successive interaction are explicitly constructed so that the sum of x fractions can never be greater than unity. In the `HERWIG` models, the Poisson estimate of $\langle n\rangle$ above is used as an initial guess, but the generation of actual MPI is stopped once the energy-momentum conservation limit is reached. Both of these approaches generate momentum (conservation) correlations among the MPI.

The second ingredient invoked to suppress the number of interactions, at low $p_{\rm T}$ and x, is color screening; if the wavelength $\sim 1/p_{\rm T}$ of an exchanged colored parton becomes larger than a typical color-anticolor separation distance, it will only see an *average* color charge that vanishes in the limit $p_{\rm T} \to 0$. This provides an infrared cutoff for MPI similar to that provided by the hadronization scale for parton showers. A first estimate of the color-screening cutoff would be the proton size, $p_{\perp\min} \approx \hbar/r_p \approx 0.3\,\text{GeV} \approx \Lambda_{\rm QCD}$, but empirically this appears to be far too low. In current models, one replaces the proton radius r_p in the above formula by a "typical color screening distance," i.e., an average size of a region within which the net compensation of a given color charge occurs. This number is not known from first principles [94] and is perceived of simply as an effective cutoff parameter. The simplest choice is to introduce a step function $\Theta(p_{\rm T} - p_{\perp\min})$. Alternatively, one may note that the jet cross section is divergent like $\alpha_{\rm S}^2({p_{\rm T}}^2)/{p_{\rm T}}^4$, cf. Eq. (43.11), and that therefore a factor

$$\frac{\alpha_{\rm S}^2({p_{\rm T}0}^2 + {p_{\rm T}}^2)}{\alpha_{\rm S}^2({p_{\rm T}}^2)} \, \frac{{p_{\rm T}}^4}{({p_{\rm T}0}^2 + {p_{\rm T}}^2)^2} \tag{43.14}$$

would smoothly regulate the divergences, now with $p_{\rm T}0$ as the free parameter. Regardless of whether it is imposed as a smooth (`PYTHIA` and `SHERPA`) or steep (`HERWIG++`) function, this is effectively the main "tuning" parameter in such models.

Note that the numerical value obtained for the cross section depends upon the PDF set used, and therefore the optimal value to use for the cutoff will also depend on this choice. Note also that the cutoff does not have to be energy-independent. Higher energies imply that parton densities can be probed at smaller x values, where the number of partons rapidly increases. Partons then become closer packed and the color screening distance d decreases. The uncertainty on the energy and/or x scaling of the cutoff is a major concern when extrapolating between different collider energies [95].

We now turn to the origin of the observational fact that hard jets appear to sit on top of a higher "pedestal" of underlying activity than events with no hard jets. This is interpreted as a consequence of impact-parameter-dependence: in peripheral collisions, only a small fraction of events contain any high-$p_{\rm T}$ activity, whereas central collisions are more likely to contain at least one hard scattering; a high-$p_{\rm T}$ triggered sample will therefore be biased towards small impact parameters, b. The ability of a model to describe both the UE in events with a hard trigger as well as the activity in inclusive "minimum-bias" (MB) samples (see below) therefore depends upon its modeling of the b-dependence, and correspondingly the impact-parameter shape constitutes another main tuning parameter.

For each impact parameter b, the number of interactions $\tilde{n}(b)$ can still be assumed to be distributed according to Eq. (43.13), again modulo momentum conservation, but now with the mean value of the Poisson distribution depending on impact parameter, $\langle\tilde{n}(b)\rangle$. This causes the final n-distribution (integrated over b) to be wider than a Poissonian.

Finally, there are two perturbative modeling aspects which go beyond the introduction of MPI themselves: 1) parton showers off the MPI, and 2) perturbative parton-rescattering effects. Without showers, MPI models would generate very sharp peaks for back-to-back MPI jets, caused by unshowered partons passed directly to the hadronization model. However, with the exception of the oldest `PYTHIA6` model, all GPMC models do include such showers [11], and hence should exhibit more realistic (i.e., broader and more decorrelated) MPI jets. On the initial-state side, the main questions are whether and how correlated multi-parton densities are taken into account and, as discussed previously, how the showers are regulated at low $p_{\rm T}$ and/or low x. Although none of the MC models currently impose a rigorous correlated multi-parton evolution, all of them include some elementary aspects. The most significant for parton-level results is arguably momentum conservation, which is enforced explicitly in all the models. The so-called "interleaved" models [28] attempt to go a step further, generating an explicitly correlated multi-parton evolution in which flavor sum rules are imposed to conserve, e.g. the total numbers of valence and sea quarks [81].

Perturbative rescattering in the final state can occur if partons are allowed to undergo several distinct interactions, with showering activity possibly taking place in-between. This has so far not been studied extensively, but a first exploratory model is available [96]. In the initial state, parton rescattering/recombination effects have so far not been included in any of the GPMC models.

43.3.2 *Bose-Einstein and Color-Reconnection Effects*

In the context of e^+e^- collisions, Bose-Einstein (BE) correlations have mostly been discussed as a source of uncertainty on high-precision W mass determinations at LEP [97]. In hadron-hadron (and nucleus-nucleus) collisions, however, BE correlations are used extensively to study the space-time structure of hadronizing matter ("femtoscopy").

In MC models of hadronization, each string break or particle/-cluster decay is normally factorized from all other ones. This reduces the number of variables that must be considered in each step, but also makes it intrinsically difficult to introduce correlations among particles from different breaks/decays. In GPMCs, a few semi-classical models are available within the `PYTHIA` 6 and 8 generators [98], in which the BE effect is mimicked by an attractive interaction between pairs of identical particles in the final state, with no higher correlations included. Variants of this model differ mainly by the assumed shape of the correlation function and how overall momentum conservation is handled.

As discussed in Sec. 43.2, leading-color ("planar") color flows are used to set up the hadronizing systems (clusters or strings) at the hadronization stage. If the systems do not overlap significantly in space and time, subleading-color ambiguities and/or nonperturbative reconnections are expected to be small. However, if the density of displaced color charges is sufficiently high that several systems can overlap significantly, full-color and/or reconnection effects should become progressively larger.

In the specific context of MPI, a crucial question is how color is neutralized *between* different MPI systems, including the remnants. The large rapidity differences involved imply large invariant masses (though normally low $p_{\rm T}$), and hence large amounts of (soft) particle production. Indeed, in the context of soft-inclusive physics, it is these "inter-system" strings/clusters that furnish the dominant particle-production mechanism, and hence their modeling is an essential part of the soft-physics description, affecting topics such as MB/UE multiplicity and $p_{\rm T}$ distributions, rapidity gaps, and precision mass measurements. Reviews of color-reconnection effects can be found in [11, 82].

43.3.3 *Minimum-Bias Events and Diffraction*

The term "minimum bias" (MB) originates from the experimental requirement of a minimal number of tracks (or hits) in a given instrumented region. In order to make MC predictions for such observables, all possible contributions to the relevant phase-space region must be accounted for. There are essentially four types of physics processes, which together make up the total hadron-

hadron (hh) cross section: 1) elastic scattering[2]: $hh \to hh$, 2) single diffractive dissociation: $hh \to h + \text{gap} + X$, with X denoting anything that is not the original beam particle, and "gap" denoting a rapidity region devoid of observed activity; 3) double diffractive dissociation: $hh \to X + \text{gap} + X$, and 4) inelastic non-diffractive scattering: everything else. A fifth class may also be defined, called central diffraction ($hh \to h + \text{gap} + X + \text{gap} + h$). Note that different terminologies exist [99]: in experimental settings, diffraction is typically defined by an observable gap, of some minimal size in rapidity, while in the MC context, each diffractive physics process produces a whole spectrum of gaps, with small ones suppressed but not excluded.

The inelastic non-diffractive part of the cross section is typically modeled either by smoothly regulating and extending the perturbative QCD scattering cross sections all the way to zero $p_\perp$ [91] (`PYTHIA` and `SHERPA`), or by regulating the QCD cross sections with a sharp cutoff [100] and adding a separate class of nonperturbative scatterings below that scale [101] (`HERWIG`). See also Sec. 43.3.1. In all cases, the most important ingredients are: 1) the IR regularization of the perturbative scattering cross sections, including their PDF dependence, 2) the assumed matter distribution of the colliding hadrons, possibly including multi-parton correlations [81] and/or x dependence [102], and 3) additional soft-QCD effects such as color reconnections, discussed in Sec. 43.3.2.

Currently, there are essentially three methods for simulating diffraction in the main MC models: 1) in `PYTHIA` 6, one picks a diffractive mass according to parameterized cross sections $\propto \mathrm{d}M^2/M^2$ [103]. This mass is represented as a string, which is hadronized as described in Sec. 43.2.1, though differences in the effective scale of the hadronization may necessitate a (re)tuning of the hadronization parameters for diffraction; 2) in `PYTHIA` 8, the high-mass tail beyond $M \sim 10\,\text{GeV}$ is augmented by a partonic description in terms of pomeron PDFs [104], allowing diffractive jet production including showers and underlying event [105]; 3) the `PHOJET` and `DPMJET` programs also include central diffraction and rely directly on a formulation in terms of pomerons (color-singlet multi-gluon states) [106–108]. Cut pomerons correspond to exchanges of soft gluons while uncut ones give elastic and diffractive topologies as well as virtual corrections that help preserve unitarity. So-called "hard pomerons" provide a transition to the perturbative regime. Hadronization is still handled using the Lund string model, so there is some overlap with the above models at the hadronization stage. In addition, a pomeron-based package exists for `HERWIG` [109], and an effort is underway to construct an MC implementation of the "KMR" model [94] within the `SHERPA` generator. Color reconnections (Sec. 43.3.2) may also play a role in creating rapidity gaps and the underlying event (Sec. 43.3.1) in filling them.

43.4 Uncertainties and Tuning

The accuracy that can be achieved by a GPMC model depends on the sophistication of the theory models it incorporates, on the available constraints on its free parameters, and on the nature of the observable(s) under study. Using existing data (or more accurate theory calculations) to constrain the model parameters is referred to as generator tuning. Although tuned models do tend to yield improved results also for observables that they have not been tuned to, the question of evaluating the remaining uncertainties reliably is still far from solved. It is worth noting, however, that all of the GPMCs now provide options for automatic evaluation of perturbative shower uncertainties (e.g., via renormalization-scale variations), in the form of vectors of alternative event weights [110–112]. One must be aware that these variations are not necessarily exhaustive and significant weight fluctuations can be a problem for processes with large shower phase spaces. Nonperturbative uncertainties must normally still be evaluated by varying salient model parameters by hand. A general method called eigentunes [113] is also available, based on global fits to data.

Typically, the overall event properties are determined by only a few, very important parameters, such as the value of α_S, for perturbative corrections, and the shape of the fragmentation functions, for nonperturbative ones. More parameters may then be introduced to describe successively more detailed aspects (e.g., the rates and decays of individual hadron species), but these should have progressively less impact on the overall modeling. One may therefore take a factorized approach, first constraining the perturbative parameters and thereafter the nonperturbative ones, in order of decreasing significance to the overall modeling. Furthermore, by identifying which measurements are most sensitive to each parameter, this ordering can be reflected in the way that data is selected and applied to constrain the models. Thus, measurements sensitive to global event properties would typically be applied first, to constrain the most inclusive parameters, and so on for progressively more exclusive aspects.

At LO×LL, perturbation theory is doing well if it agrees with an IR safe measurement within $\sim 10\%$. It would therefore not make much sense to tune a GPMC beyond roughly 5% (it might even be dangerous, due to overfitting). The advent of NLO Monte Carlos may reduce this number slightly, but only for quantities for which one expects NLO precision. For quantities governed by nonperturbative physics, uncertainties are larger. For some quantities, e.g. ones for which the underlying modeling is known to be poor, an order-of-magnitude agreement or worse may have to be accepted. Note further that the unitarity of shower and hadronization models implies that the Born-level cross-section normalization is not tunable, hence in tuning contexts one tends to focus on the shapes of distributions rather than their normalizations.

In the context of LO×LL GPMC tuning, subleading aspects of coupling-constant and PDF choices are relevant. In particular, one should be aware that the choice of QCD Λ parameter $\Lambda_\text{MC} = 1.569\Lambda_{\overline{\text{MS}}}$ (for 5 active flavors) improves the predictions of coherent shower algorithms at the NLL level for a class of relevant observables [114], and hence this scheme is often considered the baseline for shower tuning. The question of LO vs. NLO PDFs is more involved [11], but it should be emphasized that the gluon PDF at (very) low x is important for determining the level of the underlying event in MPI models (Sec. 43.3.1), and hence the MB/UE tuning (and energy scaling [95]) is linked to the choice of PDF in such models. Further issues and an example of a specific recipe that could be followed in a realistic set-up can be found in Ref. [92]. A useful online resource can be found at the mcplots.cern.ch website [115], based on the RIVET tool [116].

Recent years have seen the emergence of automated tools to reduce the amount of both computer and manpower required for tuning [113]. Automating the human expert input is more difficult. In the tools currently on the market, this is addressed by a combination of input solicited from the GPMC authors (e.g., which parameters and ranges to consider, which observables constitute a complete set, etc) and a set of weights determining the relative priority given to each bin in each distribution. The final result is therefore still subjective but at least reproducible. When backed by careful demonstrations of sensitivities, correlations, and uncertainties, the quality of the resulting tunes is by now competitive. The field is still burgeoning, with future sophistications to be expected.

[2] The QED elastic cross section diverges and is normally a non-default option.

44. Monte Carlo Neutrino Generators

Revised September 2021 by H. Gallagher (Tufts U.) and Y. Hayato (Kamioka Observatory, ICRR, UTokyo; Kavli IPMU (WPI), UTokyo).

Monte Carlo neutrino generators are programs or libraries which simulate neutrino interactions with electrons, nucleons and nuclei. In this capacity their usual task is to take an input neutrino and nucleus and produce a set of 4-vectors for particles emerging from the interaction, which are then input to full detector simulations. Since these generators have to simulate not only the initial interaction of neutrinos with target particles, but reinteractions of the generated particles in the nucleus, they contain a wide range of elementary particle and nuclear physics. Viewed more broadly, they are the access point for neutrino experimentalists to the theory inputs needed for analysis. Examples include cross section libraries for event rate calculations and parameter uncertainties and reweighting tools for systematic error evaluation.

Neutrino experiments typically operate in neutrino beams that are neither completely pure nor mono-energetic. Generators are a crucial component in the convolution of beam flux, neutrino interaction physics, and detector response that is necessary to make predictions about observable quantities. Generated events are used to define experimental analyses, like event selection criteria, for efficiency determination and background subtraction. Similarly they are used to relate reconstructed quantities back to true quantities. In these various capacities they are used from the detector design stage through the extraction of physics measurements from reconstructed observable. Monte Carlo neutrino generators play unique and important roles in the experimental study of neutrino interactions and oscillations.

There are several neutrino event generators available, such as ANIS [1], GENIE [2, 3], GiBUU [4, 5], MARLEY [6], NEGN [7], NEUT [8], NUANCE [9], the FLUKA routines NUNDIS/-NUNRES [10, 11], and NuWro [12], as well as tools to facilitate cross-generator comparisons, such as NUISANCE [13]. Historically, experiments would develop their own generators. This was often because they were focused on a particular measurement, energy range, or target, and wanted to ensure that the best physics was included for them. These 'home-grown' generators were often tuned primarily or exclusively to the neutrino data most similar to the data that the experiment would be collecting. A major advance in the field was the introduction of conference series devoted to the topic of neutrino interaction physics, NuINT (https://indico.cern.ch/event/703880/) and NuFACT (https://indico.cern.ch/event/855372/) in particular. Event generator comparisons have been a regular staple of the NuINT conference series from its inception, and a great deal of information on this topic can be found in the Proceedings of these meetings. These meetings have facilitated experiment-theory discussions leading to the first generator developed by a theory group (NuWro) [12], the extension of established nuclear interaction codes (FLUKA and GiBUU) to include neutrino-nuclear processes [4,5,10,11], and inclusion of theorists in existing generator development teams.

These activities have led to more careful scrutiny of the crucial hadron and nuclear theory inputs to these generators, which is evaluated in particular through comparisons to electron-scattering data. At this point in time all simulation codes face challenges in describing the full extent of the lepton scattering data, and the tension between incorporating the best available theory versus obtaining the best agreement with the data plays out in a variety of ways within the field. For the field to make progress, inclusion of state of the art theory needs to be coupled to global analyses that correctly incorporate correlations between measurements. Given the rapid pace of new data and the complexity of analyses, this is a significant challenge for the field in the coming years.

There are many neutrino experiments which use various sources of neutrinos, from reactors, accelerators, the atmosphere, and astrophysical sources, thereby covering a range of energies from MeV to TeV. Much of the emphasis has been on the few-GeV region in the generators, as this is the relevant energy range for short- and long-baseline neutrino oscillation experiments. These generators use the impulse approximation, which treats the nucleus as a collection of independent nucleons and the primary interaction occurs between the probe and a single nucleon, for most of the initial interaction, and subsequently simulates the interactions of secondary particles in the nucleus in semi-classical ways. Semi-classical hadron transport approaches are commonly used as they are able simulate a variety of nuclei in a single model, fully describe complex multi-particle final states, and for practical considerations as these approaches are fast. However, there are several challenges facing these simulations coming mainly from the complexity of the nuclear physics, and the need to avoid double counting in combining perturbative and non-perturbative models for the neutrino-nucleon scattering processes. The overall validity of this impulse approximation-based scheme, and in particular the importance of scattering channels that involve more than one nucleon, is a crucial question that is the topic of much current work. While generators share many common ingredients, differences in implementation, parameter values, and approaches to avoid double counting can yield dramatically different predictions [14]. In the following sections, interaction models and their implementations, including final-state interactions of hadrons produced in the nuclei, are described.

In order to assure their validity, neutrino event generators are tuned and validated against a wide variety of data. This means that the quality of the outputs from generators is limited by the quality of experimental data. The existing neutrino-nucleon and neutrino-nucleus scattering data sets are not restrictive enough to eliminate many approaches. On the other hand, there are various precise data sets, which use photon, charged lepton, and hadron probes. These data sets are extensively used to validate the generators. The results from these external data tuning exercises are important for experiments as they quantify the uncertainty on model parameters, needed by experiments in the evaluation of generator-related systematic errors. Electron scattering data plays an important role in determining the vector contribution to the form-factors and structure functions, as well as in evaluating specific aspects of the nuclear model [15, 16]. Hadron scattering data is used in validating the nuclear model, in particular of interactions between hadrons produced in the primary interaction and the residual target nucleus (final state interactions). As mentioned, tuning of neutrino-nucleon scattering and hadronization models relies heavily on the previous generation of high energy neutrino scattering and hydrogen and deuterium bubble chamber experiments. More recent data from the K2K, MiniBooNE, NOMAD, SciBooNE, MINOS, T2K, ArgoNEUT, MINERvA, NOvA, MicroBooNE, ICARUS, SBND and Ninja experiments has been, or will be, used for this purpose, although caution is advisable due to possible biases that mismodeled nuclear effects might introduce. In practice, there are often choices to be made about which models to include in an overall simulation, and which data sets to use for tuning. The process of developing a comprehensive tune in GENIE is discussed in Ref. [3].

However, all the recent experiments use nuclear targets and it is challenging to disentangle the neutrino-nucleon interaction from the effects of the nuclear environment. For example, it is difficult to separate charged current quasi-elastic scattering from the multi-nucleon quasi-elastic like scattering or single pion production, in which a pion is absorbed in the nucleus. Sometimes, there are tensions between the data sets from different experiments. Data on multi-pion and meson production are limited, but are anticipated to be measured in the near future experiments. Next generation experiments are expected to provide better detection capabilities with higher statistics and these data will help in evaluating and validating the models implemented in the generators.

44.1 Neutrino-Nucleon Scattering

Event generators typically begin with free-nucleon cross sections which are then embedded into a nuclear physics model. The most important processes are quasi-elastic (elastic for neutral current (NC)) scattering, resonance production, and non-resonant inelastic scattering, which make comparable contributions for few-GeV interactions. The neutrino cross sections in this energy range can be seen in Figure 52.1 of this *Review*.

44.1.1 *Quasi-Elastic Scattering*

The cross section for the neutrino nucleon charged current quasi-elastic scattering is described in terms of the leptonic and hadronic weak currents, where dominant contributions to the hadronic current come from the vector (V) and axial-vector (A) form factors. Contributions from the pseudo-scalar form factor (P) are typically small for muon and electron neutrinos and are related to the axial form factor (A) assuming partially conserved axial currents (PCAC). Owing to isospin symmetry, the vector form factors are related to those measured by precise electron scattering experiments [17]. Therefore, most of the generators use parametrizations of these form factors taken directly from the data. For the axial form factor there is no such precise experiment, and most of the generators use a dipole form [18]. Generally, the value of axial form factor at $q^2 = 0$ (q is the four-momentum transfer) is extracted from the polarized nucleon beta decay experiment. However, the selection of the axial vector mass parameter depends on each generator, with values typically around 1.00 GeV/c^2. Recently, there are several attempts to use the other functions for the axial form factors [19, 20] and some generators have already implemented these form factors [8, 21].

44.1.2 *Inelastic Production*

Most generators use the prescriptions of Rein-Sehgal [22] to simulate neutrino-induced single pion production, or updated versions that incorporate lepton mass terms and pion pole contributions [23, 24]. To obtain the cross section for a particular channel, they calculate the amplitude for the production of each resonance multiplied by the probability for the decay of that resonance into that particular channel. Implementation differences include the number of resonances included, whether the amplitudes are added coherently or incoherently, the invariant mass range over which the model is used, how non-resonant backgrounds are included, inclusion of lepton mass terms, and the model parameter values (in particular the axial mass). In this model it is also possible to calculate the cross-sections of single photon, and η production by changing the decay probability of the resonances, which are included in some of the programs. However, it is known that discrepancies exist between the recent pion electro/photo-production data and the results from the simulation data with the same framework, i.e. vector part of this model. There are several attempts to overcome this issue [25] and some of the generators started using more appropriate form factors. Recently, there are approaches that improve the theoretical description of non-resonant contributions in the resonance region, [26–28], and which account for interference between resonant and non-resonant amplitudes. This work is expected to be implemented in the generators soon. GiBUU and NuWro generators do not use the Rein-Sehgal model, and instead rely directly on electro-production data for the vector contribution and fit bubble chamber data to determine the remaining parameters for the axial contribution [29–32]. The dynamical coupled-channel model, which has been developed to simulate various electro- and photo-meson productions, was extended to simulate the neutrino single pion production [33]. In this approach pion-nucleon scattering is used to fix the form of the axial current at $q^2 = 0$. This model is also being implemented and expected to be available in some of the generators in future.

44.1.3 *Deep and Shallow Inelastic Scattering*

For this process the fundamental target shifts from the nucleon to its quark constituents. Therefore, the generators construct the nucleon structure functions F_2 and xF_3 from parton distributions for high Q^2 (the DIS regime: W$\gtrsim$ 2 GeV/c^2 and Q^2 $\gtrsim$ 1 GeV^2) to calculate the direction and momentum of the lepton. The first challenge is in extending this picture to the lower values of Q^2 and W that dominate the available phase space for few-GeV interactions (the so-called 'shallow inelastic scattering', or SIS regime). GRV98LO parton distribution functions [34] with the corrections proposed in [35, 36] are widely used, while others [10] implement their own modifications to the parton distributions at low Q^2. Both DIS and SIS generate hadrons but their production depends on each generator's implementation of a hadronization model as described in the next section. There are various difficulties not only in the actual hadronization but the relation with the single meson production. It is necessary to avoid double counting between the resonance and SIS/DIS models, and all generators are different in this regard. The scheme chosen can have a significant impact on the results of simulations at a few-GeV neutrino energies. For simulating ultra-high energy interactions currently being studied with neutrino telescopes, fully partonic descriptions, which utilize beyond-leading-order pQCD calculations [37, 38] are the norm [39].

44.2 Hadronization Models

For hadrons produced via baryonic resonances, the underlying model amplitudes and resonance branching fractions can be used to fully characterize the hadronic system. For shallow- and deep-inelastic scattering, a hadronization model is required. Most generators use PYTHIA [40] for this purpose, although some with modified parameters. In addition some implement their own models to handle invariant masses that are too low for PYTHIA, typically somewhere around 2.0 GeV/c^2. Such models rely heavily on measurements of neutrino hadro-production in high-resolution devices, such as bubble chambers and the CHORUS [41] and NOMAD experiments [42], to construct empirical parametrizations that reproduce the key features of the data [43, 44]. The basic ingredients are the empirical observations that average charged particle multiplicities increase logarithmically with the invariant mass of the hadronic system, and that the distribution of charged particle multiplicities about this average are described by a single function (an observation known as KNO scaling [45]). The multiplicity of the neutral particles are usually obtained by scaling the charged particle multiplicity. Simple parametrizations to more accurately reproduce differences observed in the forward/backward hemispheres of hadronic systems are included in GENIE, NEUT, and NuWro.

44.3 Nuclear Physics

The nuclear physics relevant to neutrino-nucleus scattering at few-GeV energies is complicated, involving Fermi motion, nuclear binding, Pauli blocking, in-medium modifications of form factors and hadronization, intranuclear rescattering of hadrons, and many-body scattering mechanisms including long- and short-range nucleon-nucleon correlations.

44.3.1 *Treatment of nuclear effects*

In order to obtain the cross-section off nucleons in the nucleus, it is necessary to take into account various in-medium effects. Most of the models used for neutrino-nuclear scattering kinematics were developed in the context of few-GeV inclusive electron scattering, by experiments going back nearly 50 years. The basic models employed in event generators rely on impulse approximation schemes, the most simple of which is the Relativistic Fermi Gas Model. The most common implementations have been the Smith-Moniz [46] and Bodek-Ritchie [47] models. However, the results from neutrino-nucleus scattering experiments in 2000 and afterwards, beginning with K2K, MiniBooNE have shown large discrepancies from the naive expectation from the models. Most striking differences are a suppression of forward going muons (low Q^2), a high Q^2 enhancement in the event rate, and an overall larger than expected number of observed events. In order to reproduce the data, the quasi-elastic axial mass was used as the effective parameter and increased by roughly 20% from the nominal values obtained by an earlier generation of bubble chamber experiments using hydrogen or deuterium [18]. This inconsistency between nucleon and nucleus targets suggests that the simple nuclear model is not appropriate in describing the data. Moreover, these simple Fermi-Gas models are not expected to describe the kinematical distributions of final state nucleons. Therefore, several generators have to implement better models, such as local Fermi-Gas model or more sophisticated models. Within the electron scattering community, the analogous calculations have for decades relied on spectral functions, which incorporate information about nucleon momenta and binding energies in the impulse approximation scheme [15]. Therefore, most of the generators have implemented the realistic spectral functions in their latest releases.

Actually, the discrepancies in small q^2 could not be solved alone

by just introducing the local Fermi-gas model nor spectral function models. This implies that the additional medium correction effects are needed to be taken into account. One of the implemented solutions is the local Fermi-Gas model with medium correction calculated using the random phase approximation, which is known to give large suppression in small q^2 [48,49]. Although, the fundamental parts of the models are same, actual implementations are quite different between the generators. Especially, the constructions of the final state hadron kinematics are quite different. Especially for the quasi-elastic scattering case, treatment of the nucleon masses in the nucleus, the binding and the separation energies are sometimes quite different [50]. Recently, Super-Scaling model with relativistic mean field theory effects (SuSAv2) [51,52] is implemented in some of the generators. Indications of the suppression in small q^2 in the single pion productions were also observed in K2K and MiniBooNE and it is clearly observed at the MINERνA and NOνA experiments. However, the models to explain the suppression have not been implemented, other than the phenomenological ones. Also, q^2 dependence of the cross-section is largely model and parameter dependent. Further studies of newly implemented single pion models may give new insights. The cause of the discrepancy of small q^2 seems to be identified but the issue of the observed interaction rates are not solved. This implies that there must be some interaction channels which are missing and not considered in the generators.

These led to a revisitation of the role played by excitation of multiple particle-hole states in the nucleus, and the experimental study of these scattering channels is an area of intense experimental interest [53]. The contribution of these scattering processes is an extremely active area of theoretical research as well, with significant implications for generators and analyses [54]. Several approaches, ranging from strictly phenomenological descriptions to full theoretical calculations, have recently been incorporated into generators [55–57]. One example of a phenomenological approach utilizes an Effective Spectral Function [58] and a Transverse Enhancement Model [59], which together encapsulate information derived from electron scattering experiments at relevant kinematics. The microscopic model of Nieves and collaborators is now available in GENIE and NEUT [60,61]. SuSAv2 model [52] also has capability to simulate this multi-nucleon quasi-elastic like interaction and is also implemented in GENIE.

One of the challenges in incorporating full theoretical models of these processes is that they are typically slow, so generators have developed new approaches whereby much of the computation is done offline, and the generators simply read in the hadronic tensor components. This allows for a full prediction of the lepton kinematics, however the ability to simulate the hadronic component of these multinucleon states then relies on separate models. The other challenge is that the theoretical models are not designed to describe exclusive final states. These approaches, while making simulations computationally tractable, neglect correlations between the lepton and hadron kinematics. Also, there are limitations of the model itself to describe some of the kinematic regions. However, the generators need to simulate final all the state particles and thus, several assumptions are made by authors of the generators from time to time.

Also, it is known from photo and electro-nuclear scattering that the Delta width is affected by Pauli blocking and collisional broadening. These effects are included in some, but not all generators.

The remnant nucleus after the scattering is usually in an excited state. Therefore, the remnant may emit gamma-rays, additional nucleons or an alpha particle during the de-excitation process. This de-excitation gamma-ray is used in searching for proton decay in water Cherenkov detectors. Some generators have implemented this process. NEUT implemented the de-excitation process but only for Oxygen. Recently, GENIE has de-excitation processes for various nuclei.

When scattering from a nucleus, coherent scattering of various kinds is possible. Most simulations incorporate, at least, coherent neutral and charged single pion production. While the interaction rate for these interactions is typically around a percent of the total yield, the unique kinematic features of these events can make them potential backgrounds for oscillation searches. Implemented in Monte Carlo are several PCAC-based methods [62,63]. Microscopic models, valid at lower neutrino energies [64–67], have also been implemented in several generators. One commonly used model by Rein and Sehgal [62] predicts a cross section for charged-current coherent pion production that is much larger than what is observed by K2K, MINERvA and T2K. However, the cross-section is sensitive to the pion cross-section used in the model as parameters and improved models with lepton mass correction [63] give better agreement with the recent data. This improved model is implemented in most of the generators. In addition to coherent pion production, some generators can simulate coherent single photon production [68] and coherent elastic neutrino-nucleus scattering.

44.3.2 *Hadron Production in Nuclei*

Neutrino pion production is one of the dominant neutrino scattering mechanisms in the few-GeV region and the pions produced in the nucleus have quite large interaction cross sections. Therefore, pion intranuclear scattering can have sizable effects on the results of simulations at these energies. Also, recent neutrino oscillation experiments use the observed information of protons and pions more extensively, in addition to the charged leptons. Therefore, most generators implement this physics through an intranuclear cascade simulation. In generators which utilize cascade models, a hadron, which has been formed in the nucleus, is moved step by step until it interacts with a nucleon or escapes from the nucleus. The probabilities of each interaction in nucleus are usually given as the mean free paths and used to determine whether the hadron has interacted or not. If the hadron is found to have interacted, appropriate final states are selected. Usually, absorption, elastic, charge exchange, and inelastic scatterings including particle productions are simulated as intranuclear interactions. The determination method of the kinematics for the final state particles heavily depends on the generators but most of them use experimentally validated models to simulate hadron interactions in nucleus. No two intranuclear cascade simulations implemented in neutrino event generators are the same [69]. In all cases hadrons propagate from an interaction vertex chosen based on the density distribution of the target nucleus. In determining the generated position of the hadrons in nucleus, the concept of the formation length is sometimes employed. Based on this idea, the hadronization process is not instantaneous and it takes some time before generating the hadrons [12]. The basis for formation times are measurements at relatively high energy and Q^2, and most generators that employ the concept do not apply them to resonance interactions.

GiBUU does not employ an intranuclear cascade simulation, instead, it utilizes a semi-classical transport model in coupled channels that describes the space-time evolution of a many body system in the presence of potentials and a collision term [4]. This approach assures consistency between nuclear effects in the initial state, such as Fermi motion, Pauli blocking, hadron self-energies [70], and modified cross sections, and the final state, such as particle re-interactions, since the two are derived from the same model. This model has been previously used to describe a wide variety of nuclear interaction data. Similarly, the hadronic simulation of the NUNDIS/NUNRES programs are handled by the well-established FLUKA hadronic simulation package [10]. Recently, GENIE included the interface to the external hadronic simulation package INCL++ [71].

45. Monte Carlo Particle Numbering Scheme

Revised August 2021 by F. Krauss (Durham U.), S. Navas (Granada U.), P. Richardson (Durham U.) and T. Sjöstrand (Lund U.).

The Monte Carlo particle numbering scheme presented here is intended to facilitate interfacing between matrix-element generators, event generators, detector simulators, and analysis packages used in particle physics, and is widely accepted as the "industry standard". The numbering scheme was introduced in 1988 [1], and has since been revised and expanded in the light of new information on hadronic resonances, and expanded to encompass as yet undiscovered and hypothetical particles.

The general form is a 7–digit number:

$$\pm n\ n_r\ n_L\ n_{q_1}\ n_{q_2}\ n_{q_3}\ n_J\ .$$

This encodes information about the particle's spin, flavor content, and internal quantum numbers. A 9–digit extension is used specifically for tetra- and penta-quark states, and a distinct 10-digit scheme is used for encoding (hyper)nuclear states. The details are as follows:

1. Particles are given positive numbers, antiparticles negative numbers. The PDG convention for mesons is used, so that K^+ and B^+ are particles.
2. Quarks and leptons are numbered consecutively starting from 1 and 11 respectively; to do this they are first ordered by family and within families by weak isospin.
3. In composite quark systems (diquarks, mesons, and baryons) $n_{q_{1-3}}$ are quark numbers used to specify the quark content, while the rightmost digit $n_J = 2J+1$ gives the system's spin (except for the K^0_S and K^0_L). The scheme does not cover particles of spin $J > 4$.
4. Diquarks have 4-digit numbers with $n_{q_1} \geq n_{q_2}$ and $n_{q_3} = 0$.
5. The numbering of mesons is guided by the nonrelativistic (L–S decoupled) quark model, as listed in Tables 15.2, 15.3, and 15.4.
   (a) The numbers specifying the meson's quark content conform to the convention $n_{q_1} = 0$ and $n_{q_2} \geq n_{q_3}$. The special case K^0_L is the sole exception to this rule.
   (b) The quark numbers of flavorless, light (u, d, s) mesons are: 11 for the member of the isotriplet $(\pi^0, \rho^0, \ldots)$, 22 for the lighter isosinglet $(\eta, \omega, \ldots)$, and 33 for the heavier isosinglet $(\eta', \phi, \ldots)$. Since isosinglet mesons are often large mixtures of $u\bar{u} + d\bar{d}$ and $s\bar{s}$ states, 22 and 33 are assigned by mass and do not necessarily specify the dominant quark composition.
   (c) The special numbers 310 and 130 are given to the K^0_S and K^0_L respectively.
   (d) The fifth digit n_L is reserved to distinguish mesons of the same total (J) but different spin (S) and orbital (L) angular momentum quantum numbers. For $J > 0$ the numbers are: $(L, S) = (J-1, 1)$ $n_L = 0$, $(J, 0)$ $n_L = 1$, $(J, 1)$ $n_L = 2$ and $(J+1, 1)$ $n_L = 3$. For the exceptional case $J = 0$ the numbers are $(0, 0)$ $n_L = 0$ and $(1, 1)$ $n_L = 1$ (*i.e.* $n_L = L$). See Table 45.1.
   (e) If a set of physical mesons correspond to a (non-negligible) mixture of basis states, differing in their internal quantum numbers, then the lightest physical state gets the smallest basis state number. For example the $K_1(1270)$ is numbered 10313 (1^1P_1 K_{1B}) and the $K_1(1400)$ is numbered 20313 (1^3P_1 K_{1A}).
   (f) The sixth digit n_r is used to label mesons radially excited above the ground state.
   (g) Numbers have been assigned for complete $n_r = 0$ S- and P-wave multiplets, even where states remain to be identified.
   (h) In some instances assignments within the $q\bar{q}$ meson model are only tentative; here best guess assignments are made.
   (i) Many states appearing in the Meson Listings are not yet assigned within the $q\bar{q}$ model. Here $n_{q_{2-3}}$ and n_J are assigned according to the state's likely flavors and spin; all such unassigned light isoscalar states are given the flavor code 22. Within these groups $n_L = 0, 1, 2, \ldots$ is used to distinguish states of increasing mass. These states are flagged using $n = 9$. It is to be expected that these numbers will evolve as the nature of the states are elucidated. Codes are assigned to all mesons which are listed in the one-page table at the end of the Meson Summary Table as long as they have a prefered or established spin. Additional heavy meson states expected from heavy quark spectroscopy are also assigned codes.
6. The numbering of baryons is again guided by the nonrelativistic quark model, see Table 15.6. This numbering scheme is illustrated through a few examples in Table 45.2.
   (a) The numbers specifying a baryon's quark content are such that in general $n_{q_1} \geq n_{q_2} \geq n_{q_3}$.
   (b) Two states exist for $J = 1/2$ baryons containing 3 different types of quarks. In the lighter baryon $(\Lambda, \Xi, \Omega, \ldots)$ the light quarks are in an antisymmetric ($J = 0$) state while for the heavier baryon $(\Sigma^0, \Xi', \Omega', \ldots)$ they are in a symmetric ($J = 1$) state. In this situation n_{q_2} and n_{q_3} are reversed for the lighter state, so that the smaller number corresponds to the lighter baryon.
   (c) For excited baryons a scheme is adopted, where the n_r label is used to denote the excitation bands in the harmonic oscillator model, see Sec. 15.5. Using the notation employed there, n_r is given by the N-index of the D_N band identifier.
   (d) Further degeneracies of excited hadron multiplets with the same excitation number n_r and spin J are lifted by labelling such multiplets with the n_L index according to their mass, as given by its N or Δ-equivalent.
   (e) In such excited multiplets extra singlets may occur, the $\Lambda(1520)$ being a prominent example. In such cases the ordering is reversed such that the heaviest quark label is pushed to the last position: $n_{q_3} > n_{q_1} > n_{q_2}$.
7. The gluon, when considered as a gauge boson, has official number 21. In codes for glueballs, however, 9 is used to allow a notation in close analogy with that of hadrons.
8. The pomeron and odderon trajectories and a generic reggeon trajectory of states in QCD are assigned codes 990, 9990, and 110 respectively, where the final 0 indicates the indeterminate nature of the spin, and the other digits reflect the expected "valence" flavor content. We do not attempt a complete classification of all reggeon trajectories, since there is currently no need to distinguish a specific such trajectory from its lowest-lying member.
9. Two-digit numbers in the range 21–30 are provided for the Standard Model gauge and Higgs bosons.
10. Codes 81–100 are reserved for generator-specific pseudoparticles and concepts. Codes 901–930, 1901–1930, 2901–2930, and 3901–3930 are for additional components of Standard Model parton distribution functions, where the latter three ranges are intended to distinguish left/ right/ longitudinal components. Codes 998 and 999 are reserved for GEANT tracking purposes.

Table 45.1: Meson numbering logic. Here qq stands for $n_{q2}\, n_{q3}$.

	$L = J-1$, $S = 1$			$L = J$, $S = 0$			$L = J$, $S = 1$			$L = J+1$, $S = 1$		
J	code	J^{PC}	L	code	J^{PC}	L	code	J^{PC}	L	code	J^{PC}	L
0	—	—	—	00qq1	0^{-+}	0	—	—	—	10qq1	0^{++}	1
1	00qq3	1^{--}	0	10qq3	1^{+-}	1	20qq3	1^{++}	1	30qq3	1^{--}	2
2	00qq5	2^{++}	1	10qq5	2^{-+}	2	20qq5	2^{--}	2	30qq5	2^{++}	3

11. The search for physics beyond the Standard Model is an active area, so these codes are also standardized as far as possible.

    (a) A standard fourth generation of fermions is included by analogy with the first three.

    (b) The graviton and the boson content of a two-Higgs-doublet scenario and of additional SU(2)×U(1) groups are found in the range 31–40.

    (c) "One-of-a-kind" exotic particles are assigned numbers in the range 41–80.The subrange 61-80 can be used for new heavier fermions in generic models, where partners to the SM fermions would have codes offset by 60. If required, however, other assignments could be made.

    (d) Fundamental supersymmetric particles are identified by adding a nonzero n to the particle number. The superpartner of a boson or a left-handed fermion has $n = 1$ while the superpartner of a right-handed fermion has $n = 2$. When mixing occurs, such as between the winos and charged Higgsinos to give charginos, or between left and right sfermions, the lighter physical state is given the smaller basis state number.

    (e) Technicolor states have $n = 3$, with technifermions treated like ordinary fermions. States which are ordinary color singlets have $n_r = 0$. Color octets have $n_r = 1$. If a state has non-trivial quantum numbers under the topcolor groups $\mathrm{SU}(3)_1 \times \mathrm{SU}(3)_2$, the quantum numbers are specified by tech,ij, where i and j are 1 or 2. n_L is then $2i + j$. The coloron, V_8, is a heavy gluon color octet and thus is 3100021.

    (f) Excited (composite) quarks and leptons are identified by setting $n = 4$ and $n_r = 0$.

    (g) Within several scenarios of new physics, it is possible to have colored particles sufficiently long-lived for color-singlet hadronic states to form around them. In the context of supersymmetric scenarios, these states are called R-hadrons, since they carry odd R-parity. R-hadron codes, defined here, should be viewed as templates for corresponding codes also in other scenarios, for any long-lived particle that is either an unflavored color octet or a flavored color triplet. The R-hadron code is obtained by combining the SUSY particle code with a code for the light degrees of freedom, with as many intermediate zeros removed from the former as required to make place for the latter at the end. (To exemplify, a sparticle $n00000n_{\tilde{q}}$ combined with quarks q_1 and q_2 obtains code $n00n_{\tilde{q}}n_{q_1}n_{q_2}n_J$.) Specifically, the new-particle spin decouples in the limit of large masses, so that the final n_J digit is defined by the spin state of the light-quark system alone. An appropriate number of n_q digits is used to define the ordinary-quark content. As usual, 9 rather than 21 is used to denote a gluon/gluino in composite states. The sign of the hadron agrees with that of the constituent new particle (a color triplet) where there is a distinct new antiparticle, and else is defined as for normal hadrons. Particle names are R with the flavor content as lower index.

    (h) A black hole in models with extra dimensions has code 5000040. Kaluza-Klein excitations in models with extra dimensions have $n = 5$ or $n = 6$, to distinquish excitations of left- or right-handed fermions or, in case of mixing, the lighter or heavier state (cf. 11d). The nonzero n_r digit gives the radial excitation number, in scenarios where the level spacing allow these to be distinguished. Should the model also contain supersymmetry, excited SUSY states would be denoted by an $n_r > 0$, with $n = 1$ or 2 as usual. Should some colored states be long-lived enough that hadrons would form around them, the coding strategy of 11g applies, with the initial two nn_r digits preserved in the combined code.

    (i) Magnetic monopoles and dyons are assumed to have one unit of Dirac monopole charge and a variable integer number $n_{q1}n_{q_2}n_{q_3}$ units of electric charge. Codes $411n_{q1}n_{q_2}n_{q_3}0$ are then used when the magnetic and electrical charge sign agree and $412n_{q1}n_{q_2}n_{q_3}0$ when they disagree, with the overall sign of the particle set by the magnetic charge. For now no spin information is provided.

    (j) The nature of Dark Matter (DM) is not known, and therefore a definitive classification is too early. Candidates within specific scenarios are classified therein, such as 1000022 for the lightest neutralino. Generic fundamental states can be given temporary codes in the range 51 - 60, with 51, 52 and 53 reserved for spin 0, 1/2 and 1 ones (this could also be an axion state). Generic mediators of s-channel DM pair creation of annihilation can be given codes 54 and 55 for spin 0 or 1 ones. Separate antiparticles, with negative codes, may or may not exist. More elaborate new scenarios should be constructed with $n = 5$ and $n_r = 9$.

    (k) Hidden Valley particles have $n = 4$ and $n_r = 9$, and trailing numbers in agreement with their nearest-analog standard particles, as far as possible. Thus 4900021 is the gauge boson g_v of a confining gauge field, $490000n_{q_v}$ and $490001n_{\ell_v}$ fundamental constituents charged or not under this, 4900022 is the γ_v of a non-confining field, and $4900n_{q_{v1}}n_{q_{v2}}n_J$ a Hidden Valley meson.

12. Occasionally program authors add their own states. To avoid confusion, these should be flagged by setting $nn_r = 99$.

13. Concerning the non-99 numbers, it may be noted that only quarks, excited quarks, squarks, and diquarks have $n_{q_3} = 0$; only diquarks, baryons, and the odderon have $n_{q_1} \neq 0$; and only mesons, the reggeon, and the pomeron have $n_{q_1} = 0$ and $n_{q_2} \neq 0$. Concerning mesons (not antimesons), if n_{q_1} is odd then it labels a quark and an antiquark if even.

14. The 9-digit tetra-quark codes are $\pm 1 n_r n_L n_{q_1} n_{q_2} 0 n_{q_3} n_{q_4} n_J$. For the particle q_1q_2 is a diquark and $\bar{q}_3\bar{q}_4$ an antidiquark,

sorted such that $n_{q_1} \geq n_{q_2}$, $n_{q_3} \geq n_{q_4}$, $n_{q_1} \geq n_{q_3}$, and $n_{q_2} \geq n_{q_4}$ if $n_{q_1} = n_{q_3}$. For the antiparticle, given with a negative sign, $\bar{q}_1\bar{q}_2$ is an antidiquark and q_3q_4 a diquark, with the same sorting except that either $n_{q_1} > n_{q_3}$ or $n_{q_2} > n_{q_4}$ (so that flavour-diagonal states are particles). The n_r, n_L, and n_J numbers have the same meaning as for ordinary hadrons.

15. The 9-digit penta-quark codes are $\pm 1 n_r n_L n_{q_1} n_{q_2} n_{q_3} n_{q_4} n_{q_5} n_J$, sorted such that $n_{q_1} \geq n_{q_2} \geq n_{q_3} \geq n_{q_4}$. In the particle the first four are quarks and the fifth an antiquark while the opposite holds in the antiparticle, which is given with a negative sign. The n_r, n_L, and n_J numbers have the same meaning as for ordinary hadrons.

16. Nuclear codes are given as 10-digit numbers $\pm 10LZZZAAAI$. For a (hyper)nucleus consisting of n_p protons, n_n neutrons and n_Λ Λ's, $A = n_p + n_n + n_\Lambda$ gives the total baryon number, $Z = n_p$ the total charge and $L = n_\Lambda$ the total number of strange quarks. I gives the isomer level, with $I = 0$ corresponding to the ground state and $I > 0$ to excitations, see [2], where states denoted m, n, p, q translate to $I = 1$–4. As examples, the deuteron is 1000010020 and ^{235}U is 1000922350. To avoid ambiguities, nuclear codes should not be applied to a single hadron, like p, n or Λ^0, where quark-contents-based codes already exist.

PENTAQUARKS	
$\boldsymbol{\Theta^+}$	**100221132**∗
$\boldsymbol{\Phi^{--}}$	**100331122**∗

Footnotes to the tables:

∗) Numbers or names in bold face are new or have changed since the 2020 *Review*.

a) Particulary in the third generation, the left and right sfermion states may mix, as shown.

The lighter mixed state is given the smaller number.

b) The physical $\widetilde{\chi}$ states are admixtures of the pure $\widetilde{\gamma}$, $\widetilde{Z}^0$, $\widetilde{W}^+$, $\widetilde{H}_1^0$, $\widetilde{H}_2^0$, and $\widetilde{H}^+$ states.

c) Σ^* and Ξ^* are alternate names for $\Sigma(1385)$ and $\Xi(1530)$.

46. Clebsch-Gordan Coefficients, Spherical Harmonics, and *d* Functions

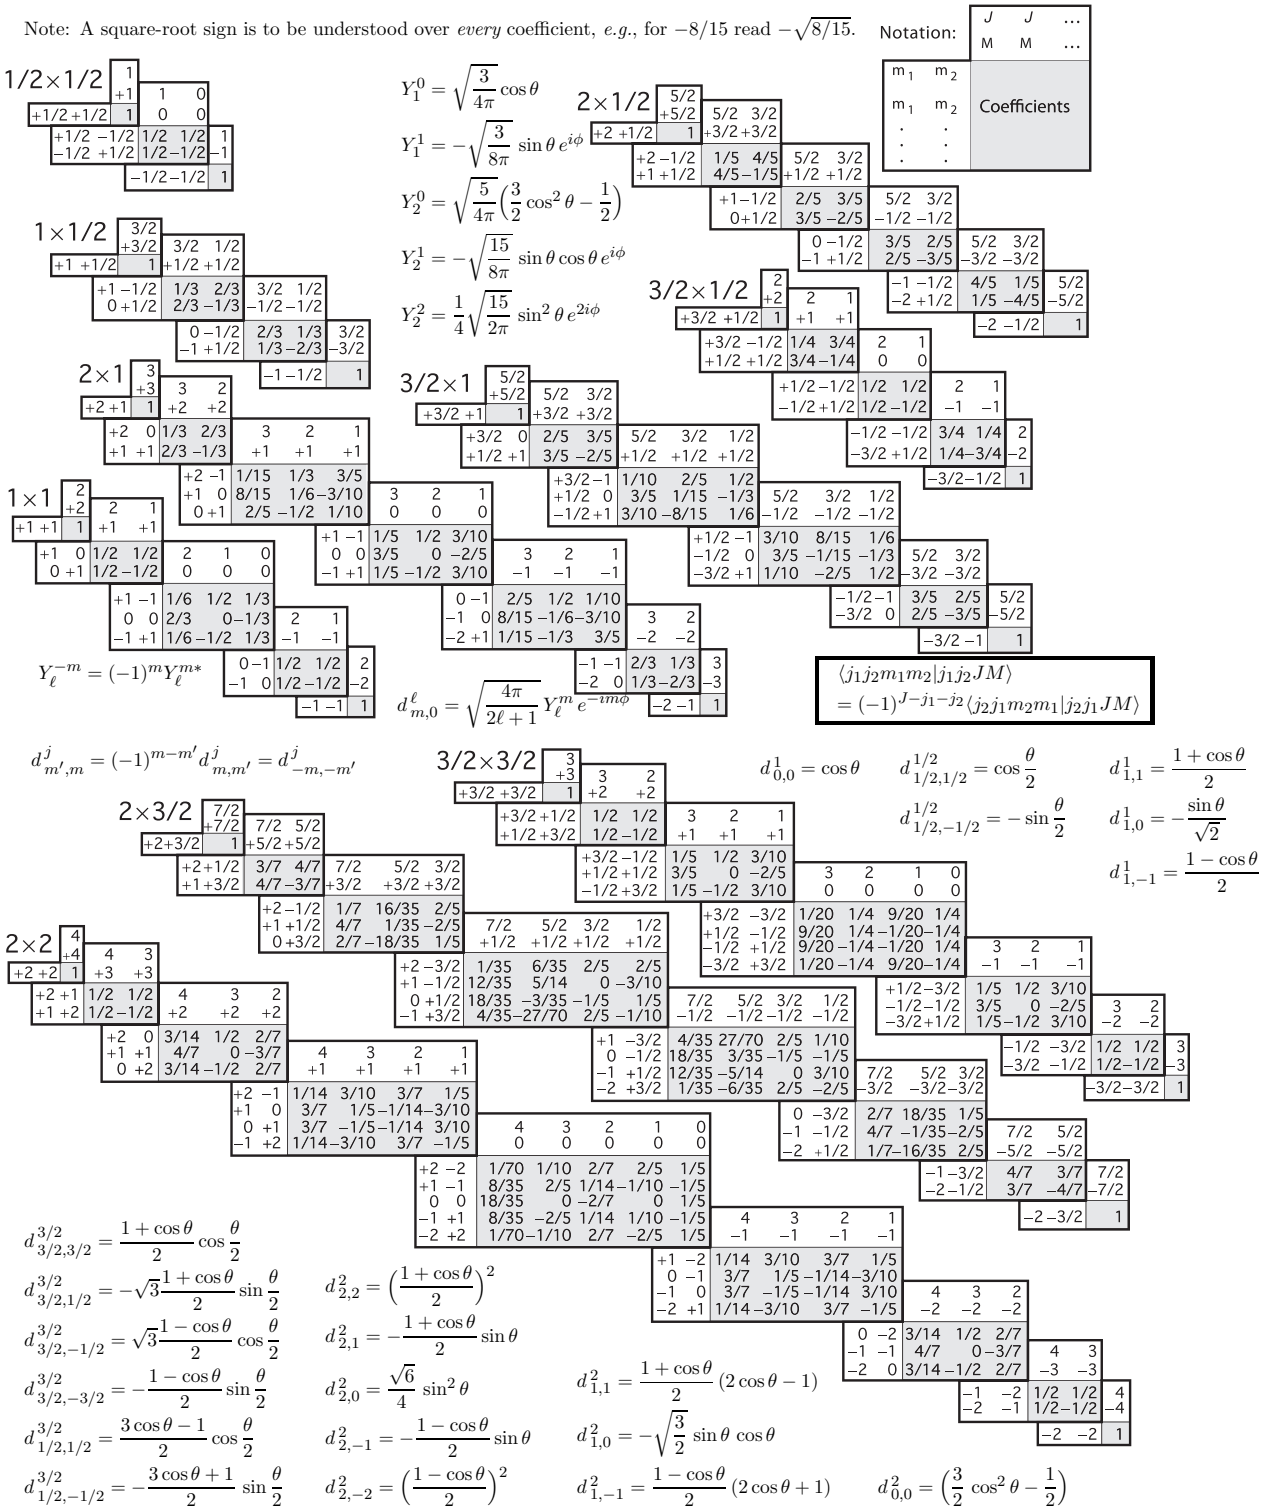

Figure 46.1: The sign convention is that of Wigner (*Group Theory*, Academic Press, New York, 1959), also used by Condon and Shortley (*The Theory of Atomic Spectra*, Cambridge Univ. Press, New York, 1953), Rose (*Elementary Theory of Angular Momentum*, Wiley, New York, 1957), and Cohen (*Tables of the Clebsch-Gordan Coefficients*, North American Rockwell Science Center, Thousand Oaks, Calif., 1974).

47. SU(3) Isoscalar Factors and Representation Matrices

Revised August 2019 by R. Kelly (LBNL).

The most commonly used SU(3) isoscalar factors, corresponding to the singlet, octet, and decuplet content of $8 \otimes 8$ and $10 \otimes 8$, are shown at the right. The notation uses particle names to identify the coefficients, so that the pattern of relative couplings may be seen at a glance. We illustrate the use of the coefficients below. See J.J de Swart, Rev. Mod. Phys. **35**, 916 (1963) for detailed explanations and phase conventions.

A $\sqrt{\ }$ is to be understood over every integer in the matrices; the exponent 1/2 on each matrix is a reminder of this. For example, the $\Xi \to \Omega K$ element of the $10 \to 10 \otimes 8$ matrix is $-\sqrt{6}/\sqrt{24} = -1/2$.

Intramultiplet relative decay strengths may be read directly from the matrices. For example, in decuplet $\to$ octet + octet decays, the ratio of $\Omega^* \to \Xi\overline{K}$ and $\Delta \to N\pi$ partial widths is, from the $10 \to 8 \times 8$ matrix,

$$\frac{\Gamma\,(\Omega^* \to \Xi\overline{K})}{\Gamma\,(\Delta \to N\pi)} = \frac{12}{6} \times \text{ (phase space factors)} \,. \tag{47.1}$$

Including isospin Clebsch-Gordan coefficients, we obtain, *e.g.*,

$$\frac{\Gamma(\Omega^{*-} \to \Xi^0 K^-)}{\Gamma(\Delta^+ \to p\,\pi^0)} = \frac{1/2}{2/3} \times \frac{12}{6} \times p.s.f. = \frac{3}{2} \times p.s.f. \tag{47.2}$$

Partial widths for $8 \to 8 \otimes 8$ involve a linear superposition of 8_1 (symmetric) and 8_2 (antisymmetric) couplings. For example,

$$\Gamma(\Xi^* \to \Xi\pi) \sim \left(-\sqrt{\frac{9}{20}}\, g_1 + \sqrt{\frac{3}{12}}\, g_2\right)^2 \,. \tag{47.3}$$

The relations between g_1 and g_2 (with de Swart's normalization) and the standard D and F couplings that appear in the interaction Lagrangian,

$$\mathscr{L} = -\sqrt{2}\; D\; Tr\,(\{\overline{B}, B\}M) + \sqrt{2}\; F\; Tr\,([\overline{B}, B]\,M) \;\;, \tag{47.4}$$

where $[\overline{B}, B] \equiv \overline{B}B - B\overline{B}$ and $\{\overline{B}, B\} \equiv \overline{B}B + B\overline{B}$, are

$$D = \frac{\sqrt{30}}{40}\; g_1 \;, \qquad F = \frac{\sqrt{6}}{24}\; g_2 \;. \tag{47.5}$$

Thus, for example,

$$\Gamma(\Xi^* \to \Xi\pi) \sim (F - D)^2 \sim (1 - 2\alpha)^2 \;, \tag{47.6}$$

where $\alpha \equiv F/(D + F)$. (This definition of α is de Swart's. The alternative $D/(D + F)$, due to Gell-Mann, is also used.)

The generators of SU(3) transformations, λ_a $(a = 1, 8)$, are 3×3 matrices that obey the following commutation and anticommutation relationships:

$$[\lambda_a,\ \lambda_b] \equiv \lambda_a\lambda_b - \lambda_b\lambda_a = 2if_{abc}\lambda_c \tag{47.7}$$

$$\{\lambda_a,\ \lambda_b\} \equiv \lambda_a\lambda_b + \lambda_b\lambda_a = \frac{4}{3}\delta_{ab}I + 2d_{abc}\lambda_c \;, \tag{47.8}$$

where I is the 3×3 identity matrix, and δ_{ab} is the Kronecker delta symbol. The f_{abc} are odd under the permutation of any pair of indices, while the d_{abc} are even. The nonzero values are:

$1 \to 8 \otimes 8$

$$\begin{pmatrix}\Lambda\end{pmatrix} \to \begin{pmatrix} N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \end{pmatrix} = \frac{1}{\sqrt{8}} \begin{pmatrix} 2 & 3 & -1 & -2 \end{pmatrix}^{1/2}$$

$8_1 \to 8 \otimes 8$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{20}} \begin{pmatrix} 9 & -1 & -9 & -1 \\ -6 & 0 & 4 & 4 & -6 \\ 2 & -12 & -4 & -2 \\ 9 & -1 & -9 & -1 \end{pmatrix}^{1/2}$$

$8_2 \to 8 \otimes 8$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} 3 & 3 & 3 & -3 \\ 2 & 8 & 0 & 0 & -2 \\ & 6 & 0 & 0 & 6 \\ & 3 & 3 & 3 & -3 \end{pmatrix}^{1/2}$$

$10 \to 8 \otimes 8$

$$\lambda_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_2 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

$$\lambda_4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \lambda_5 = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix} \quad \lambda_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

$$\lambda_7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad \lambda_8 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}$$

Equation (47.7) defines the Lie algebra of SU(3). A general d-dimensional representation is given by a set of $d \times d$ matrices satisfying Eq. (47.7) with the f_{abc} given above. Equation (47.8) is specific to the defining 3-dimensional representation.

48. SU(n) Multiplets and Young Diagrams

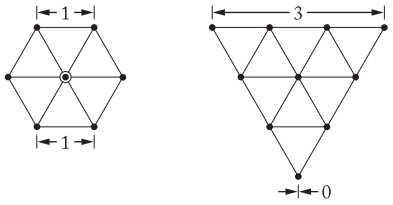
Revised August 2019 by C.G. Wohl (LBNL).

This note tells (1) how SU(n) particle multiplets are identified or labeled, (2) how to find the number of particles in a multiplet from its label, (3) how to draw the Young diagram for a multiplet, and (4) how to use Young diagrams to determine the overall multiplet structure of a composite system, such as a 3-quark or a meson-baryon system.

In much of the literature, the word "representation" is used where we use "multiplet," and "tableau" is used where we use "diagram."

48.1 Multiplet labels

An SU(n) multiplet is uniquely identified by a string of ($n-1$) nonnegative integers: $(\alpha, \beta, \gamma, \ldots)$. Any such set of integers specifies a multiplet. For an SU(2) multiplet such as an isospin multiplet, the single integer α is the number of *steps* from one end of the multiplet to the other (*i.e.*, it is one fewer than the number of particles in the multiplet). In SU(3), the two integers α and β are the numbers of steps across the top and bottom levels of the multiplet diagram. Thus the labels for the SU(3) octet and decuplet



are (1,1) and (3,0). For larger n, the interpretation of the integers in terms of the geometry of the multiplets, which exist in an ($n-1$)-dimensional space, is not so readily apparent.

The label for the SU(n) singlet is $(0, 0, \ldots, 0)$. In a flavor SU(n), the n quarks together form a $(1, 0, \ldots, 0)$ multiplet, and the n antiquarks belong to a $(0, \ldots, 0, 1)$ multiplet. These two multiplets are *conjugate* to one another, which means their labels are related by $(\alpha, \beta, \ldots) \leftrightarrow (\ldots, \beta, \alpha)$.

48.2 Number of particles

The number of particles in a multiplet, $N = N(\alpha, \beta, \ldots)$, is given as follows (note the pattern of the equations). In SU(2), $N = N(\alpha)$ is

$$N = \frac{(\alpha+1)}{1} \ . \tag{48.1}$$

In SU(3), $N = N(\alpha, \beta)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} \ . \tag{48.2}$$

In SU(4), $N = N(\alpha, \beta, \gamma)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\gamma+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} \cdot \frac{(\beta+\gamma+2)}{2} \cdot \frac{(\alpha+\beta+\gamma+3)}{3} \ . \tag{48.3}$$

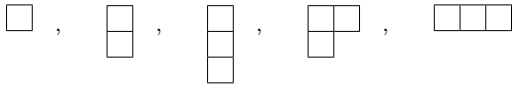
Note that in Eq. (48.3) there is no factor with $(\alpha+\gamma+2)$: only a *consecutive* sequence of the label integers appears in any factor. One more example should make the pattern clear for any SU(n). In SU(5), $N = N(\alpha, \beta, \gamma, \delta)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\gamma+1)}{1} \cdot \frac{(\delta+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} \cdot \frac{(\beta+\gamma+2)}{2} \times \frac{(\gamma+\delta+2)}{2} \cdot \frac{(\alpha+\beta+\gamma+3)}{3} \cdot \frac{(\beta+\gamma+\delta+3)}{3} \cdot \frac{(\alpha+\beta+\gamma+\delta+4)}{4} \ . \tag{48.4}$$

From the symmetry of these equations, it is clear that multiplets that are conjugate to one another have the same number of particles, but so can other multiplets. For example, the SU(4) multiplets (3,0,0) and (1,1,0) each have 20 particles. Try the equations and see.

48.3 Young diagrams

A Young diagram consists of an array of boxes (or some other symbol) arranged in one or more *left-justified* rows, with each row being *at least as long* as the row beneath. The correspondence between a diagram and a multiplet label is: The top row juts out α boxes to the right past the end of the second row, the second row juts out β boxes to the right past the end of the third row, *etc.* A diagram in SU(n) has at most n rows. There can be any number of "completed" columns of n boxes buttressing the left of a diagram; these don't affect the label. Thus in SU(3) the diagrams



represent the multiplets (1,0), (0,1), (0,0), (1,1), and (3,0). In any SU(n), the quark multiplet is represented by a single box, the antiquark multiplet by a column of ($n-1$) boxes, and a singlet by a completed column of n boxes.

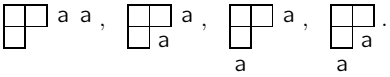
48.4 Coupling multiplets together

The following recipe tells how to find the multiplets that occur in coupling two multiplets together. To couple together more than two multiplets, first couple two, then couple a third with each of the multiplets obtained from the first two, *etc.*

First a definition: A sequence of the letters $a, b, c, \ldots$ is *admissible* if at any point in the sequence at least as many a's have occurred as b's, at least as many b's have occurred as c's, *etc.* Thus *abcd* and *aabcb* are admissible sequences and *abb* and *acb* are not. Now the recipe:

(a) Draw the Young diagrams for the two multiplets, but in one of the diagrams replace the boxes in the first row with a's, the boxes in the second row with b's, *etc.* Thus, to couple two SU(3) octets (such as the π-meson octet and the baryon octet), we start with  and . The *unlettered* diagram forms the *upper left-hand corner* of all the enlarged diagrams constructed below.

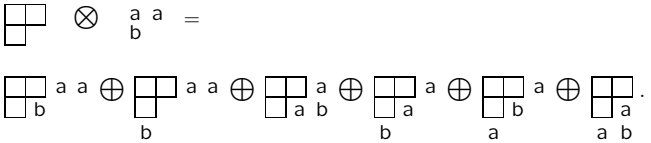
(b) Add the a's from the lettered diagram to the right-hand ends of the rows of the unlettered diagram to form all possible legitimate Young diagrams that have no more than one a per column. In general, there will be several distinct diagrams, and all the a's appear in each diagram. At this stage, for the coupling of the two SU(3) octets, we have:



(c) Use the b's to further enlarge the diagrams already obtained, subject to the same rules. Then throw away any diagram in which the full sequence of letters formed by reading *right to left* in the first row, then the second row, *etc.*, is not admissible.

(d) Proceed as in (c) with the c's (if any), *etc.*

The final result of the coupling of the two SU(3) octets is:



Here only the diagrams with admissible sequences of a's and b's and with fewer than four rows (since $n = 3$) have been kept. In terms of multiplet labels, the above may be written

$$(1,1) \otimes (1,1) = (2,2) \oplus (3,0) \oplus (0,3) \oplus (1,1) \oplus (1,1) \oplus (0,0) \ .$$

In terms of numbers of particles, it may be written

$$\mathbf{8} \otimes \mathbf{8} = \mathbf{27} \oplus \mathbf{10} \oplus \overline{\mathbf{10}} \oplus \mathbf{8} \oplus \mathbf{8} \oplus \mathbf{1} \ .$$

The product of the numbers on the left here is equal to the sum on the right, a useful check. (See also Sec. 15 on the Quark Model.)

Kinematics, Cross-Section Formulae, and Plots

49. Kinematics

Reviewed August 2021 by D. Miller (Glasgow), D.R. Tovey (Sheffield), written January 2000 by J.D. Jackson (LBNL).

Throughout this section units are used in which $\hbar = c = 1$. The following conversions are useful: $\hbar c = 197.3$ MeV fm, $(\hbar c)^2 = 0.3894$ (GeV)^2 mb.

49.1 Lorentz transformations

The energy E and 3-momentum $\boldsymbol{p}$ of a particle of mass m form a 4-vector $p = (E, \boldsymbol{p})$ whose square $p^2 \equiv E^2 - |\boldsymbol{p}|^2 = m^2$. The velocity of the particle is $\boldsymbol{\beta} = \boldsymbol{p}/E$. The energy and momentum $(E^*, \boldsymbol{p}^*)$ viewed from a frame moving with velocity $\boldsymbol{\beta}_f$ are given by

$$\begin{pmatrix} E^* \\ p_\parallel^* \end{pmatrix} = \begin{pmatrix} \gamma_f & -\gamma_f \beta_f \\ -\gamma_f \beta_f & \gamma_f \end{pmatrix} \begin{pmatrix} E \\ p_\parallel \end{pmatrix} , \quad p_T^* = p_T , \tag{49.1}$$

where $\gamma_f = (1 - \beta_f^2)^{-1/2}$ and p_T ($p_\parallel$) are the components of $\boldsymbol{p}$ perpendicular (parallel) to $\boldsymbol{\beta}_f$. Other 4-vectors, such as the space-time coordinates of events, of course transform in the same way. The scalar product of two 4-momenta $p_1 \cdot p_2 = E_1 E_2 - \boldsymbol{p}_1 \cdot \boldsymbol{p}_2$ is invariant (frame independent).

49.2 Center-of-mass energy and momentum

In the collision of two particles of masses m_1 and m_2 the total center-of-mass energy can be expressed in the Lorentz-invariant form

$$\begin{aligned} E_{\rm cm} &= \left[(E_1 + E_2)^2 - (\boldsymbol{p}_1 + \boldsymbol{p}_2)^2\right]^{1/2} , \\ &= \left[m_1^2 + m_2^2 + 2E_1 E_2 (1 - \beta_1 \beta_2 \cos\theta)\right]^{1/2} , \end{aligned} \tag{49.2}$$

where θ is the angle between the particles. In the frame where one particle (of mass m_2) is at rest (lab frame),

$$E_{\rm cm} = (m_1^2 + m_2^2 + 2E_{1\,\rm lab}\, m_2)^{1/2} . \tag{49.3}$$

The velocity of the center-of-mass in the lab frame is

$$\boldsymbol{\beta}_{\rm cm} = \boldsymbol{p}_{\rm lab}/(E_{1\,\rm lab} + m_2) , \tag{49.4}$$

where $\boldsymbol{p}_{\rm lab} \equiv \boldsymbol{p}_{1\,\rm lab}$ and

$$\gamma_{\rm cm} = (E_{1\,\rm lab} + m_2)/E_{\rm cm} . \tag{49.5}$$

The c.m. momenta of particles 1 and 2 are of magnitude

$$p_{\rm cm} = p_{\rm lab} \frac{m_2}{E_{\rm cm}} . \tag{49.6}$$

For example, if a 0.80 GeV/c kaon beam is incident on a proton target, the center of mass energy is 1.699 GeV and the center of mass momentum of either particle is 0.442 GeV/c. It is also useful to note that

$$E_{\rm cm}\, dE_{\rm cm} = m_2\, dE_{1\,\rm lab} = m_2\, \beta_{1\,\rm lab}\, dp_{\rm lab} . \tag{49.7}$$

49.3 Lorentz-invariant amplitudes

The matrix elements for a scattering or decay process are written in terms of an invariant amplitude $-i\mathscr{M}$. As an example, the S-matrix for $2 \to 2$ scattering is related to $\mathscr{M}$ by

$$\langle p_1' p_2' \,|S-1|\, p_1 p_2\rangle = i(2\pi)^4\, \delta^4(p_1 + p_2 - p_1' - p_2')\mathscr{M}(p_1,\, p_2;\, p_1',\, p_2') . \tag{49.8}$$

The state normalization is such that

$$\langle p'|p\rangle = (2\pi)^3\, 2E_p\, \delta^3(\boldsymbol{p}' - \boldsymbol{p}) , \tag{49.9}$$

with $E_p = \sqrt{\boldsymbol{p}^2 + m^2}$.

For a $2 \to 2$ scattering process producing unstable particles $1'$ and $2'$ decaying via $1' \to 3'4'$ and $2' \to 5'6'$ the matrix element for the complete process can be written in the narrow width approximation as:

$$\begin{aligned} &\mathscr{M}(12 \to 3'4'5'6') = \\ &\sum_{h_{1'}, h_{2'}} \frac{\mathscr{M}(12 \to 1'2')\mathscr{M}(1' \to 3'4')\mathscr{M}(2' \to 5'6')}{(m_{3'4'}^2 - m_{1'}^2 + i m_{1'}\Gamma_{1'})(m_{5'6'}^2 - m_{2'}^2 + i m_{2'}\Gamma_{2'})} . \end{aligned} \tag{49.10}$$

Here, m_{ij} is the invariant mass of particles i and j, m_k and Γ_k are the mass and total width of particle k, and the sum runs over the helicities of the intermediate particles. This enables the cross section for such a process to be written as the product of the cross section for the initial $2 \to 2$ scattering process with the branching ratios (relative partial decay rates) of the subsequent decays. A more sophisticated treatment, beyond the narrow width approximation, can be found in the review on "Resonances".

49.4 Particle decays

The partial decay rate of a particle of mass M into n bodies in its rest frame is given in terms of the Lorentz-invariant matrix element $\mathscr{M}$ by

$$d\Gamma = \frac{(2\pi)^4}{2M} |\mathscr{M}|^2\, d\Phi_n\, (P;\, p_1,\, \ldots,\, p_n), \tag{49.11}$$

where $d\Phi_n$ is an element of n-body phase space given by

$$d\Phi_n(P;\, p_1,\, \ldots,\, p_n) = \delta^4\, (P - \sum_{i=1}^{n} p_i)\, \prod_{i=1}^{n} \frac{d^3 p_i}{(2\pi)^3 2E_i} . \tag{49.12}$$

This phase space is reduced by combinatoric factors whenever there are identical particles in the final state. The phase space can be generated recursively, viz.

$$\begin{aligned} d\Phi_n(P;\, p_1,\, \ldots,\, p_n) &= d\Phi_j(q;\, p_1,\, \ldots,\, p_j) \\ &\times\ d\Phi_{n-j+1}\, (P;\, q,\, p_{j+1},\, \ldots,\, p_n)(2\pi)^3 dq^2 , \end{aligned} \tag{49.13}$$

where $q^2 = (\sum_{i=1}^{j} E_i)^2 - \left|\sum_{i=1}^{j} \boldsymbol{p}_i\right|^2$. This form is particularly useful in the case where a particle decays into another particle that subsequently decays.

49.4.1 *Survival probability*

If a particle of mass M has mean proper lifetime τ ($= 1/\Gamma$) and has momentum $(E, \boldsymbol{p})$, then the probability that it lives for a time t_0 or greater before decaying is given by

$$P(t_0) = e^{-t_0\, \Gamma/\gamma} = e^{-M t_0\, \Gamma/E} , \tag{49.14}$$

and the probability that it travels a distance x_0 or greater is

$$P(x_0) = e^{-M x_0\, \Gamma/|\boldsymbol{p}|} . \tag{49.15}$$

49.4.2 *Two-body decays*

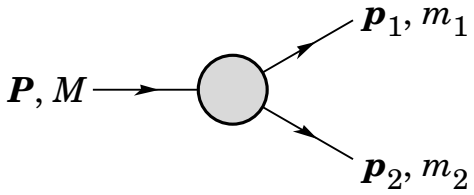


Figure 49.1: Definitions of variables for two-body decays.

In the rest frame of a particle of mass M, decaying into 2 particles labeled 1 and 2,

$$E_1 = \frac{M^2 - m_2^2 + m_1^2}{2M} , \tag{49.16}$$

$$|\boldsymbol{p}_1| = |\boldsymbol{p}_2| = \frac{1}{2M} \sqrt{\lambda(M^2, m_1^2, m_2^2)} , \tag{49.17}$$

and

$$d\Gamma = \frac{1}{32\pi^2}\, |\mathscr{M}|^2\, \frac{|\boldsymbol{p}_1|}{M^2}\, d\Omega , \tag{49.18}$$

where $\lambda(\alpha,\beta,\gamma) = \alpha^2+\beta^2+\gamma^2-2\alpha\beta-2\alpha\gamma-2\beta\gamma$ is the Källén function and $d\Omega = d\phi_1 d(\cos\theta_1)$ is the solid angle of particle 1. The invariant mass M can be determined from the energies and momenta using Eq. (49.2) with $M = E_{\rm cm}$.

49.4.3 *Three-body decays*

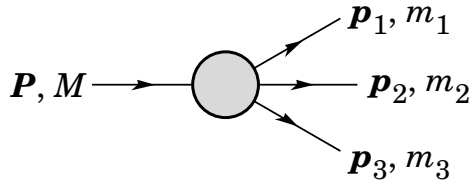

Figure 49.2: Definitions of variables for three-body decays.

Defining $p_{ij} = p_i + p_j$ and $m_{ij}^2 = p_{ij}^2$, then $m_{12}^2+m_{23}^2+m_{13}^2 = M^2+m_1^2+m_2^2+m_3^2$ and $m_{12}^2 = (P-p_3)^2 = M^2+m_3^2-2ME_3$, where E_3 is the energy of particle 3 in the rest frame of M. In that frame, the momenta of the three decay particles lie in a plane. The relative orientation of these three momenta is fixed if their energies are known. The momenta can therefore be specified in space by giving three Euler angles (α,β,γ) that specify the orientation of the final system relative to the initial particle. The direction of any one of the particles relative to the frame in which the initial particle is described can be specified in space by two angles (α,β) while a third angle, γ, can be set as the azimuthal angle of a second particle around the first [1]. Then

$$d\Gamma = \frac{1}{(2\pi)^5}\frac{1}{16M}\,|\mathscr{M}|^2\,dE_1\,dE_3\,d\alpha\,d(\cos\beta)\,d\gamma\ . \tag{49.19}$$

Alternatively

$$d\Gamma = \frac{1}{(2\pi)^5}\frac{1}{16M^2}\,|\mathscr{M}|^2\,|\boldsymbol{p}_1^*|\,|\boldsymbol{p}_3|\,dm_{12}\,d\Omega_1^*\,d\Omega_3\ , \tag{49.20}$$

where $(|\boldsymbol{p}_1^*|,\ \Omega_1^*)$ is the momentum of particle 1 in the rest frame of 1 and 2, and Ω_3 is the angle of particle 3 in the rest frame of the decaying particle. $|\boldsymbol{p}_1^*|$ and $|\boldsymbol{p}_3|$ are given by

$$|\boldsymbol{p}_1^*| = \frac{1}{2m_{12}}\sqrt{\lambda(m_{12}^2,m_1^2,m_2^2)}\ , \tag{49.21a}$$

and

$$|\boldsymbol{p}_3| = \frac{1}{2M}\sqrt{\lambda(M^2,m_{12}^2,m_3^2)}\ . \tag{49.21b}$$

[Compare with Eq. (49.17).]

If the decaying particle is a scalar, or we average over its spin states, then integration over the angles in Eq. (49.19) gives

$$\begin{aligned} d\Gamma &= \frac{1}{(2\pi)^3}\frac{1}{8M}\,\overline{|\mathscr{M}|^2}\,dE_1\,dE_3 \\ &= \frac{1}{(2\pi)^3}\frac{1}{32M^3}\,\overline{|\mathscr{M}|^2}\,dm_{12}^2\,dm_{23}^2\ . \end{aligned} \tag{49.22}$$

This is the standard form for the Dalitz plot.

49.4.3.1 *Dalitz plot*

For a given value of m_{12}^2, the range of m_{23}^2 is determined by its values when $\boldsymbol{p}_2$ is parallel or antiparallel to $\boldsymbol{p}_3$:

$$(m_{23}^2)_{\rm max} = (E_2^*+E_3^*)^2 - \left(\sqrt{E_2^{*2}-m_2^2}-\sqrt{E_3^{*2}-m_3^2}\right)^2\ , \tag{49.23a}$$

$$(m_{23}^2)_{\rm min} = (E_2^*+E_3^*)^2 - \left(\sqrt{E_2^{*2}-m_2^2}+\sqrt{E_3^{*2}-m_3^2}\right)^2\ . \tag{49.23b}$$

Here $E_2^* = (m_{12}^2-m_1^2+m_2^2)/2m_{12}$ and $E_3^* = (M^2-m_{12}^2-m_3^2)/2m_{12}$ are the energies of particles 2 and 3 in the m_{12} rest frame. The scatter plot in m_{12}^2 and m_{23}^2 is called a Dalitz plot. If $\overline{|\mathscr{M}|^2}$ is constant, the allowed region of the plot will be uniformly populated with events [see Eq. (49.22)]. A nonuniformity in the plot gives immediate information on $|\mathscr{M}|^2$. For example, in the case of $D \to K\pi\pi$, bands appear when $m_{(K\pi)} = m_{K^*(892)}$, reflecting the appearance of the decay chain $D \to K^*(892)\pi \to K\pi\pi$.

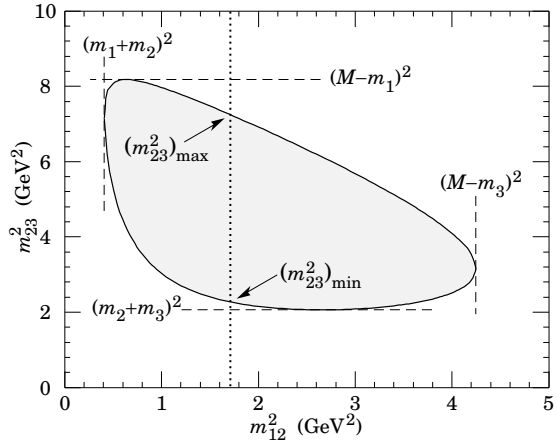

Figure 49.3: Dalitz plot for a three-body final state. In this example, the state is $\pi^+\overline{K}^0 p$ at 3 GeV. Four-momentum conservation restricts events to the shaded region.

49.4.4 *Kinematic limits*

49.4.4.1 *Three-body decays*

In a three-body decay (Fig. 49.2) the maximum of $|\boldsymbol{p}_3|$, [given by Eq. (49.21)], is achieved when $m_{12} = m_1+m_2$, *i.e.*, particles 1 and 2 have the same vector velocity in the rest frame of the decaying particle. If, in addition, $m_3 > m_1, m_2$, then $|\boldsymbol{p}_3|_{\rm max} > |\boldsymbol{p}_1|_{\rm max}$, $|\boldsymbol{p}_2|_{\rm max}$. The distribution of m_{12} values possesses an end-point or maximum value at $m_{12} = M-m_3$. This can be used to constrain the mass difference of a parent particle and one invisible decay product.

49.4.4.2 *Sequential two-body decays*

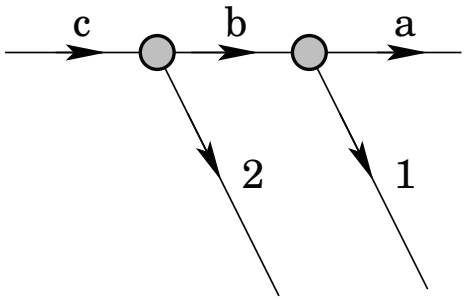

Figure 49.4: Particles participating in sequential two-body decay chain. Particles labeled 1 and 2 are visible while the particle terminating the chain (a) is invisible.

When a heavy particle initiates a sequential chain of two-body decays terminating in an invisible particle, constraints on the masses of the states participating in the chain can be obtained from end-points and thresholds in invariant mass distributions of the aggregated decay products. For the two-step decay chain depicted in Fig. 49.4 the invariant mass distribution of the two visible particles possesses an end-point given by:

$$(m_{12}^{\rm max})^2 = \frac{(m_{\rm c}^2-m_{\rm b}^2)(m_{\rm b}^2-m_{\rm a}^2)}{m_{\rm b}^2}\ , \tag{49.24}$$

provided particles 1 and 2 are massless. If visible particle 1 has

non-zero mass m_1 then Eq. (49.24) is replaced by

$$(m_{12}^{\max})^2 = m_1^2 + \frac{(m_c^2 - m_b^2)}{2m_b^2} \times \left(m_1^2 + m_b^2 - m_a^2 + \sqrt{(-m_1^2 + m_b^2 - m_a^2)^2 - 4m_1^2 m_a^2} \right) \quad (49.25)$$

See Refs. [2] and [3] for other cases.

49.4.5 *Multibody decays*

The above results may be generalized to final states containing any number of particles by combining some of the particles into "effective particles" and treating the final states as 2 or 3 "effective particle" states. Thus, if $p_{ijk\ldots} = p_i + p_j + p_k + \ldots$, then

$$m_{ijk\ldots} = \sqrt{p^2{}_{ijk\ldots}} \ , \quad (49.26)$$

and $m_{ijk\ldots}$ may be used in place of *e.g.*, m_{12} in the relations in Sec. 49.4.3 or Sec. 49.4.4 above.

49.5 Cross sections

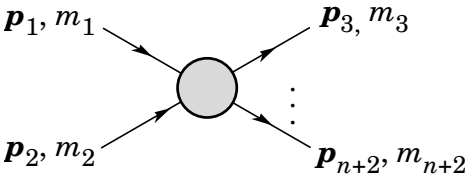

Figure 49.5: Definitions of variables for production of an n-body final state.

The differential cross section is given by

$$d\sigma = \frac{(2\pi)^4 |\mathscr{M}|^2}{4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}} \times \ d\Phi_n(p_1 + p_2;\ p_3,\ \ldots,\ p_{n+2}) \ . \quad (49.27)$$

[See Eq. (49.12).] In the rest frame of m_2(lab),

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = m_2 p_{1\,\mathrm{lab}}; \quad (49.28a)$$

while in the center-of-mass frame

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = p_{1\mathrm{cm}} \sqrt{s} \ . \quad (49.28b)$$

49.5.1 *Two-body reactions*

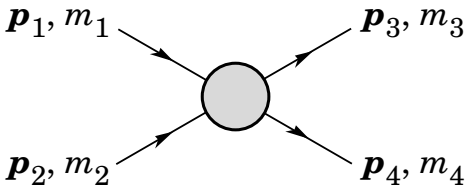

Figure 49.6: Definitions of variables for a two-body final state.

Two particles of momenta p_1 and p_2 and masses m_1 and m_2 scatter to particles of momenta p_3 and p_4 and masses m_3 and m_4; the Lorentz-invariant Mandelstam variables are defined by

$$\begin{aligned} s &= (p_1 + p_2)^2 = (p_3 + p_4)^2 \\ &= m_1^2 + 2E_1E_2 - 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_2 + m_2^2 \ , \quad (49.29) \\ t &= (p_1 - p_3)^2 = (p_2 - p_4)^2 \\ &= m_1^2 - 2E_1E_3 + 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_3 + m_3^2 \ , \quad (49.30) \\ u &= (p_1 - p_4)^2 = (p_2 - p_3)^2 \\ &= m_1^2 - 2E_1E_4 + 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_4 + m_4^2 \ , \quad (49.31) \end{aligned}$$

and they satisfy

$$s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2 \ . \quad (49.32)$$

The two-body cross section may be written as

$$\frac{d\sigma}{dt} = \frac{1}{64\pi s} \ \frac{1}{|\boldsymbol{p}_{1\mathrm{cm}}|^2} \ |\mathscr{M}|^2 \ . \quad (49.33)$$

In the center-of-mass frame

$$\begin{aligned} t &= (E_{1\mathrm{cm}} - E_{3\mathrm{cm}})^2 - (p_{1\mathrm{cm}} - p_{3\mathrm{cm}})^2 - 4p_{1\mathrm{cm}}\, p_{3\mathrm{cm}}\, \sin^2(\theta_{\mathrm{cm}}/2) \\ &= t_0 - 4p_{1\mathrm{cm}}\, p_{3\mathrm{cm}}\, \sin^2(\theta_{\mathrm{cm}}/2) \ , \end{aligned} \quad (49.34)$$

where θ_{cm} is the angle between particle 1 and 3. The limiting values t_0 ($\theta_{\mathrm{cm}} = 0$) and t_1 ($\theta_{\mathrm{cm}} = \pi$) for $2 \to 2$ scattering are

$$t_0(t_1) = \left[\frac{m_1^2 - m_3^2 - m_2^2 + m_4^2}{2\sqrt{s}} \right]^2 - (p_{1\,\mathrm{cm}} \mp p_{3\,\mathrm{cm}})^2 \ . \quad (49.35)$$

In the literature the notation $t_{\min}$ ($t_{\max}$) for t_0 (t_1) is sometimes used, which should be discouraged since $t_0 > t_1$. The center-of-mass energies and momenta of the incoming particles are

$$E_{1\mathrm{cm}} = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}} \ , \qquad E_{2\mathrm{cm}} = \frac{s + m_2^2 - m_1^2}{2\sqrt{s}} \ , \quad (49.36)$$

For $E_{3\mathrm{cm}}$ and $E_{4\mathrm{cm}}$, change m_1 to m_3 and m_2 to m_4. Then

$$p_{i\,\mathrm{cm}} = \sqrt{E_{i\,\mathrm{cm}}^2 - m_i^2} \text{ and } p_{1\mathrm{cm}} = \frac{p_{1\,\mathrm{lab}}\, m_2}{\sqrt{s}} \ . \quad (49.37)$$

Here the subscript lab refers to the frame where particle 2 is at rest. [For other relations see Eqs. (49.2)–(49.4).]

49.5.2 *Inclusive reactions*

Choose some direction (usually the beam direction) for the z-axis; then the energy and momentum of a particle can be written as

$$E = m_T \cosh y \ , \ p_x \ , \ p_y \ , \ p_z = m_T \sinh y \ , \quad (49.38)$$

where m_T, conventionally called the 'transverse mass', is given by

$$m_T^2 = m^2 + p_x^2 + p_y^2 \ . \quad (49.39)$$

and the rapidity y is defined by

$$\begin{aligned} y &= \frac{1}{2} \ln \left(\frac{E + p_z}{E - p_z} \right) \\ &= \ln \left(\frac{E + p_z}{m_T} \right) = \tanh^{-1} \left(\frac{p_z}{E} \right) \ . \end{aligned} \quad (49.40)$$

Note that the definition of the transverse mass in Eq. (49.39) differs from that used by experimentalists at hadron colliders (see Sec. 49.6.1 below). Under a boost in the z-direction to a frame with velocity β, $y \to y - \tanh^{-1}\beta$. Hence, the shape of the rapidity distribution dN/dy is invariant, as are differences in rapidity. The invariant cross section may also be rewritten

$$E\frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi\, dy\, p_T\, dp_T} \Longrightarrow \frac{d^2\sigma}{\pi\, dy\, d(p_T^2)} \ . \quad (49.41)$$

The second form is obtained using the identity $dy/dp_z = 1/E$, and the third form represents the average over ϕ.

Feynman's x variable is given by

$$x = \frac{p_z}{p_{z\,\max}} \approx \frac{E + p_z}{(E + p_z)_{\max}} \quad (p_T \ll |p_z|) \ . \quad (49.42)$$

In the c.m. frame,

$$x \approx \frac{2p_{z\,\mathrm{cm}}}{\sqrt{s}} = \frac{2m_T \sinh y_{\mathrm{cm}}}{\sqrt{s}} \quad (49.43)$$

and

$$= (y_{\rm cm})_{\rm max} = \ln(\sqrt{s}/m) \ . \quad (49.44)$$

The invariant mass M of the two-particle system described in Sec. 49.4.2 can be written in terms of these variables as

$$M^2 = m_1^2 + m_2^2 + 2[E_T(1)E_T(2)\cosh\Delta y - \boldsymbol{p}_T(1)\cdot\boldsymbol{p}_T(2)] \ , \quad (49.45)$$

where

$$E_T(i) = \sqrt{|\boldsymbol{p}_T(i)|^2 + m_i^2} \ , \quad (49.46)$$

and $\boldsymbol{p}_T(i)$ denotes the transverse momentum vector of particle i.

For $p \gg m$, the rapidity [Eq. (49.40)] may be expanded to obtain

$$y = \frac{1}{2}\ln\frac{\cos^2(\theta/2) + m^2/4p^2 + \ldots}{\sin^2(\theta/2) + m^2/4p^2 + \ldots} \approx -\ln\tan(\theta/2) \equiv \eta \quad (49.47)$$

where $\cos\theta = p_z/p$. The pseudorapidity η defined by the second line is approximately equal to the rapidity y for $p \gg m$ and $\theta \gg 1/\gamma$, and in any case can be measured when the mass and momentum of the particle are unknown. From the definition one can obtain the identities

$$\sinh\eta = \cot\theta \ , \ \ \cosh\eta = 1/\sin\theta \ , \ \ \tanh\eta = \cos\theta \ . \quad (49.48)$$

49.6 Transverse variables

At hadron colliders, a significant and unknown proportion of the energy of the incoming hadrons in each event escapes down the beam-pipe. Consequently, if invisible particles are created in the final state, their net momentum can only be constrained in the plane transverse to the beam direction. Defining the z-axis as the beam direction, this net momentum is equal to the missing transverse energy vector

$$\boldsymbol{E}_T^{\rm miss} = -\sum_i \boldsymbol{p}_T(i) \ , \quad (49.49)$$

where the sum runs over the transverse momenta of all visible final state particles.

49.6.1 *Single production with semi-invisible final state*

Consider a single heavy particle of mass M produced in association with visible particles which decays as in Fig. 49.1 to two particles, of which one (labeled particle 1) is invisible. The mass of the parent particle can be constrained with the quantity M_T defined by

$$M_T^2 \equiv [E_T(1) + E_T(2)]^2 - [\boldsymbol{p}_T(1) + \boldsymbol{p}_T(2)]^2 = m_1^2 + m_2^2 + 2[E_T(1)E_T(2) - \boldsymbol{p}_T(1)\cdot\boldsymbol{p}_T(2)] \ , \quad (49.50)$$

where

$$\boldsymbol{p}_T(1) = \boldsymbol{E}_T^{\rm miss} \ . \quad (49.51)$$

This quantity is called the 'transverse mass' by hadron collider experimentalists but it should be noted that it is quite different from that used in the description of inclusive reactions [Eq. (49.39)]. The distribution of event M_T values possesses an end-point at $M_T^{\rm max} = M$. If $m_1 = m_2 = 0$ then

$$M_T^2 = 2|\boldsymbol{p}_T(1)||\boldsymbol{p}_T(2)|(1 - \cos\phi_{12}) \ , \quad (49.52)$$

where ϕ_{ij} is defined as the angle between particles i and j in the transverse plane.

49.6.2 *Pair production with semi-invisible final states*

Consider two identical heavy particles of mass M produced such that their combined center-of-mass is at rest in the transverse plane (Fig. 49.7). Each particle decays to a final state consisting of an invisible particle of fixed mass m_1 together with an additional visible particle. M and m_1 can be constrained with the variables M_{T2} and M_{CT} which are defined in Refs. [4] and [5].

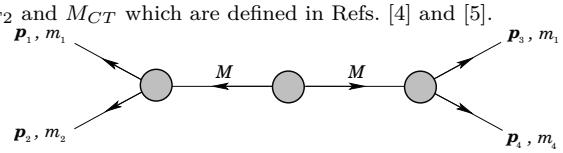

Figure 49.7: Definitions of variables for pair production of semi-invisible final states. Particles 1 and 3 are invisible while particles 2 and 4 are visible.

50. Resonances

Revised August 2021 by D.M. Asner (BNL) and C. Hanhart (Jülich).

50.1 General Considerations

Perturbative methods can be applied to systems of quarks and gluons only for large momentum transfers (see review on 'Quantum Chromodynamics') and, under certain conditions, to some properties of systems that contain heavy quarks or very large momentum scales (see review on "Heavy-quark and soft-collinear effective theory"). Dealing with Quantum Chromodynamics (QCD) in the low momentum transfer region is a very complicated, nonperturbative problem. Accordingly, most hadrons are resonances, which means that they appear as poles of the S-matrix in the complex plane on unphysical sheets. These resonances can show up either in so-called formation experiments,

$$A + B \to \mathbf{R} \to C_1 + ... + C_n \ ,$$

where they become visible in an energy scan (for example, the R-function measured in e^+e^- annihilations — *cf.* the corresponding plots in the review on "Plots of Cross Sections and Related Quantities"), or together with a spectator particle S in production experiments of the kind

$$\begin{aligned} A + B \to \mathbf{R} + S \to [C_1 + ... + C_n] + S \ , \\ Z \to \mathbf{R} + S \to [C_1 + ... + C_n] + S \ , \end{aligned}$$

where the first reaction corresponds to an associated production, the second is a decay (see "Review of Multibody Charm Analyses"). In the latter case, the resonance properties are commonly extracted from a Dalitz-plot analysis (see review on "Kinematics") or projections thereof.

Resonance phenomena are very rich: while typical hadronic widths are of the order of 100 MeV (*e.g.*, for the meson resonances $\rho(770)$ or $\psi(4040)$ or the baryon resonance $\Delta(1232)$) corresponding to a lifetime of 10^{-23} s, the widths can also be as small as a few MeV (*e.g.* of $\phi(1020)$ or J/ψ) or as large as several hundred MeV (*e.g.* of the meson resonances $f_0(500)$ or $D_1(2430)$ or the baryon resonance $N(2190)$).

Typically, a resonance appears as a peak in the total cross section. If the structure is narrow and if there are no relevant thresholds or other resonances nearby, the resonance properties may be extracted employing a Breit–Wigner parameterization, if necessary improved by using an energy-dependent width (*cf.* Sec. 50.3.1 of this review). However, in general, unitarity and analyticity call for the use of more refined tools. When there are overlapping resonances with the same quantum numbers, the resonance terms should not simply be added but combined in a non-trivial way either in a K-matrix approach (*cf.* Sec. 50.3.2 of this review) or using other advanced methods (*cf.* Sec. 50.3.6 of this review). Additional constraints from the S-matrix allow one to build more reliable amplitudes and, in turn, to reduce the systematic uncertainties of the resonance parameters: pole locations and residues. In addition, for broad resonances there is no direct relation between pole location and the total width/lifetime — then, the pole residues need to be used in order to quantify the decay properties.

For simplicity, throughout this review the formulas are given for resonances in a system of distinguishable, scalar particles. The additional complications that appear in the presence of spins can be controlled in the helicity framework developed by Jacob and Wick [1], or in a non-covariant [2] or covariant [3] tensor-operator formalisms. Within these approaches, sequential (cascade) decays are commonly treated as a coherent sum of two-body interactions. Most of the expressions below are given for two-body kinematics.

50.1.1 *Properties of the S-matrix*

The unitary operator that connects asymptotic *in* and *out* states is called the S-matrix. The scattering amplitude is defined as the interacting part of the S matrix. For a two-particles scattering process, it reads:

$$\begin{aligned} i(2\pi)^4\delta^4(p_1 + p_2 - p_1' - p_2')\,\mathcal{M}(p_1, p_2; p_1', p_2')_{ba} = \\ = {}_{\rm out}\left\langle p_1' p_2', b\right| S - 1 \left|p_1 p_2, a\right\rangle_{\rm in} \end{aligned} \qquad (50.1)$$

where $|p_1 p_2, a\rangle$ and $\left|p_1' p_2', b\right\rangle$ are asymptotic states of two non-interacting particles with momentum p_1, p_2 and p_1', p_2'. The channel labels a and b are multi-indices specifying all additional properties of the channel. In general, $\mathcal{M}$ is a matrix in channel space. For a single-particle state, we employ the relativistic normalization,

$$\left\langle p'|p\right\rangle = (2\pi)^3 2E_p\,\delta^3(\vec{p}\,' - \vec{p}), \qquad (50.2)$$

with $E_p = \sqrt{\vec{p}^{\,2} + m^2}$. The Mandelstam variables $s = (p_1+p_2)^2$, $t = (p_1 - p_1')^2$, and $u = (p_1 - p_2')^2$ are the invariant variables describing the scattering. With these definitions the process in Eq. (50.1) is referred to as the s-channel scattering, where the total energy of the interacting system is given by $\sqrt{s}$, while the variable t is related to the scattering angle, *i.e.* the angle between the momenta of the particles 1 and $1'$ in the center-of-momentum frame. The variable u is not independent of s and t, but the relation

$$s + t + u = m_1^2 + m_2^2 + m_{1'}^2 + m_{2'}^2$$

holds, where the m_i denote the masses of the incoming and outgoing particles, $i \in 1, 1', 2, 2'$. Therefore, the reaction amplitude is a function of two variables, $\mathcal{M}(s,t)$. The function $\mathcal{M}(s,t)$ is a multi-valued function due to the complex branch points in the Mandelstam variables. Branch points appear whenever there is a channel opening. Each two-particle threshold introduces a square-root singularity and the number of Riemann sheets doubles. For resonances coupled to multi-particle states with odd number of particles the threshold branch point is logarithmic [4]. The branch points appear in the complex plane of an unphysical sheet when there is a resonance in a subsystem of the final-state particles [4]. The cuts related to the openings of the crossed channels are located on the left-hand side of the complex plane, and, therefore, are referred to as the left-hand cuts. Triangle topologies can induce logarithmic branch points on the unphysical sheets often called triangle singularities (TS) [4–6].

Poles of reaction amplitude refer either to bound states or to resonances. The former poles are located on the physical sheet, the latter are located on unphysical sheets. Naturally, those located on the unphysical sheet closest to the physical one, often called the second sheet, have usually the largest impact on observables. Moreover, as follows from analyticity, if there is a pole at some complex value of s, there must be another pole at its complex conjugate value, s^*. For a single-channel case this is illustrated in Fig. 50.1: the pole with a negative imaginary part is closer to the physical axis and thus influences the observables in the vicinity of the resonance region more strongly. However, at the threshold both poles are equally distant and accordingly equally important. Any of these singularities can lead to some structure in the observables (see also Ref. [7]). If certain kinematical constraints are met, especially the TS can mimic resonance signals, as claimed in Refs. [8–13] or cause significant changes of resonance signals [14]. In addition to not all bumps being resonances, not every resonance generates a bump in all observables. For instance, there is no clear trace of the $N(1440)1/2^+$, the so called Roper resonance, in the πN observables or phase shifts, although careful analyses reveal a pole [15].

In case of two relevant channels we are faced with four Riemann sheets. Then, the sheet that is the closest to the physical axis changes, as the energy increases. This can be seen from the illustration in Fig. 50.2: for energies higher than the first, but lower than the second threshold, the sheet that connects smoothly to the upper half plane of the physical sheet (11) is sheet (21). However, for energies above the second threshold this role is taken over by sheet (22). Accordingly, a pole on sheet (21), but above the second threshold, will show up in data only as a cusp exactly at the second threshold. Sheet (12), on the other hand, is remote for all energies.

The analyticity principle of the S-matrix forbids any singularities on the first Riemann sheet except poles and branch points on the real axis. Unitarity constrains the imaginary part of the amplitude on the real axis as further discussed in the following

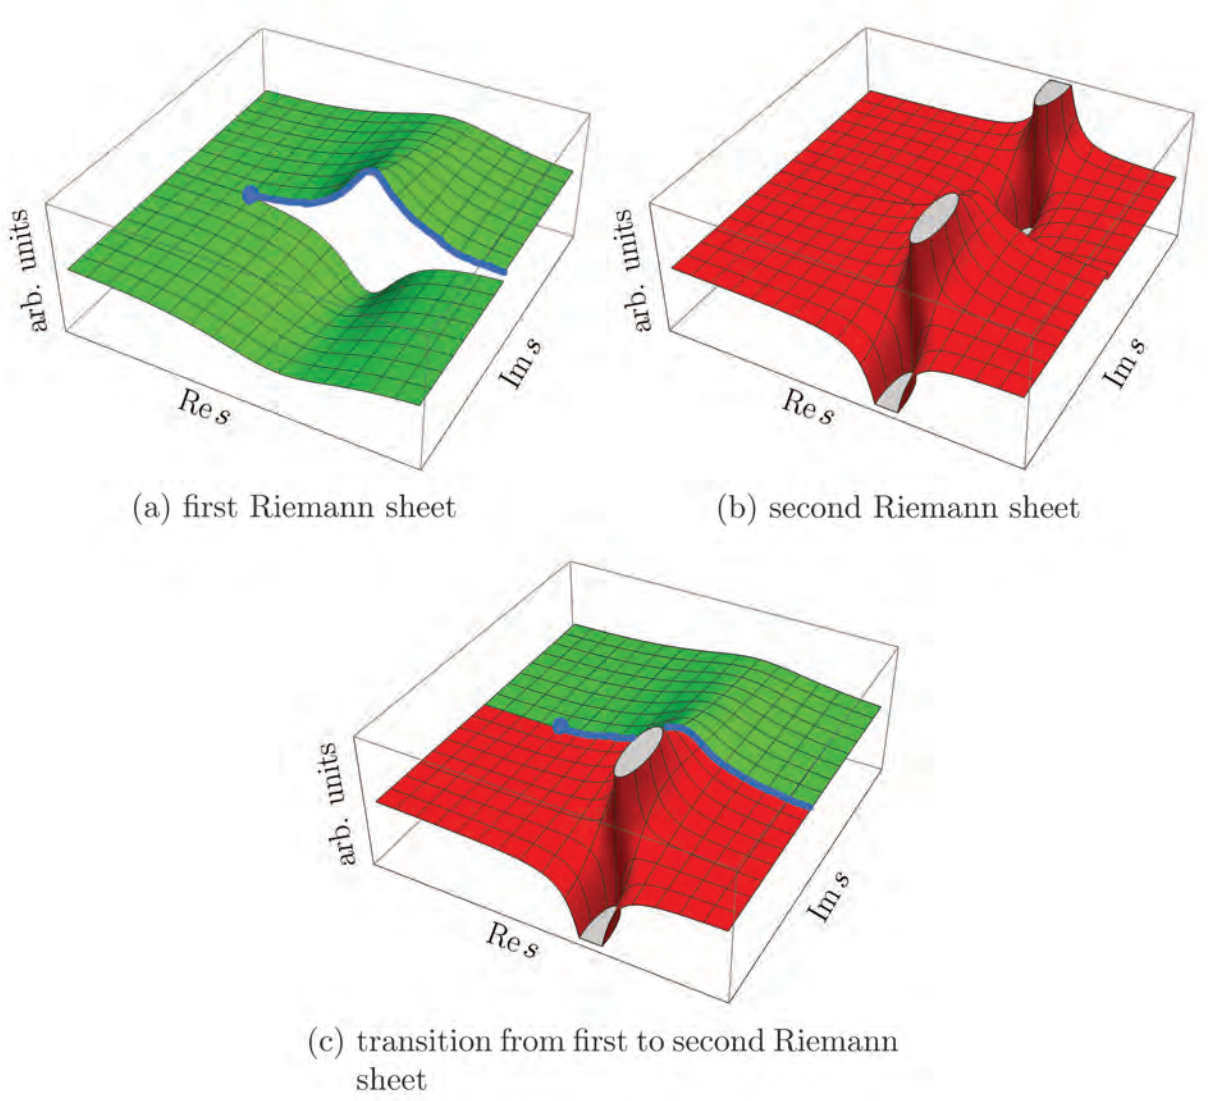

Figure 50.1: Imaginary part of a typical single-channel scattering amplitude with an isolated resonance. The blue line shows the physical range of the Mandelstam variable s: it is real and starts from the threshold shown by the blue dot. Plot (a) shows the imaginary part of the amplitude in the complex s-plane that corresponds to the first or physical sheet (green surface), plot (b) shows the related unphysical or the second sheet (red surface) which contains the resonance poles, and plot (c) shows the analytic continuation of the same amplitude from the upper half plane of the physical sheet to the lower half plane of the unphysical sheet. The two sheets are connected smoothly along the real axis above the threshold.

section. Further constraints come, *e.g.*, from crossing symmetry and duality [16]. Approaches based on analyticity and crossing symmetry, implemented via dispersion theory, like the Roy equations [17] or variants thereof, were developed and applied to $\pi\pi \to \pi\pi$ scattering [18–20], πK scattering [21], $\gamma\gamma \to \pi\pi$ [22] as well as pion-nucleon scattering [23, 24].

50.1.2 *Consequences from unitarity*

In what follows, scattering amplitudes, $\mathcal{M}$, and production amplitudes, $\mathcal{A}$, will be distinguished, since unitarity puts different constraints on these. For the scattering amplitude, all considered channels are supposed to be of comparable importance, while for the production amplitudes we require that the initial state is only weakly coupled and, therefore, the probability of the time-reversed reaction is negligibly small compared to the other coupled channels. Most of the strong-interaction processes are then described by the scattering amplitude, *e.g.* $\pi^+\pi^- \to K\bar{K}$, or $D^0\bar{D}^0 \to D^0\bar{D}^0$. Examples for production processes are $e^+e^- \to \pi^+\pi^-$, $\tau \to K^-\pi^0\nu$, $B^0 \to J/\psi\pi^+\pi^-$.

Unitarity of the S matrix, $S^\dagger S = 1$, which is equivalent to the conservation of probability, translates to a constraint for the imaginary part of the reaction amplitude. The amplitude is real below the first threshold. Above the threshold, the discontinuity across the cut related to the threshold branch point, obeys the relation [25]:

$$\mathcal{M}_{ba} - \mathcal{M}^*_{ab} = i\,(2\pi)^4 \sum_c \int d\Phi_c \mathcal{M}^*_{cb}\mathcal{M}_{ca}\ , \qquad (50.3)$$

where Φ_c is the invariant phase space for channel c. The sum includes only open channels, *i.e.* those for which the production threshold is below the energy of the scattered system. Complementary, the channels with the threshold higher than the energy of the system are called closed. Using time-reversal symmetry, and $\mathrm{Disc}\,\mathcal{M}(s,t) = 2i\,\mathrm{Im}(\mathcal{M}(s+i\epsilon,t))$ for the s-channel, the optical theorem follows:

$$\mathrm{Im}\,\mathcal{M}_{aa}(s,0) = 2q_a\sqrt{s}\,\sigma_{\mathrm{tot}}(a \to \mathrm{anything})\,. \qquad (50.4)$$

Here, q_a is the momentum of particles in their center-of-

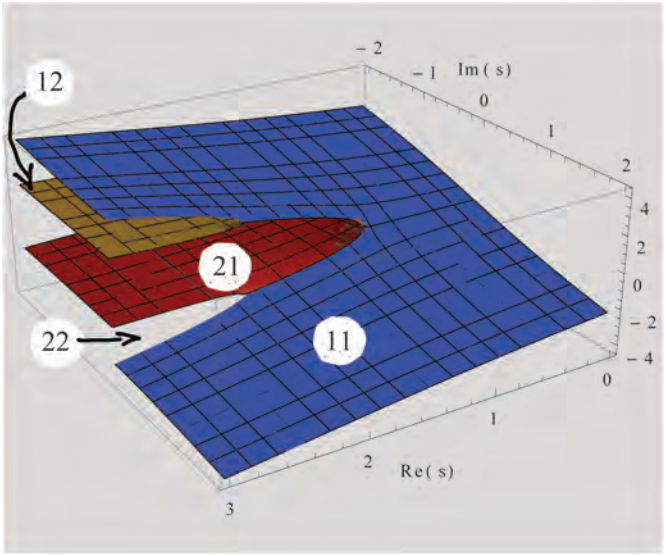

Figure 50.2: Cut structure of the S-matrix in the presence of two-channels. The four sheets are labelled as (ij) with $i = 1, 2$ and $j = 1, 2$ referring to the doubling of the sheets at the first and the second thresholds, respectively.

momentum frame,

$$q_a = \frac{\lambda^{1/2}(s, m_{1,a}^2, m_{2,a}^2)}{2\sqrt{s}} \,, \tag{50.5}$$

where $\lambda(x, y, z) = x^2 + y^2 + z^2 - 2xy - 2yz - 2yx$ is the Källén function, $m_{1,a}$ and $m_{2,b}$ are the masses of the two particles in the channel a, *cf.* Eq. (17) of the review on "Kinematics". The value $t = 0$ in Eq. (50.4) corresponds to forward scattering.

The unitarity relation for a production amplitude for a channel a is given by

$$\mathcal{A}_a - \mathcal{A}_a^* = i\,(2\pi)^4 \sum_c \int d\Phi_c \mathcal{M}_{ca}^* \mathcal{A}_c \,. \tag{50.6}$$

Note that production amplitude written as a linear combination of the scattering amplitudes satisfies Eq. (50.6) due to Eq. (50.3). This solution are often practical, especially, when the scattering matrix is well known, as for example for $\pi\pi$ system below 1.1 GeV [26, 27]. However, it should be understood that this kind of treatment is only approximate, since it imports the analytic structure of the scattering amplitude including its left-hand cuts to the production amplitude which in general has a different cut structure. A more sophisticated application of the two-body-unitarity constraints from Eq. (50.6) is the Khuri-Treiman framework often employed to study three-body decays [28]. The standard procedure here is to derive the equations for the production amplitude for small values of the mass of the decaying particle in the scattering domain and relate it to the decay kinematics by an analytic continuation in the decay mass. The method was successfully applied to various decays of light mesons, $\eta \to 3\pi$ in Refs. [29–34], $\phi/\omega \to 3\pi$ in Ref. [35, 36], $\eta' \to \eta\pi\pi$ in Ref. [37], as well as to the charm-mesons decays $D^+ \to K^{0/-}\pi^{0/+}\pi^+$ [38, 39].

50.1.3 *Partial-wave decomposition*

It is often convenient to expand the scattering amplitude in partial waves. Since resonances have a well-defined spin, they appear only in a specific partial wave of the reaction amplitude. For scalar particles the expansion reads:

$$\mathcal{M}_{ba}(s, t) = \sum_{j=0}^{\infty} (2j + 1) \mathcal{M}_{ba}^{j}(s) P_j(\cos(\theta)) \,, \tag{50.7}$$

where j denotes the total angular momentum and the $P_j(\cos(\theta))$ denotes the Legendre polynomials. In the presence of spins an expansion more complicated than Eq. (50.7) is necessary. In the absence of spins the parameter j coincides with the orbital angular momentum of the particle pairs in the initial and the final state. To simplify notations we will drop the label j for the single-argument function $\mathcal{M}_{ba}(s)$. The unitarity constraint for $\mathcal{M}_{ba}(s)$ reads,

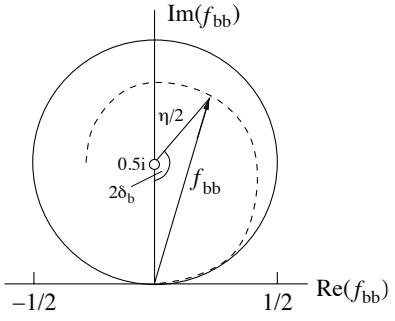

Figure 50.3: Argand plot showing a diagonal element of a partial-wave amplitude, a_{bb}, as a function of energy. The amplitude leaves the unitary circle (solid line) as soon as inelasticity sets in, $\eta < 1$ (dashed line).

$$\mathrm{Im}\, \mathcal{M}_{ba}(s) = \sum_c \mathcal{M}_{cb}(s)^*\, \rho_c(s)\, \mathcal{M}_{ca}(s) \tag{50.8}$$

with $\rho_c(s)$ being a factor that is related to the two-body phase space in Eq. (12) of the review on "Kinematics",

$$\rho_c(s) = \frac{(2\pi)^4}{2} \int \mathrm{d}\Phi_2 = \frac{1}{16\pi} \frac{2|\vec{q}_c|}{\sqrt{s}} \,, \tag{50.9}$$

with the momentum q_c being defined in Eq. (50.5). Note that in case of the two particles being identical the inclusion of symmetry factors becomes necessary. The partial-wave amplitude $f_{ba}(s)$ is introduced via

$$f_{ba}(s) = \sqrt{\rho_b}\, \mathcal{M}_{ba}(s)\, \sqrt{\rho_a} \,. \tag{50.10}$$

From the unitarity condition Eq. (50.8) it follows that $\mathrm{Im}\, f_{ba}^{-1} = -\delta_{ba}$. Moreover, $\mathbb{I} + 2if$ is a unitary matrix. Hence, the diagonal elements of f can be parameterized as,

$$f_{bb} = (\eta_b \exp(2i\delta_b) - 1)/2i \,, \tag{50.11}$$

where δ_b denotes the phase shift for the scattering from channel b to channel b, η_b is elasticity parameter — also called inelasticity. One has $0 \le \eta_b \le 1$, where $\eta_b = 1$ is referred to as a purely elastic scattering. The evolution of the partial-wave amplitude f_{bb} with energy can be displayed as a trajectory in the Argand plot, as shown in Fig. 50.3. In case of a two-channel problem, $\eta_b = \eta_a = \eta$, and the off-diagonal element is $f_{ba} = \sqrt{1 - \eta^2}/2 \exp(i(\delta_b + \delta_a))$. The unitarity condition Eq. (50.11) sets the limit to the squared amplitude f_{bb}:

$$|f_{bb}|^2 = \frac{1}{4}(\eta_b^2 - 2\eta_b \cos(2\delta_b) + 1) \le \frac{1}{4}(\eta_b + 1)^2 \,, \tag{50.12}$$

where the maximum value is achieved for $\delta_b = \pi/2$. For the partial-wave-projected scattering amplitude the unitarity bound reads:

$$|\mathcal{M}_{bb}| \;\le\; \frac{1}{2\rho_b}(\eta_b + 1) \;\le\; \frac{8\pi}{q_b}\sqrt{s} \,, \tag{50.13}$$

where the second inequality comes from $\eta_b \le 1$. For energies much larger than the masses of the scattering particles. One finds that the upper bound for $|\mathcal{M}_{bb}|$ tends to 16π for large s.

The partial-wave-projected production amplitude $\mathcal{A}(s)$ (the label j is dropped for consistency) is also constrained by unitarity. From Eq. (50.6) it follows:

$$\mathrm{Im}\, \mathcal{A}_a = \sum_b \mathcal{M}_{ba}^*\, \rho_b\, \mathcal{A}_b \,, \tag{50.14}$$

where the sum runs over all open channels. For elastic processes, the sum collapses to the channel a. In this case, the phase of $\mathcal{A}_a$ must agree with the phase of $\mathcal{M}_{aa}$ since the left-hand side of Eq. (50.14) is a real number. The statement is known as the Watson theorem [40].

50.2 Properties of resonances

The main characteristics of a resonance is its pole position in the complex s-plane, s_R. The pole mass M_R and pole width Γ_R are introduced via the pole parameters

$$\sqrt{s_\mathrm{R}} = M_\mathrm{R} - i\Gamma_\mathrm{R}/2 \ . \tag{50.15}$$

Note that the standard Breit–Wigner parameters M_BW and Γ_BW, also introduced below, in general, deviate from the pole parameters, *e.g.*, due to finite width effects and the influence of thresholds. It should be stressed, however, that the pole location s_R as well as the pole residues to be introduced below, are the only resonance properties that are model- and parametrisation independent.

In addition to the pole position, a resonance is characterized by its couplings to the various channels called residues. The Baryon Particle Listings give the elastic pole residues and normalized transition residues. However, different conventions are used in the two sectors, which are shortly outlined here.

In the close vicinity of the resonance pole the scattering matrix $\mathcal{M}$ can be written as

$$\lim_{s\to s_R} (s - s_R)\mathcal{M}_{ba} = -\mathcal{R}_{ba} \ . \tag{50.16}$$

The residues are calculated via an integration along a closed contour around the pole using

$$\mathcal{R}_{ba} = -\frac{1}{2\pi i}\oint ds\mathcal{M}_{ba} \ . \tag{50.17}$$

The factorization of the residue $(\mathcal{R}_{ba})^2 = \mathcal{R}_{aa} \times \mathcal{R}_{bb}$ allows one to introduce pole couplings according to

$$\tilde{g}_a = \mathcal{R}_{ba}/\sqrt{\mathcal{R}_{bb}} \ . \tag{50.18}$$

The pole couplings characterize the transition strength of a given resonance to some channel a independently of how the particular resonance was produced. For a two-particle decays in the S-wave, one may define a partial width and a branching fraction for a resonance via

$$\Gamma_{\mathrm{R}\to a} = \frac{|\tilde{g}_a|^2}{M_\mathrm{R}}\rho_a(M_\mathrm{R}^2) \quad \text{and} \quad \mathrm{Br}_a = \Gamma_{\mathrm{R}\to a}/\Gamma_\mathrm{R} \ , \tag{50.19}$$

where M_R and Γ_R were introduced in Eq. (50.15). This expression was used to define a two-photon width for the broad $f_0(500)$ [41, 42] as well as in the corresponding section of the Meson Particle Listings. Analogously, one should use residues to quantify the coupling of resonances to certain production channels [43]. For an application of this formalism to the coupling of the $K_0^*(1430)$ resonance to a leptonic current see Ref. [44]. Equation (50.19) defines a partial-decay width independent of the reaction used to extract the parameters. For a narrow resonances it maps smoothly onto the other common definition of the branching fraction, discussed in Eq. (50.20) more closely related to observables. For broad, overlapping resonances, however, it should be understood that Eq. (50.19) serves the purpose to convert the residues to quantities that allow for a more direct comparison of resonance transitions to different channels. In case of resonances with significant couplings to channels that are still closed at the resonance mass, Eq. (50.19) cannot be used since the phase-space factor yields zero.

In the baryon sector, it is common to define the residue of the pole of the f_{ba} amplitude defined in Eq. (50.10) in variable $\sqrt{s}$ instead of s. Accordingly, in the baryon listings the elastic pole residue, which refers to $\pi N \to \pi N$ scattering, is related to the residues introduced above via

$$r_{\pi N,\pi N} = \frac{\rho_{\pi N}(s_\mathrm{R})}{\sqrt{4s_\mathrm{R}}}\,\mathcal{R}_{\pi N,\pi N} \ , \tag{50.20}$$

where s_R is the position of the pole. For evaluation of the phase-space factor for the complex argument, analytic continuation is required.

In the literature there are alternative definitions of a branching fraction, which are more close to what is observed in experiment than what follows from Eq. (50.19). Usually those are defined from the probability of the decay of a resonance to a certain channel as provided by the corresponding amplitude on the real axis, where the measurements are performed. It should be understood that in order to isolate an individual resonance in an amplitude defined on the real axis in general some model dependence is unavoidable (*e.g.* this is possible if the amplitude is provided by a sum of Breit–Wigner functions, however, since such a sum violates unitarity the parametrisation comes with an intrinsic theoretical uncertainty difficult to quantify). Having that said one may define the partial width of a resonance alternatively via

$$\Gamma_{\mathrm{R}\to a} = \frac{(2\pi)^4}{2M_\mathrm{R}}\int |\mathcal{A}_a|^2\,\mathrm{d}\Phi_a \ , \tag{50.21}$$

where $\mathcal{A}_a$ is the decay amplitude of the resonance into channel a, which for multi-body final states may even contain resonances in a subchannel. For the two-body decay of a narrow, isolated resonance, $\mathcal{A}_a$ is to a good approximation just $\tilde{g}_a$ and we get back to Eq. (50.19). If the mass of the decaying resonance lies below the threshold of the final state, an integration over the resonance lineshape needs to be employed in addition. For example, for some generic three-body decay with two of the final-state particles going through a resonance one commonly defines (avoiding complications from spins or centrifugal barrier factors), for simplicity written in terms of Breit–Wigner functions (see next section)

$$\mathrm{Br}_{R\to cR'}\mathrm{Br}_{R'\to ab} = (2\pi)^3\int_{m^2_{\mathrm{min}R}}^{\infty} dm^2 \left|\frac{g_{R\to R'c}}{M^2_{\mathrm{BW}R} - m^2 - iM_{\mathrm{BW}R}\Gamma_R(m^2)}\right|^2$$
$$\times(2\pi)^3\int_{m^2_{\mathrm{min}R'}}^{(m-m_c)^2} dm^2_{ab}\left|\frac{g_{R'\to ab}}{M^2_{\mathrm{BW}R'} - m^2_{ab} - iM_{\mathrm{BW}R'}\Gamma_{R'}(m^2_{ab})}\right|^2 \int \mathrm{d}\Phi_{ab}\int \mathrm{d}\Phi_{R'(m^2_{ab})c} \ , \tag{50.22}$$

where $\Gamma_{R^{(\prime)}}(m^2)$ denotes the energy dependent width of resonance R (R') (details are given in the next section), $\mathrm{d}\Phi_{R'(m^2_{ab})c}$ denotes the two-body phase space for resonance R', at a fixed mass m_{ab}, and particle c for a total energy m, and $\mathrm{d}\Phi_{ab}$ the two-body phase space for particles a and b for a total energy m_{ab}, respectively. Furthermore, $m^2_{\mathrm{min}R^{(\prime)}}$ denotes the threshold of the lightest channel resonance R (R') couples to. For example, employing the parameters of the decay of $N^*(1520)$ to ρN one observes that the equation given above only allows the tail of the ρ-meson to contribute to the partial width of the $N^*(1520)$. If in a certain experiment the kinematics do not allow for a scan of the complete line shape of the mother particle, the appropriate procedure to determine the partial width in the approximation outlined above is to determine the effective resonance parameters from a fit to data and to then evaluate Eq. (50.22) in the limits given there. As stressed above, Eq. (50.22) is correct only,

if the use of Breit–Wigner functions is indeed justified for the mother and the daughter particles, which is often not the case. Then, to compare with experiment, the amplitudes need to be parametrised in a more sophisticated way and branching ratios can model independently only be defined via the residues.

In studies of decays where resonance R is very narrow, the first integral in Eq. (50.22) is obsolete and m in the boundaries of the second integral gets fixed to the mass of the mother particle. For recent use of such formulas for B-decays see, e.g., Refs. [45–48]. They were applied to study the three-pion system in Ref. [49].

50.3 Common parameterizations

In general, there is no universal, model-independent recipe to build scattering amplitudes. However, a few approaches presented in this section are practical to extract resonance properties in experimental analyses. The systematic theory uncertainties need to be assessed from a range of model variations that are permitted by general S-matrix principles and that provide a sufficient quality of description of the available data.

50.3.1 *The Breit–Wigner parametrization*

The relativistic Breit–Wigner parametrization provides a propagator for a single, isolated resonance,

$$\mathcal{A}(s) = \frac{N_a(s)}{M_{\rm BW}^2 - s - iM_{\rm BW}\Gamma(s)} \tag{50.23}$$

where $M_{\rm BW}$ is the Breit–Wigner mass, and $\Gamma_{\rm BW} = \Gamma(M_{\rm BW}^2)$ is the Breit–Wigner width. The function $\Gamma(s)$ is determined by the channels that the resonance can decay to. The numerator function $N_a(s)$ is specific to the production process. It includes kinematic factors and couplings related to the production process and the decay. Breit–Wigner functions with a s-independent width are justified only, if there is no relevant threshold in the vicinity of the resonance.

To give a concrete example, we consider a resonance observed in the channel a, that is also coupled to a set of channels labeled by index $b = 1, 2, \ldots$, with the orbital angular momentum l_b. Couplings to the channels are denoted, g_b.

$$N_a(s) = \alpha\, g_a\, n_a(s) \tag{50.24}$$

$$\Gamma(s) = \frac{1}{M_{\rm BW}} \sum_b g_b^2 \rho_b(s) n_b^2(s) \tag{50.25}$$

where the factor $n_a(s)$ includes the kinematic threshold factor q^{l_a}, and the barrier factor $F_{l_a}(q_a/q_0)$ that regularize the high–energy behaviour:

$$n_a = (q_a/q_0)^{l_a} F_{l_a}(q_a/q_0)\,, \tag{50.26}$$

with l_a being the orbital angular momentum in channel a, $q_a(s)$ is defined in Eq. (50.5), and q_0 denotes some conveniently chosen momentum scale. The factor $(q_a)^l$ guarantees the correct threshold behavior. The rapid growth of this factor for angular momenta $l > 0$ is commonly compensated at higher energies by a phenomenological form factor, here denoted by $F_{l_a}(q_a, q_0)$. Often, the Blatt-Weisskopf form factors, $F_j(q/q_0)$, are used [50–52]:

$$\begin{aligned} F_0^2(z) &= 1\,, \\ F_1^2(z) &= 1/(1+z^2)\,, \\ F_2^2(z) &= 1/(9+3z^2+z^4)\,, \end{aligned} \tag{50.27}$$

with the scale parameter $R = 1/q_0$ in the range from $1\,\mathrm{GeV}^{-1}$ to $5\,\mathrm{GeV}^{-1}$. Instead of using coupling constant in Eq. (50.25), one can define the energy-dependent partial width:

$$\Gamma_b(s) = \Gamma_{{\rm BW},b} \frac{\rho_b(s)}{\rho_b(M_{\rm BW}^2)} \left(\frac{q_b}{q_{b\,\rm R}}\right)^{2l_b} \frac{F_{l_b}^2(q_b, q_0)}{F_{l_b}^2(q_{b\,\rm R}, q_0)}\,. \tag{50.28}$$

Here $q_{a\,\rm R}$ are the values of the break-up momentum evaluated at $s = M_{\rm BW}^2$. The substitution is possible only for those channels where the threshold of the decay channel is located below the nominal resonance mass, otherwise, Eq. (50.25) should be used.

The Breit–Wigner parametrization provides an effective description of resonance phenomena. However, the parameters agree with the pole parameters only if the resonance is narrow, isolated (no nearby resonances in the same partial wave) and the background is smooth. Otherwise, the Breit–Wigner parameters deviate from the pole parameters and are reaction-dependent. If there is more than one resonance in one partial wave that significantly couples to the same channel, it is in general incorrect to use a sum of Breit–Wigner functions, for this usually leads to a violation of unitarity constraints, and hence, a non-quantifiable bias to resonance properties which are inferred from the reaction amplitude. In case of overlapping resonances in the same partial wave more refined methods should be used, like the K-matrix approach described in the next section.

50.3.2 *K-matrix approach and Flatté parameterizations*

The K-matrix method is a general construction for coupled-channel scattering amplitudes $\mathcal{M}_{ba}$ that guarantees two-particle unitarity, but does not allow for the inclusion of left-hand cuts [53]. The amplitude reads,

$$n_b\, \mathcal{M}_{ba}^{-1}\, n_a = \mathcal{K}_{ba}^{-1} - i\delta_{ba}\rho_a n_a^2, \tag{50.29}$$

where $\mathcal{K}_{ba}$ is a real function, a subject to modeling. The factor n_a, defined in Eq. (50.26), becomes important for waves with non-zero angular momentum. As there is no unique rigorous recipe to build $\mathcal{K}$, various parameterizations thereof have to be studied, in order to get access to the theoretical systematic uncertainty. One possible choice for the K-matrix is

$$\mathcal{K}_{ba}(s) = \sum_R \frac{g_b^R g_a^R}{m_R^2 - s} + \sum_{i=0}^{N_{\rm b.g.}} b_{ba}^{(i)} s^i, \tag{50.30}$$

where m_R is referred to as the bare mass of the resonance R (not to be confused with the physical mass), the g_a^R are the bare couplings of the resonance R to the channel a (not to be confused with the residues). The $b_{ba}^{(i)}$ are matrices parameterizing the non-pole parts of the K-matrix. As long as all parameters appearing in Eq. (50.30) are real the amplitude is unitary. From the ansatz given above the scattering amplitude $\mathcal{M}$ can be calculated directly using the matrix form,

$$\mathcal{M} = n[1 - \mathcal{K}\, i\rho\, n^2]^{-1}\mathcal{K}\, n\ , \tag{50.31}$$

where the diagonal matrix in the channel space $n = \mathrm{diag}(n_a, n_b, \ldots)$. As an alternative to Eq. (50.30), the same functional form as on the right side of Eq. (50.30) can be used to parameterize the inverse K-matrix, called by authors of Ref. [54] the M-matrix. Many other alternative expressions in the K-matrix framework are used for amplitude studies in lattice-QCD calculations [55–57].

Evaluation of the K-matrix amplitude for the multichannel problem requires an analytic continuation already on the real axis. For a given closed channel c, the factor $q_c(s)$ that enters ρ_c and n_c has to be calculated below the corresponding threshold, *i.e.* in the unphysical region of the particular channel c. This is done using analytic continuation as described *e.g.* in Refs. [27, 58]:

$$q_c = i\sqrt{-q_c^2} \quad \text{for} \quad q_c^2 < 0. \tag{50.32}$$

The resulting line shape above and below the threshold of channel c is called the Flatté parameterization [58]. The contiuation given above stays on the physical sheet. To reach the unphysical sheet the negative square root needs to be chosen. If the coupling of a resonance to the channel opening nearby is very strong, the Flatté parameterization shows a scaling invariance and does not allow for an extraction of individual partial decay widths, but only of ratios [59]. The position of the resonance poles can be determined by a study of the zeros of the analytic function $\det[1 - \mathcal{K}\, i\rho\, n^2]$. Due to the ρ factor, this determinant has a complicated multisheet structure, however, the closest unphysical sheet is always the one which is determined by the heaviest threshold below the studied point in s (*cf.* Fig. 50.2).

50.3.3 *Scattering-length approximation*

A scattering length, a, is defined as the first term in an expansion of the scattering phase shift introduced in Eq. (50.11). For S-waves one finds,

$$q \cot \delta = 1/a + O(q^2)\,, \tag{50.33}$$

where q is the break-up momentum of the scattering system. The sign convention used in Eq. (50.33) is the one commonly employed in particle physics. In this convention a positive scattering length indicates attraction; if, however, the attraction is strong enough to generate a bound state, the scattering length changes sign and turns negative. A negative scattering length also occurs for repulsive interactions. Note that in nuclear physics the leading term in the expansion of Eq. (50.33) is usually defined as $-1/a$ such that *e.g.* a bound state would be related to a positive scattering length. Employing Eq. (50.33) the scattering amplitude reads

$$\mathcal{M}(s) = \frac{8\pi\sqrt{s}}{1/a - iq(s)}\,. \tag{50.34}$$

The scattering length is proportional to the value of the amplitude at threshold. A scattering length approximation is applicable only in a very limited energy range, however, might well be appropriate to analyse the recently discovered narrow near-threshold states [60,61] from this point of view, *e.g.*, in Refs. [62–64]. Moreover, it is possible to introduce the effect of a weakly coupled lower channel. To see this one might start from

$$\mathcal{K} = \begin{pmatrix} \gamma & \beta \\ \beta & 0 \end{pmatrix}\,, \tag{50.35}$$

with β, γ being real numbers. It leads to

$$\mathcal{M}_{\rm el.}(s) = \frac{1}{1/(\gamma + i\beta^2\rho_{\rm inel.}(s)) - i\rho(s)}\,, \tag{50.36}$$

with $\rho_{\rm inel.}(s)$ being the phase-space factor of the inelastic channel. The scattering length for the amplitude in Eq. (50.36) obtains an imaginary part due to the coupling to the lower channel,

$$a = \frac{1}{8\pi\sqrt{s_{\rm thr}}}\left(\gamma + i\beta^2\rho_{\rm inel.}(s_{\rm thr})\right)\,. \tag{50.37}$$

If the function $\beta^2\rho_{\rm inel.}(s)$ does not vary significantly in the energy range studied, the scattering-length approximation with a complex value is justified. For large values of a the amplitude of Eq. (50.36) develops a near-threshold pole located on the physical or unphysical sheet for negative or positive values of γ, respectively. While easy to use, it is important to stress, however, that the approximation in Eq. (50.35) is a specific choice of the dynamic function that produces a single pole near the physical region pointing at a hadronic molecule nature of the state studied [64–67]. Virtual states are discussed in this context in Ref. [68]. For practical analyses, various modifications of the parameterization have to be tested.

50.3.4 *Two methods to build the production amplitude*

When the unitary scattering amplitude is fixed, it can be used to build the production amplitude in a way that it is consistent with unitarity [52, 69].

1. The Q**-vector** approach is discussed in Ref. [52, 54, 70]. It reads,

$$\mathcal{A}_a(s) = \sum_c \mathcal{M}_{ac}(s) Q_c(s)/n_c, \qquad Q_c(s) = \sum Q_c^{(i)} s^i. \tag{50.38}$$

The unitarity condition of Eq. (50.14) is satisfied when $Q_c(s)$ is a real function and in particular does not have singularities above the lowest threshold for all channels c. Besides these conditions $Q_c(s)$ is arbitrary. Note that in the Q-vector approach the left hand cuts of the scattering matrix $\mathcal{M}_{ac}(s)$ get imported to the production amplitude which might generate a wrong analytic structure. If this problem is relevant needs to be investigated on a case-by-case basis. In a study of $\gamma\gamma \to \pi\pi$, *cf.* Ref. [41, 42] a low-order polynomial is claimed to be sufficient to parametrize the energy dependence of the function $Q_c(s)$. The Q-vector method is convenient, if the full matrix $\mathcal{M}$ is known, *cf.* Ref. [54].

2. The P**-vector** is a parameterization that exploits the K-matrix of the scattering amplitude [53, 69]. It contains two components: the background term B_c that is coupled to the K-matrix via an intermediate loop represented by the $i\rho$ factor, and the "direct" resonance production term with couplings α_c^R:

$$\begin{aligned} \mathcal{A}_a(s) &= n_a \sum_c \left[1 - \mathcal{K}\, i\rho n^2\right]^{-1}_{ac} P_c, \\ P_c &= \sum_R \frac{\alpha^R g_c^R}{m_R^2 - s} + B_c. \end{aligned} \tag{50.39}$$

Again, unitarity requires the parameters B_c and α^R to be real.Here, the masses m_R and the couplings g_c^R need to agree with those in $\mathcal{K}$ in Eq. (50.30).

An important difference between the methods is to be noticed [69]. When the two-particle scattering amplitude goes to zero, the production amplitude in the Q–vector method vanishes for finite values of Q_c, while it stays finite in the P-vector approach. An version of the P-vector approach that exploits the analytic properties of production amplitudes [69, 71, 72] is widely used, *e.g.* in the dispersive Khuri-Treiman framework [28, 73] for the construction of three-body-decay amplitudes.

50.3.5 *Further improvements: Chew-Mandelstam function*

The K-matrix described above usually allows one to get a proper fit of physical amplitudes and it is easy to deal with, however, it also has an important deficit: it violates constraints from analyticity — *e.g.*, ρ_a, given by Eq. (50.9), is ill-defined at $s = 0$, and for unequal masses it develops an unphysical cut (see left panel of Fig. 50.4). A method to improve the analytic properties was suggested in Refs. [74–78]. It replaces the phase-space factor $i\rho_a(s)$ in Eq. (50.29) by the analytic function $\Sigma_a(s)$ that produces the identical imaginary part on the right-hand cut. This function is called the Chew-Mandelstam function and for S-waves it reads [72, 76]:

$$\begin{aligned} \Sigma_a(s) = \frac{1}{16\pi^2}\Bigg[&\frac{2q_a}{\sqrt{s}} \log \frac{m_1^2 + m_2^2 - s + 2\sqrt{s}q_a}{2m_1 m_2} - \\ &- (m_1^2 - m_2^2)\left(\frac{1}{s} - \frac{1}{(m_1+m_2)^2}\right)\log\frac{m_1}{m_2}\Bigg], \end{aligned} \tag{50.40}$$

where m_1 and m_2 are masses of the final-state particles in channel a, $s_{{\rm thr}_a} = (m_1+m_2)^2$. The function along the real axis is plotted in the right panel of Fig. 50.4. For channels with $j > 0$, the threshold behavior has to be incorporated properly. This can be done, *e.g.*, by computing the dispersion integral

$$\Sigma_a(s + i0) = \frac{s - s_{{\rm thr}_a}}{\pi}\int_{s_{{\rm thr}_a}}^{\infty} \frac{\rho_a(s')n_a^2(s')}{(s' - s_{{\rm thr}_a})(s' - s - i0)}\,{\rm d}s'. \tag{50.41}$$

A further discussion of the calculation of the Chew-Mandelstam function can be found in Refs. [79, 80].

If there is only a single resonance in a given channel, it is possible to feed the imaginary part of the Breit–Wigner function, Eq. (50.23) with an energy-dependent width, directly into a dispersion integral to get a resonance propagator with the correct analytic structure [81, 82].

50.3.6 *Two-potential decomposition*

Another advanced technique to construct the scattering amplitude which is widely used in the literature [83–87] is based on the two-potential formalism [88]. The method is usually formulated for the full unprojected amplitude $\mathcal{M}_{ba}(s,t)$, however, in order to simplify the discussion we present the equations in the partial-wave-projected form.

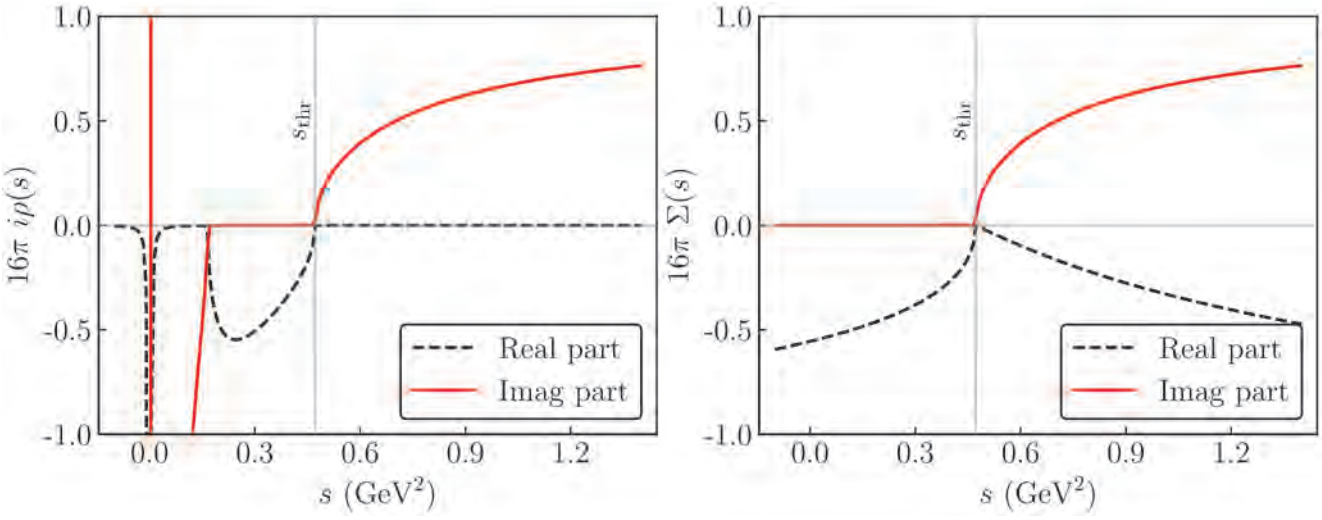

Figure 50.4: Comparison of the $i\rho$ function (left plot) to the Chew-Mandelstam function from Eq. (50.40) (right plot), evaluated for the case of S-wave $\eta\pi$ scattering. The values of s are taken slightly above the real axis, $s + i0$. The solid red line shows the imaginary part that is the same for both functions above threshold. The dashed black line presents the real part. One finds indications of the unphysical left-hand singularities of the function $i\rho$ on the left plot, while the Chew-Mandelstam function in analytic below the two-particle threshold.

The scattering amplitude $\mathcal{M}$ is decomposed into a pole part and a non-pole part, often called background (b.g.)

$$\mathcal{M}(s) = \mathcal{M}^{\rm b.g.}(s) + \mathcal{M}^{\rm pole}(s)\,. \tag{50.42}$$

The splitting given in Eq. (50.42) is not unique and model-dependent (see, *e.g.*, the discussions in Refs. [89, 90]). The background scattering matrix is assumed to be unitary by itself. One option is to parameterize it, *e.g.* at low energies directly in terms of phase shifts and inelasticities — see, *e.g.*, Refs. [44, 87, 91]. In this case the vertex functions $\Omega(s)_{ab}$ introduced below can be written in terms of an Omnes matrix [91], which reduces to the well-known Omnes function in the single-channel case [71]. Alternatively, it can be computed based on some potential, $V^{\rm b.g.}$, fed into a proper scattering equation.

The complete amplitude $\mathcal{M}$ of Eq. (50.42) is unitary, if the pole part is chosen as

$$\mathcal{M}^{\rm pole}(s) = \Omega(s)\ [1 - V^{\rm R}(s)\Sigma^u(s)]^{-1} V^{\rm R}(s)\ \Omega^T(s)\ . \tag{50.43}$$

where the resonance potential reads in channel space

$$V^{\rm R}_{ab}(s) = \sum_R \frac{g^R_a\ g^R_b}{M^2_R - s}\ , \tag{50.44}$$

Σ^u_{ab} denotes the self-energy matrix, and g^R_a and M_R denote the bare coupling of the resonance R to channel a and its bare mass, respectively. A relation analogous to Eq. (50.6) holds for the normalized vertex functions, however, with the final state interaction provided by $\mathcal{M}^{\rm b.g.}$

$$\text{Disc}\ \Omega_{ab}(s) = 2i \sum_c \mathcal{M}^{\rm b.g.\,*}_{ca}(s)\,\rho_c(s)\,\Omega_{cb}(s)\ . \tag{50.45}$$

The discontinuity of the self-energy matrix $\Sigma^u(s)$ is

$$\text{Disc}\ \Sigma^u_{ab}(s) = 2i \sum_c \Omega^*_{ca}(s)\,\rho_c(s)\,\Omega_{cb}(s)\ . \tag{50.46}$$

The real part of Σ^u can be calculated from Eq. (50.46) via a properly subtracted dispersion integral. If $\mathcal{M}^{\rm b.g.}$ is unitary, the use of Eq. (50.43) leads to a unitary full amplitude, *cf.* Eq. (50.42). However, the pole term alone is unitary only for a vanishing background amplitude. In this situation the amplitude just described reduces to the analytically improved K-matrix of Sec. 50.3.5. While the omission of non-pole terms is a bad approximation for, *e.g.*, scalar-isoscalar $\pi\pi$ interactions at low energies [92], it typically works well for higher partial waves.

The algebra of the two potential splitting presented in Eq. (50.42) is found to be very practical in various other cases, beyond the pole-background separation. It was employed in Refs. [87, 91] to treat the pion vector and scalar form factor, respectively, over a sizable energy range including inelasticities. A similar decomposition applied to the $3 \to 3$ scattering problem provided a way to isolate the non-separable one-particle exchange singularity from the short-range resonance interaction [93].

51. Cross-Section Formulae for Specific Processes

Revised August 2019 by H. Baer (Oklahoma U.) and R.N. Cahn (LBNL).

PART I: STANDARD MODEL PROCESSES

Setting aside leptoproduction (for which, see Sec. 16 of this *Review*), the cross sections of primary interest are those with light incident particles, e^+e^-, $\gamma\gamma$, $q\overline{q}$, gq , gg, *etc.*, where g and q represent gluons and light quarks. The produced particles include both light particles and heavy ones - t, W, Z, and the Higgs boson H. We provide the production cross sections calculated within the Standard Model for several such processes.

51.1 Resonance Formation

Resonant cross sections are generally described by the Breit-Wigner formula (Sec. 50.3 of this *Review*).

$$\sigma(E) = \frac{2J+1}{(2S_1+1)(2S_2+1)}\frac{4\pi}{k^2}\left[\frac{\Gamma^2/4}{(E-E_0)^2+\Gamma^2/4}\right]B_{in}B_{out}, \tag{51.1}$$

where E is the c.m. energy, J is the spin of the resonance, and the number of polarization states of the two incident particles are $2S_1+1$ and $2S_2+1$. The c.m. momentum in the initial state is k, E_0 is the c.m. energy at the resonance, and Γ is the full width at half maximum height of the resonance. The branching fraction for the resonance into the initial-state channel is B_{in} and into the final-state channel is B_{out}. For a narrow resonance, the factor in square brackets may be replaced by $\pi\Gamma\delta(E-E_0)/2$.

51.2 Production of light particles

The production of point-like, spin-1/2 fermions in e^+e^- annihilation through a virtual photon, $e^+e^- \to \gamma^* \to f\overline{f}$, at c.m. energy squared s is given by

$$\frac{d\sigma}{d\Omega} = N_c\frac{\alpha^2}{4s}\beta\left[1+\cos^2\theta+(1-\beta^2)\sin^2\theta\right]Q_f^2 \ , \tag{51.2}$$

where β is v/c for the produced fermions in the c.m., θ is the c.m. scattering angle, and Q_f is the charge of the fermion. The factor N_c is 1 for charged leptons and 3 for quarks. In the ultrarelativistic limit, $\beta \to 1$,

$$\sigma = N_cQ_f^2\frac{4\pi\alpha^2}{3s} = N_cQ_f^2\frac{86.8\text{ nb}}{s\,(\text{GeV}^2)} \ . \tag{51.3}$$

The cross section for the annihilation of a $q\overline{q}$ pair into a distinct pair $q'\overline{q}'$ through a gluon is completely analogous up to color factors, with the replacement $\alpha \to \alpha_s$. Treating all quarks as massless, averaging over the colors of the initial quarks and defining $t=-s\sin^2(\theta/2)$, $u=-s\cos^2(\theta/2)$, one finds [1]

$$\frac{d\sigma}{d\Omega}(q\overline{q}\to q'\overline{q}') = \frac{\alpha_s^2}{9s}\frac{t^2+u^2}{s^2} \ . \tag{51.4}$$

Crossing symmetry gives

$$\frac{d\sigma}{d\Omega}(qq'\to qq') = \frac{\alpha_s^2}{9s}\frac{s^2+u^2}{t^2} \ . \tag{51.5}$$

If the quarks q and q' are identical, we have

$$\frac{d\sigma}{d\Omega}(q\overline{q}\to q\overline{q}) = \frac{\alpha_s^2}{9s}\left[\frac{t^2+u^2}{s^2}+\frac{s^2+u^2}{t^2}-\frac{2u^2}{3st}\right] \ , \tag{51.6}$$

and by crossing

$$\frac{d\sigma}{d\Omega}(qq\to qq) = \frac{\alpha_s^2}{9s}\left[\frac{t^2+s^2}{u^2}+\frac{s^2+u^2}{t^2}-\frac{2s^2}{3ut}\right]. \tag{51.7}$$

Annihilation of e^+e^- into $\gamma\gamma$ has the cross section

$$\frac{d\sigma}{d\Omega}(e^+e^-\to\gamma\gamma) = \frac{\alpha^2}{2s}\frac{u^2+t^2}{tu} \ . \tag{51.8}$$

The related QCD process also has a triple-gluon coupling. The cross section is

$$\frac{d\sigma}{d\Omega}(q\overline{q}\to gg) = \frac{8\alpha_s^2}{27s}(t^2+u^2)\left(\frac{1}{tu}-\frac{9}{4s^2}\right) \ . \tag{51.9}$$

The crossed reactions are

$$\frac{d\sigma}{d\Omega}(qg\to qg) = \frac{\alpha_s^2}{9s}(s^2+u^2)(-\frac{1}{su}+\frac{9}{4t^2}) \tag{51.10}$$

and

$$\frac{d\sigma}{d\Omega}(gg\to q\overline{q}) = \frac{\alpha_s^2}{24s}(t^2+u^2)(\frac{1}{tu}-\frac{9}{4s^2}) \ . \tag{51.11}$$

Finally,

$$\frac{d\sigma}{d\Omega}(gg\to gg) = \frac{9\alpha_s^2}{8s}(3-\frac{ut}{s^2}-\frac{su}{t^2}-\frac{st}{u^2}) \ . \tag{51.12}$$

Lepton-quark scattering is analogous (neglecting Z exchange)

$$\frac{d\sigma}{d\Omega}(eq\to eq) = \frac{\alpha^2}{2s}e_q^2\frac{s^2+u^2}{t^2} \ . \tag{51.13}$$

where e_q is the charge of the quark. For neutrino scattering with the four-Fermi interaction

$$\frac{d\sigma}{d\Omega}(\nu d\to\ell^- u) = \frac{G_F^2 s}{4\pi^2} \ , \tag{51.14}$$

where the Cabibbo angle suppression is ignored. Similarly

$$\frac{d\sigma}{d\Omega}(\nu\overline{u}\to\ell^-\overline{d}) = \frac{G_F^2 s}{4\pi^2}\frac{(1+\cos\theta)^2}{4} \ . \tag{51.15}$$

To obtain the formulae for deep inelastic scattering (presented in more detail in Section 18) we consider quarks of type i carrying a fraction $x = Q^2/(2M\nu)$ of the nucleon's energy, where $\nu = E-E'$ is the energy lost by the lepton in the nucleon rest frame. With $y=\nu/E$ we have the correspondences

$$1+\cos\theta \to 2(1-y) \ ,$$

$$d\Omega_{cm} \to 4\pi f_i(x)dx\,dy \ , \tag{51.16}$$

where the latter incorporates the quark distribution, $f_i(x)$. In this way we find

$$\frac{d\sigma}{dx\,dy}(eN\to eX) = \frac{4\pi\alpha^2 xs}{Q^4}\frac{1}{2}\left[1+(1-y)^2\right] \times \left[\frac{4}{9}(u(x)+\overline{u}(x)+\ldots)+\frac{1}{9}(d(x)+\overline{d}(x)+\ldots)\right] \tag{51.17}$$

where now $s=2ME$ is the cm energy squared for the electron-nucleon collision, and we have suppressed contributions from higher mass quarks.

Similarly,

$$\frac{d\sigma}{dx\,dy}(\nu N\to\ell^- X) = \frac{G_F^2 xs}{\pi}[(d(x)+\ldots)+(1-y)^2(\overline{u}(x)+\ldots)] \tag{51.18}$$

and

$$\frac{d\sigma}{dx\,dy}(\overline{\nu}N\to\ell^+ X) = \frac{G_F^2 xs}{\pi}[(\overline{d}(x)+\ldots)+(1-y)^2(u(x)+\ldots)] \ . \tag{51.19}$$

Quasi-elastic neutrino scattering ($\nu_\mu n\to\mu^- p$, $\overline{\nu}_\mu p\to\mu^+ n$) is directly related to the crossed reaction, neutron decay. The formula for the differential cross section is presented, for example, in N.J. Baker *et al.*, Phys. Rev. **D23**, 2499 (1981).

51.3 Hadroproduction of heavy quarks

For hadroproduction of heavy quarks $Q = c,\ b,\ t$, it is important to include mass effects in the formulae. For $q\bar{q} \to Q\bar{Q}$, one has

$$\frac{d\sigma}{d\Omega}(q\bar{q} \to Q\bar{Q}) = \frac{\alpha_s^2}{9s^3}\sqrt{1-\frac{4m_Q^2}{s}} \times \left[(m_Q^2-t)^2 + (m_Q^2-u)^2 + 2m_Q^2 s\right], \tag{51.20}$$

while for $gg \to Q\bar{Q}$ one has

$$\begin{aligned}\frac{d\sigma}{d\Omega}(gg \to Q\bar{Q}) = \frac{\alpha_s^2}{32s}\sqrt{1-\frac{4m_Q^2}{s}}\Bigg[&\frac{6}{s^2}(m_Q^2-t)(m_Q^2-u) - \\ &-\frac{m_Q^2(s-4m_Q^2)}{3(m_Q^2-t)(m_Q^2-u)} + \\ &\frac{4}{3}\frac{(m_Q^2-t)(m_Q^2-u)-2m_Q^2(m_Q^2+t)}{(m_Q^2-t)^2} \\ &+\frac{4}{3}\frac{(m_Q^2-t)(m_Q^2-u)-2m_Q^2(m_Q^2+u)}{(m_Q^2-u)^2} \\ &-3\frac{(m_Q^2-t)(m_Q^2-u)+m_Q^2(u-t)}{s(m_Q^2-t)} \\ &-3\frac{(m_Q^2-t)(m_Q^2-u)+m_Q^2(t-u)}{s(m_Q^2-u)}\Bigg].\end{aligned} \tag{51.21}$$

51.4 Production of Weak Gauge Bosons

51.4.1 *W and Z resonant production*

Resonant production of a single W or Z is governed by the partial widths

$$\Gamma(W \to \ell_i \overline{\nu}_i) = \frac{\sqrt{2}G_F m_W^3}{12\pi} \tag{51.22}$$

$$\Gamma(W \to q_i \overline{q}_j) = 3\frac{\sqrt{2}G_F |V_{ij}|^2 m_W^3}{12\pi} \tag{51.23}$$

$$\Gamma(Z \to f\overline{f}) = N_c \frac{\sqrt{2}G_F m_Z^3}{6\pi} \times \left[(T_3 - Q_f \sin^2\theta_W)^2 + (Q_f \sin^2\theta_W)^2\right]. \tag{51.24}$$

The weak mixing angle is θ_W. The CKM matrix elements are indicated by V_{ij} and N_c is 3 for $q\overline{q}$ final states and 1 for leptonic final states.

The full differential cross section for $f_i\bar{f}_j \to (W,Z) \to f_{i'}\bar{f}_{j'}$ is given by

$$\begin{aligned}\frac{d\sigma}{d\Omega} = &\frac{N_c^f}{N_c^i}\cdot\frac{1}{256\pi^2 s}\cdot\frac{s^2}{(s-M^2)^2+s\Gamma^2} \\ &\times\Big[(L^2+R^2)(L'^2+R'^2)(1+\cos^2\theta) \\ &+(L^2-R^2)(L'^2-R'^2)2\,cos\theta\Big]\end{aligned} \tag{51.25}$$

where M is the mass of the W or Z. The couplings for the W are $L = (8G_F m_W^2/\sqrt{2})^{1/2} V_{ij}/\sqrt{2}; R = 0$ where V_{ij} is the corresponding CKM matrix element, with an analogous expression for L' and R'. For Z, the couplings are $L = (8G_F m_Z^2/\sqrt{2})^{1/2}(T_3 - \sin^2\theta_W Q); R = -(8G_F m_Z^2/\sqrt{2})^{1/2}\sin^2\theta_W Q$, where T_3 is the weak isospin of the initial left-handed fermion and Q is the initial fermion's electric charge. The expressions for L' and R' are analogous. The color factors $N_c^{i,f}$ are 3 for initial or final quarks and 1 for initial or final leptons.

51.4.2 *Production of pairs of weak gauge bosons*

The cross section for $f\bar{f} \to W^+W^-$ is given in term of the couplings of the left-handed and right-handed fermion f, $\ell = 2(T_3 - Qx_W)$, $r = -2Qx_W$, where T_3 is the third component of weak isospin for the left-handed f, Q is its electric charge (in units of the proton charge), and $x_W = \sin^2\theta_W$:

$$\begin{aligned}\frac{d\sigma}{dt} = &\frac{2\pi\alpha^2}{N_c s^2}\Bigg\{\Bigg[\left(Q + \frac{\ell+r}{4x_W}\frac{s}{s-m_Z^2}\right)^2 \\ &+\left(\frac{\ell-r}{4x_W}\frac{s}{s-m_Z^2}\right)^2\Bigg]A(s,t,u) \\ &+\frac{1}{2x_W}\left(Q+\frac{\ell}{2x_W}\frac{s}{s-m_Z^2}\right) \\ &\qquad(\Theta(-Q)I(s,t,u) - \Theta(Q)I(s,u,t)) \\ &+\frac{1}{8x_W^2}\left(\Theta(-Q)E(s,t,u) + \Theta(Q)E(s,u,t)\right)\Bigg\},\end{aligned} \tag{51.26}$$

where $\Theta(x)$ is 1 for $x > 0$ and 0 for $x < 0$, and where

$$\begin{aligned}A(s,t,u) &= \left(\frac{tu}{m_W^4}-1\right)\left(\frac{1}{4}-\frac{m_W^2}{s}+3\frac{m_W^4}{s^2}\right)+\frac{s}{m_W^2}-4, \\ I(s,t,u) &= \left(\frac{tu}{m_W^4}-1\right)\left(\frac{1}{4}-\frac{m_W^2}{2s}-\frac{m_W^4}{st}\right)+\frac{s}{m_W^2}-2+2\frac{m_W^2}{t}, \\ E(s,t,u) &= \left(\frac{tu}{m_W^4}-1\right)\left(\frac{1}{4}+\frac{m_W^4}{t^2}\right)+\frac{s}{m_W^2},\end{aligned} \tag{51.27}$$

and s,t,u are the usual Mandelstam variables with $s = (p_f + p_{\bar{f}})^2, t = (p_f - p_{W^-})^2, u = (p_f - p_{W^+})^2$. The factor N_c is 3 for quarks and 1 for leptons.

The analogous cross-section for $q_i\bar{q}_j \to W^\pm Z^0$ is

$$\begin{aligned}\frac{d\sigma}{dt} = &\frac{\pi\alpha^2|V_{ij}|^2}{6s^2x_W^2}\Bigg\{\left(\frac{1}{s-m_W^2}\right)^2\Bigg[\left(\frac{9-8x_W}{4}\right)\left(ut - m_W^2 m_Z^2\right) \\ &+(8x_W-6)\,s\left(m_W^2+m_Z^2\right)\Bigg] \\ &+\left[\frac{ut-m_W^2m_Z^2-s(m_W^2+m_Z^2)}{s-m_W^2}\right]\left[\frac{\ell_j}{t}-\frac{\ell_i}{u}\right] \\ &+\frac{ut-m_W^2m_Z^2}{4(1-x_W)}\left[\frac{\ell_j^2}{t^2}+\frac{\ell_i^2}{u^2}\right]+\frac{s(m_W^2+m_Z^2)}{2(1-x_W)}\frac{\ell_i\ell_j}{tu}\Bigg\},\end{aligned} \tag{51.28}$$

where ℓ_i and ℓ_j are the couplings of the left-handed q_i and q_j as defined above. The CKM matrix element between q_i and q_j is V_{ij}.

The cross section for $q_i\bar{q}_i \to Z^0Z^0$ is

$$\frac{d\sigma}{dt} = \frac{\pi\alpha^2}{96}\frac{\ell_i^4+r_i^4}{x_W^2(1-x_W^2)^2s^2}\left[\frac{t}{u}+\frac{u}{t}+\frac{4m_Z^2 s}{tu}-m_Z^4\left(\frac{1}{t^2}+\frac{1}{u^2}\right)\right]. \tag{51.29}$$

51.5 Production of Higgs Bosons

51.5.1 *Resonant Production*

The Higgs boson of the Standard Model can be produced resonantly in the collisions of quarks, leptons, W or Z bosons, gluons, or photons. The production cross section is thus controlled by the partial width of the Higgs boson into the entrance channel and its total width. The branching fractions for the Standard Model Higgs boson are shown in Fig. 1 of the "Searches for Higgs bosons"

review in the Particle Listings section, as a function of the Higgs boson mass. The partial widths are given by the relations

$$\Gamma(H \to f\bar{f}) = \frac{G_F m_f^2 m_H N_c}{4\pi\sqrt{2}} \left(1 - 4m_f^2/m_H^2\right)^{3/2}, \quad (51.30)$$

$$\Gamma(H \to W^+W^-) = \frac{G_F m_H^3 \beta_W}{32\pi\sqrt{2}} \left(4 - 4a_W + 3a_W^2\right), \quad (51.31)$$

$$\Gamma(H \to ZZ) = \frac{G_F m_H^3 \beta_Z}{64\pi\sqrt{2}} \left(4 - 4a_Z + 3a_Z^2\right), \quad (51.32)$$

where N_c is 3 for quarks and 1 for leptons and where $a_W = 1 - \beta_W^2 = 4m_W^2/m_H^2$ and $a_Z = 1 - \beta_Z^2 = 4m_Z^2/m_H^2$. The decay to two gluons proceeds through quark loops, with the t quark dominating [2]. Explicitly,

$$\Gamma(H \to gg) = \frac{\alpha_s^2 G_F m_H^3}{36\pi^3\sqrt{2}} \left| \sum_q I(m_q^2/m_H^2) \right|^2, \quad (51.33)$$

where $I(z)$ is complex for $z < 1/4$. For $z < 2 \times 10^{-3}$, $|I(z)|$ is small so the light quarks contribute negligibly. For $m_H < 2m_t$, $z > 1/4$ and

$$I(z) = 3\left[2z + 2z(1-4z)\left(\sin^{-1}\frac{1}{2\sqrt{z}}\right)^2\right], \quad (51.34)$$

which has the limit $I(z) \to 1$ as $z \to \infty$.

51.5.2 *Higgs Boson Production in W^* and Z^* decay*

The Standard Model Higgs boson can be produced in the decay of a virtual W or Z ("Higgstrahlung") [3,4]: In particular, if k is the c.m. momentum of the Higgs boson,

$$\sigma(q_i\bar{q}_j \to WH) = \frac{\pi\alpha^2|V_{ij}|^2}{36\sin^4\theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_W^2}{(s - m_W^2)^2} \quad (51.35)$$

$$\sigma(f\bar{f} \to ZH) = \frac{2\pi\alpha^2(\ell_f^2 + r_f^2)}{48N_c\sin^4\theta_W\cos^4\theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_Z^2}{(s - m_Z^2)^2}, \quad (51.36)$$

where ℓ and r are defined as above.

51.5.3 *W and Z Fusion*

Just as high-energy electrons can be regarded as sources of virtual photon beams, at very high energies they are sources of virtual W and Z beams. For Higgs boson production, it is the longitudinal components of the Ws and Zs that are important [5]. The distribution of longitudinal Ws carrying a fraction y of the electron's energy is [6]

$$f(y) = \frac{g^2}{16\pi^2}\frac{1-y}{y}, \quad (51.37)$$

where $g = e/\sin\theta_W$. In the limit $s \gg m_H \gg m_W$, the partial decay rate is $\Gamma(H \to W_L W_L) = (g^2/64\pi)(m_H^3/m_W^2)$ and in the equivalent W approximation [7]

$$\sigma(e^+e^- \to \overline{\nu}_e\nu_e H) = \frac{1}{16m_W^2}\left(\frac{\alpha}{\sin^2\theta_W}\right)^3 \times \left[\left(1 + \frac{m_H^2}{s}\right)\log\frac{s}{m_H^2} - 2 + 2\frac{m_H^2}{s}\right]. \quad (51.38)$$

There are significant corrections to this relation when m_H is not large compared to m_W [8]. For $m_H = 150$ GeV, the estimate is too high by 51% for $\sqrt{s} = 1000$ GeV, 32% too high at $\sqrt{s} = 2000$ GeV, and 22% too high at $\sqrt{s} = 4000$ GeV. Fusion of ZZ to make a Higgs boson can be treated similarly. Identical formulae apply for Higgs production in the collisions of quarks whose charges permit the emission of a W^+ and a W^-, except that QCD corrections and CKM matrix elements are required. Even in the absence of QCD corrections, the fine-structure constant ought to be evaluated at the scale of the collision, say m_W. All quarks contribute to the ZZ fusion process.

51.6 Inclusive hadronic reactions

One-particle inclusive cross sections $Ed^3\sigma/d^3p$ for the production of a particle of momentum p are conveniently expressed in terms of rapidity y (see above) and the momentum p_T transverse to the beam direction (in the c.m.):

$$E\frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi\, dy\, p_T\, dp_T}. \quad (51.39)$$

In appropriate circumstances, the cross section may be decomposed as a partonic cross section multiplied by the probabilities of finding partons of the prescribed momenta:

$$\sigma_{\rm hadronic} = \sum_{ij}\int dx_1\, dx_2\, f_i(x_1)\, f_j(x_2)\, d\widehat{\sigma}_{\rm partonic}, \quad (51.40)$$

The probability that a parton of type i carries a fraction of the incident particle's that lies between x_1 and $x_1 + dx_1$ is $f_i(x_1)dx_1$ and similarly for partons in the other incident particle. The partonic collision is specified by its c.m. energy squared $\hat{s} = x_1x_2s$ and the momentum transfer squared $\hat{t}$. The final hadronic state is more conveniently specified by the rapidities y_1, y_2 of the two jets resulting from the collision and the transverse momentum p_T. The connection between the differentials is

$$dx_1dx_2d\hat{t} = dy_1dy_2\frac{\hat{s}}{s}dp_T^2, \quad (51.41)$$

so that

$$\frac{d^3\sigma}{dy_1dy_2dp_T^2} = \frac{\hat{s}}{s}\left[f_i(x_1)f_j(x_2)\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{t},\hat{u}) + f_i(x_2)f_j(x_1)\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{u},\hat{t})\right], \quad (51.42)$$

where we have taken into account the possibility that the incident parton types might arise from either incident particle. The second term should be dropped if the types are identical: $i = j$.

51.7 Two-photon processes

In the Weizsäcker-Williams picture, a high-energy electron beam is accompanied by a spectrum of virtual photons of energies ω and invariant-mass squared $q^2 = -Q^2$, for which the photon number density is

$$dn = \frac{\alpha}{\pi}\left[1 - \frac{\omega}{E} + \frac{\omega^2}{E^2} - \frac{m_e^2\,\omega^2}{Q^2E^2}\right]\frac{d\omega}{\omega}\frac{dQ^2}{Q^2}, \quad (51.43)$$

where E is the energy of the electron beam. The cross section for $e^+e^- \to e^+e^-X$ is then [9]

$$d\sigma_{e^+e^-\to e^+e^-X}(s) = dn_1dn_2d\sigma_{\gamma\gamma\to X}(W^2), \quad (51.44)$$

where $W^2 = m_X^2$. Integrating from the lower limit $Q^2 = m_e^2\frac{\omega_i^2}{E_i(E_i-\omega_i)}$ to a maximum Q^2 gives

$$\sigma_{e^+e^-\to e^+e^-X}(s) = \frac{\alpha^2}{\pi^2}\int_{z_{th}}^1\frac{dz}{z} \times \left[\left(\ln\frac{Q^2_{max}}{zm_e^2} - 1\right)^2 f(z) + \frac{1}{3}(\ln z)^3\right]\sigma_{\gamma\gamma\to X}(zs), \quad (51.45)$$

where

$$f(z) = \left(1 + \tfrac{1}{2}z\right)^2\ln(1/z) - \tfrac{1}{2}(1-z)(3+z). \quad (51.46)$$

The appropriate value of Q^2_{max} depends on the properties of the produced system X. For production of hadronic systems, $Q^2_{max} \approx m^2_\rho$, while for lepton-pair production, $Q^2 \approx W^2$. For production of a resonance with spin $J \neq 1$, we have

$$\sigma_{e^+e^-\to e^+e^- R}(s) = (2J+1)\frac{8\alpha^2\Gamma_{R\to\gamma\gamma}}{m_R^3} \times \left[f(m_R^2/s)\left(\ln\frac{m_V^2 s}{m_e^2 m_R^2} - 1\right)^2 - \frac{1}{3}\left(\ln\frac{s}{M_R^2}\right)^3\right], \tag{51.47}$$

where m_V is the mass that enters into the form factor for the $\gamma\gamma \to R$ transition, typically m_ρ.

PART II: PROCESSES BEYOND THE STANDARD MODEL

51.8 Production of supersymmetric particles

In supersymmetric (SUSY) theories (see Supersymmetric Particle Searches in this *Review*), every boson has a fermionic superpartner, and every fermion has a bosonic superpartner. The minimal supersymmetric Standard Model (MSSM) is a direct supersymmetrization of the Standard Model (SM), although a second Higgs doublet is needed to avoid triangle anomalies [10]. Under *soft* SUSY breaking, superpartner masses are lifted above the SM particle masses. In weak scale SUSY, the superpartners are invoked to stabilize the weak scale under radiative corrections, so the superpartners are expected to have masses of order the TeV scale.

51.8.1 *Gluino and squark production*

The superpartners of gluons are the color octet, spin$-\frac{1}{2}$ gluinos ($\tilde{g}$), while each helicity component of quark flavor has a spin-0 *squark* partner, *e.g.* $\tilde{q}_L$ and $\tilde{q}_R$. Third generation left- and right- squarks are expected to have large mixing, resulting in mass eigenstates $\tilde{q}_1$ and $\tilde{q}_2$, with $m_{\tilde{q}_1} < m_{\tilde{q}_2}$ (here, q denotes any of the SM flavors of quarks and $\tilde{q}_i$ the corresponding flavor and type ($i = L, R$ or $1, 2$) of squark). Gluino pair production ($\tilde{g}\tilde{g}$) takes place via either glue-glue or quark-antiquark annihilation [11].

The subprocess cross sections are usually presented as differential distributions in the Mandelstam variables s, t and u. Note that for a $2 \to 2$ scattering subprocess $ab \to cd$, the Mandelstam variable $s = (p_a + p_b)^2 = (p_c + p_d)^2$, where p_a is the 4-momentum of particle a, and so forth. The variable $t = (p_c - p_a)^2$, where c and a are taken conventionally to be the most similar particles in the subprocess. The variable u would then be equal to $(p_d - p_a)^2$. Note that since s, t and u are squares of 4-vectors, they are invariants in any inertial reference frame.

Gluino pair production at hadron colliders is described by:

$$\begin{aligned}\frac{d\sigma}{dt}(gg \to \tilde{g}\tilde{g}) = \frac{9\pi\alpha_s^2}{4s^2}\Bigg\{ &\frac{2(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)}{s^2} \\ &+ \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + t)}{(m_{\tilde{g}}^2 - t)^2} \\ &+ \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + u)}{(m_{\tilde{g}}^2 - u)^2} + \frac{m_{\tilde{g}}^2(s - 4m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)} \\ &- \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(u - t)}{s(m_{\tilde{g}}^2 - t)} \\ &- \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(t - u)}{s(m_{\tilde{g}}^2 - u)}\Bigg\},\end{aligned} \tag{51.48}$$

where α_s is the strong fine structure constant. Also,

$$\begin{aligned}\frac{d\sigma}{dt}(q\bar{q} \to \tilde{g}\tilde{g}) = \frac{8\pi\alpha_s^2}{9s^2}\Bigg\{ &\frac{4}{3}\left(\frac{m_{\tilde{g}}^2 - t}{m_{\tilde{q}}^2 - t}\right)^2 + \frac{4}{3}\left(\frac{m_{\tilde{g}}^2 - u}{m_{\tilde{q}}^2 - u}\right)^2 \\ &+ \frac{3}{s^2}\left[(m_{\tilde{g}}^2 - t)^2 + (m_{\tilde{g}}^2 - u)^2 + 2m_{\tilde{g}}^2 s\right] \\ &- 3\frac{\left[(m_{\tilde{g}}^2 - t)^2 + m_{\tilde{g}}^2 s\right]}{s(m_{\tilde{q}}^2 - t)} \\ &- 3\,\frac{\left[(m_{\tilde{g}}^2 - u)^2 + m_{\tilde{g}}^2 s\right]}{s(m_{\tilde{q}}^2 - u)} + \frac{1}{3}\frac{m_{\tilde{g}}^2 s}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)}\Bigg\}.\end{aligned} \tag{51.49}$$

Gluinos can also be produced in association with squarks: $\tilde{g}\tilde{q}_i$ production, where $\tilde{q}_i$ represents any of the various types (left, right- or mixed) and flavors of squarks. The subprocess cross section is independent of whether the squark is the right-, left- or mixed type:

$$\begin{aligned}\frac{d\sigma}{dt}(gq \to \tilde{g}\tilde{q}_i) = \frac{\pi\alpha_s^2}{24s^2}&\frac{\left[\frac{16}{3}(s^2 + (m_{\tilde{q}_i}^2 - u)^2) + \frac{4}{3}s(m_{\tilde{q}_i}^2 - u)\right]}{s(m_{\tilde{g}}^2 - t)(m_{\tilde{q}_i}^2 - u)^2} \\ &\times \left((m_{\tilde{g}}^2 - u)^2 + (m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)^2 + \frac{2sm_{\tilde{g}}^2(m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)}\right).\end{aligned} \tag{51.50}$$

There are many different subprocesses for production of squark pairs. Since left- and right- squarks generally have different masses and different decay patterns, we present the differential cross section for each subprocess of $\tilde{q}_i$ ($i = L,\ R$ or 1, 2) separately. (In early literature, the following formulae were often combined into a single equation which didn't differentiate the various squark types.) The result for $gg \to \tilde{q}_i\bar{\tilde{q}}_i$ is:

$$\begin{aligned}\frac{d\sigma}{dt}(gg \to \tilde{q}_i\bar{\tilde{q}}_i) = \frac{\pi\alpha_s^2}{4s^2}\Bigg\{ &\frac{1}{3}\left(\frac{m_{\tilde{q}}^2 + t}{m_{\tilde{q}}^2 - t}\right)^2 + \frac{1}{3}\left(\frac{m_{\tilde{q}}^2 + u}{m_{\tilde{q}}^2 - u}\right)^2 \\ &+ \frac{3}{32s^2}\left(8s(4m_{\tilde{q}}^2 - s) + 4(u - t)^2\right) + \frac{7}{12} \\ &- \frac{1}{48}\frac{(4m_{\tilde{q}}^2 - s)^2}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)} \\ &+ \frac{3}{32}\frac{\left[(t - u)(4m_{\tilde{q}}^2 + 4t - s) - 2(m_{\tilde{q}}^2 - u)(6m_{\tilde{q}}^2 + 2t - s)\right]}{s(m_{\tilde{q}}^2 - t)} \\ &+ \frac{3}{32}\frac{\left[(u - t)(4m_{\tilde{q}}^2 + 4u - s) - 2(m_{\tilde{q}}^2 - t)(6m_{\tilde{q}}^2 + 2u - s)\right]}{s(m_{\tilde{q}}^2 - u)} \\ &+ \frac{7}{96}\frac{\left[4m_{\tilde{q}}^2 + 4t - s\right]}{m_{\tilde{q}}^2 - t} + \frac{7}{96}\frac{\left[4m_{\tilde{q}}^2 + 4u - s\right]}{m_{\tilde{q}}^2 - u}\Bigg\},\end{aligned} \tag{51.51}$$

which has an obvious $u \leftrightarrow t$ symmetry.

For $q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i$ with the same initial and final state flavors, we have

$$\begin{aligned}\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i) = \frac{2\pi\alpha_s^2}{9s^2}&\left\{\frac{1}{(t - m_{\tilde{g}}^2)^2} + \frac{2}{s^2} - \frac{2/3}{s(t - m_{\tilde{g}}^2)}\right\} \\ &\times \left[-st - (t - m_{\tilde{q}_i}^2)^2\right],\end{aligned} \tag{51.52}$$

while if initial and final state flavors are different ($q\bar{q} \to \tilde{q}_i'\bar{\tilde{q}}_i'$) we

instead have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i'\bar{\tilde{q}}_i') = \frac{4\pi\alpha_s^2}{9s^4}\left[-st - (t-m_{\tilde{q}_i'}^2)^2\right]. \quad (51.53)$$

If the two initial state quarks are of different flavors, then we have

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{\tilde{q}}_i') = \frac{2\pi\alpha_s^2}{9s^2}\frac{-st-(t-m_{\tilde{q}_i}^2)^2}{(t-m_{\tilde{g}}^2)^2}. \quad (51.54)$$

If the initial quarks are of different flavor and final state squarks are of different type ($i \neq j$) then

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{\tilde{q}}_j') = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.55)$$

For same-flavor initial state quarks, but final state unlike-type squarks, we also have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_j) = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.56)$$

There also exist cross sections for quark-quark annihilation to squark pairs. For same flavor quark-quark annihilation to same flavor/same type final state squarks,

$$\frac{d\sigma}{dt}(qq \to \tilde{q}_i\tilde{q}_i) =$$

$$= \frac{\pi\alpha_s^2}{9s^2}m_{\tilde{g}}^2 s\left\{\frac{1}{(t-m_{\tilde{g}}^2)^2} + \frac{1}{(u-m_{\tilde{g}}^2)^2} - \frac{2/3}{(t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)}\right\}, \quad (51.57)$$

while if the final type squarks are different ($i \neq j$), we have

$$\frac{d\sigma}{dt}(qq \to \tilde{q}_i\tilde{q}_j) =$$

$$\frac{2\pi\alpha_s^2}{9s^2}\times$$
$$\left\{\frac{[-st-(t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2)]}{(t-m_{\tilde{g}}^2)} + \frac{[-su-(u-m_{\tilde{q}_i}^2)(u-m_{\tilde{q}_j}^2)]}{(u-m_{\tilde{g}}^2)}\right\}. \quad (51.58)$$

If initial/final state flavors are different, but final state squark types are the same, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i\tilde{q}_i') = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.59)$$

If initial quark flavors are different and final squark types are different, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i\tilde{q}_j') = \frac{2\pi\alpha_s^2}{9s^2}\frac{-st-(t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2)}{(t-m_{\tilde{g}}^2)^2}. \quad (51.60)$$

51.8.2 *Gluino and squark associated production*

In the MSSM, the charged spin-$\frac{1}{2}$ winos and higgsinos mix to make chargino states $\chi_1^\pm$ and $\chi_2^\pm$, with $m_{\chi_1^\pm} < m_{\chi_2^\pm}$. The spin$-\frac{1}{2}$ neutral bino, wino and higgsino fields mix to give four neutralino mass eigenstates $\chi_{1,2,3,4}^0$ ordered according to mass. We sometimes denote the charginos and neutralinos collectively as -inos for notational simplicity

For gluino and squark production in association with charginos and neutralinos [12], the quark-squark-neutralino couplings[1] are defined by the interaction Lagrangian terms

$$\mathcal{L}_{\tilde{f}f\tilde{\chi}_i^0} = \left[iA_{\tilde{\chi}_i^0}^f \tilde{f}_L^\dagger \bar{\tilde{\chi}}_i^0 P_L f + iB_{\tilde{\chi}_i^0}^f \tilde{f}_R^\dagger \bar{\tilde{\chi}}_i^0 P_R f + \text{h.c.}\right]$$

[1]The couplings $A_{\tilde{\chi}_i^0}^f$ and $B_{\tilde{\chi}_i^0}^f$ are given explicitly in Ref. [13] in Eq. (8.87). Also, the couplings $A_{\tilde{\chi}_i^-}^d$ and $A_{\tilde{\chi}_i^-}^u$ are given in Eq. (8.93). The couplings X_i^j and Y_i^j are given by Eq. (8.103), while the x_i and y_i couplings are given in Eq. (8.100). Finally, the couplings W_{ij} are given in Eq. (8.101).

, where $A_{\tilde{\chi}_i^0}^f$ and $B_{\tilde{\chi}_i^0}^f$ are coupling constants involving gauge couplings, neutralino mixing elements and in the case of third generation fermions, Yukawa couplings. Their form depends on the conventions used for setting up the MSSM Lagrangian, and can be found in various reviews [14] and textbooks [13, 15]. P_L and P_R are the usual left- and right- spinor projection operators and f denotes any of the SM fermions u, d, e, $\nu_e, \cdots$. The fermion-sfermion- chargino couplings have the form $\mathcal{L} = \left[iA_{\tilde{\chi}_i^-}^d \tilde{u}_L^\dagger \overline{\tilde{\chi}_i^-} P_L d + iA_{\tilde{\chi}_i^-}^u \tilde{d}_L^\dagger \overline{\tilde{\chi}_i^c} P_L u + \text{h.c.}\right]$ for u and d quarks, where the $A_{\tilde{\chi}_i^-}^d$ and $A_{\tilde{\chi}_i^-}^u$ couplings are again convention-dependent, and can be found in textbooks. The superscript c denotes "charge conjugate spinor", defined by $\psi^c \equiv C\bar{\psi}^T$.

The subprocess cross sections for chargino-squark associated production occur via squark exchange and are given by

$$\frac{d\sigma}{dt}(\bar{u}g \to \tilde{\chi}_i^- \bar{\tilde{d}}_L) = \frac{\alpha_s}{24s^2}|A_{\tilde{\chi}_i^-}^u|^2 \psi(m_{\tilde{d}_L}, m_{\tilde{\chi}_i^-}, t), \quad (51.61)$$

$$\frac{d\sigma}{dt}(dg \to \tilde{\chi}_i^- \tilde{u}_L) = \frac{\alpha_s}{24s^2}|A_{\tilde{\chi}_i^-}^d|^2 \psi(m_{\tilde{u}_L}, m_{\tilde{\chi}_i^-}, t), \quad (51.62)$$

while neutralino-squark production is given by

$$\frac{d\sigma}{dt}(qg \to \tilde{\chi}_i^0 \tilde{q}) = \frac{\alpha_s}{24s^2}\left(|A_{\tilde{\chi}_i^0}^q|^2 + |B_{\tilde{\chi}_i^0}^q|^2\right)\psi(m_{\tilde{q}}, m_{\tilde{\chi}_i^0}, t), \quad (51.63)$$

where

$$\psi(m_1, m_2, t) = \frac{s+t-m_1^2}{2s} - \frac{m_1^2(m_2^2-t)}{(m_1^2-t)^2} + \frac{t(m_2^2-m_1^2)+m_2^2(s-m_2^2+m_1^2)}{s(m_1^2-t)}. \quad (51.64)$$

Here, the variable t is given by the square of "squark-minus-quark" four-momentum. The neutralino-gluino associated production cross section also occurs via squark exchange and is given by

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{\chi}_i^0 \tilde{g}) = \frac{\alpha_s}{18s^2}\left(|A_{\tilde{\chi}_i^0}^q|^2 + |B_{\tilde{\chi}_i^0}^q|^2\right)\left[\frac{(m_{\tilde{\chi}_i^0}^2 - t)(m_{\tilde{g}}^2 - t)}{(m_{\tilde{q}}^2 - t)^2} + \frac{(m_{\tilde{\chi}_i^0}^2 - u)(m_{\tilde{g}}^2 - u)}{(m_{\tilde{q}}^2 - u)^2} - \frac{2\eta_i\eta_{\tilde{g}} m_{\tilde{g}} m_{\tilde{\chi}_i^0} s}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)}\right], \quad (51.65)$$

where η_i is the sign of the neutralino mass eigenvalue and $\eta_{\tilde{g}}$ is the sign of the gluino mass eigenvalue. We also have chargino-gluino associated production:

$$\frac{d\sigma}{dt}(\bar{u}d \to \tilde{\chi}_i^- \tilde{g}) = \frac{\alpha_s}{18s^2}\left[|A_{\tilde{\chi}_i^-}^u|^2 \frac{(m_{\tilde{\chi}_i^-}^2 - t)(m_{\tilde{g}}^2 - t)}{(m_{\tilde{d}_L}^2 - t)^2} + |A_{\tilde{\chi}_i^-}^d|^2 \frac{(m_{\tilde{\chi}_i^-}^2 - u)(m_{\tilde{g}}^2 - u)}{(m_{\tilde{u}_L}^2 - u)^2} + \frac{2\eta_{\tilde{g}} Re(A_{\tilde{\chi}_i^-}^u A_{\tilde{\chi}_i^-}^{d\,*}) m_{\tilde{g}} m_{\tilde{\chi}_i} s}{(m_{\tilde{d}_L}^2 - t)(m_{\tilde{u}_L}^2 - u)}\right], \quad (51.66)$$

where $\hat{t} = (\tilde{g} - d)^2$ and in the third term one must take the real part of the in general complex coupling constant product.

51.8.3 *Slepton and sneutrino production*

The subprocess cross section for $\tilde{\ell}_L\bar{\tilde{\nu}}_{\ell_L}$ production ($\ell = e$ or μ) occurs via s-channel W exchange and is given by

$$\frac{d\sigma}{dt}(d\bar{u} \to \tilde{\ell}_L\bar{\tilde{\nu}}_{\ell_L}) = \frac{g^4|D_W(s)|^2}{192\pi s^2}\left(tu - m_{\tilde{\ell}_L}^2 m_{\tilde{\nu}_{\ell_L}}^2\right), \quad (51.67)$$

where $D_W(s) = 1/(s - M_W^2 + iM_W\Gamma_W)$ is the W-boson propagator denominator. The production of $\tilde{\tau}_1\bar{\tilde{\nu}}_\tau$ is given as above, but

replacing $m_{\tilde{\ell}_L} \to m_{\tilde{\tau}_1}$, $m_{\tilde{\nu}_{\ell_L}} \to m_{\tilde{\nu}_\tau}$ and multiplying by an overall factor of $\cos^2\theta_\tau$ (where θ_τ is the tau-slepton mixing angle). Similar substitutions hold for $\tilde{\tau}_2\bar{\tilde{\nu}}_\tau$ production, except the overall factor is $\sin^2\theta_\tau$.

Table 51.1: The constants α_f and β_f that appear in in the SM neutral current Lagrangian. Here $t \equiv \tan\theta_W$ and $c \equiv \cot\theta_W$.

f	q_f	α_f	β_f
ℓ	-1	$\frac{1}{4}(3t-c)$	$\frac{1}{4}(t+c)$
ν_ℓ	0	$\frac{1}{4}$(t+c)	$-\frac{1}{4}(t+c)$
u	$\frac{2}{3}$	$-\frac{5}{12}t+\frac{1}{4}c$	$-\frac{1}{4}(t+c)$
d	$-\frac{1}{3}$	$\frac{1}{12}t-\frac{1}{4}c$	$\frac{1}{4}(t+c)$

The subprocess cross section for $\tilde{\ell}_L\bar{\tilde{\ell}}_L$ production occurs via s-channel γ and Z exchange, and depends on the neutral current interaction, with fermion couplings to γ and Z^0 given by $\mathcal{L}_{\rm neutral} = -eq_f\bar{f}\gamma^\mu f A_\mu + e\bar{f}\gamma^\mu(\alpha_f+\beta_f\gamma_5)fZ_\mu$ (with values of q_f, α_f, and β_f given in Table-51.1.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\ell}_L\bar{\tilde{\ell}}_L) = \frac{e^4}{24\pi s^2}\left(tu-m^4_{\tilde{\ell}_L}\right)\times$$
$$\left\{\frac{q_\ell^2 q_q^2}{s^2} + (\alpha_\ell-\beta_\ell)^2(\alpha_q^2+\beta_q^2)|D_Z(s)|^2\right.$$
$$\left. + \frac{2q_\ell q_q\alpha_q(\alpha_\ell-\beta_\ell)(s-M_Z^2)}{s}|D_Z(s)|^2\right\}, \qquad (51.68)$$

where $D_Z(s) = 1/(s-M_Z^2+iM_Z\Gamma_Z)$. The cross section for sneutrino production is given by the same formula, but with α_ℓ, β_ℓ, q_ℓ and $m_{\tilde{\ell}_L}$ replaced by α_ν, β_ν, 0 and $m_{\tilde{\nu}_L}$, respectively. The cross section for $\tilde{\tau}_1\bar{\tilde{\tau}}_1$ production is obtained by replacing $m_{\tilde{\ell}_L} \to m_{\tilde{\tau}_1}$ and $\beta_\ell \to \beta_\ell\cos 2\theta_\tau$. The cross section for $\tilde{\ell}_R\bar{\tilde{\ell}}_R$ production is given by substituting $\alpha_\ell-\beta_\ell \to \alpha_\ell+\beta_\ell$ and $m_{\tilde{\ell}_L} \to m_{\tilde{\ell}_R}$ in the equation above. The cross section for $\tilde{\tau}_2\bar{\tilde{\tau}}_2$ production is obtained from the formula for $\tilde{\ell}_R\bar{\tilde{\ell}}_R$ production by replacing $m_{\tilde{\ell}_R} \to m_{\tilde{\tau}_2}$ and $\beta_\ell \to \beta_\ell\cos 2\theta_\tau$.

Finally, the cross section for $\tilde{\tau}_1\bar{\tilde{\tau}}_2$ production occurs only via Z exchange, and is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\tau}_1\bar{\tilde{\tau}}_2) = \frac{d\sigma}{dt}(q\bar{q}\to\bar{\tilde{\tau}}_1\tilde{\tau}_2) =$$
$$\frac{e^4}{24\pi s^2}(\alpha_q^2+\beta_q^2)\beta_\ell^2\sin^2 2\theta_\tau|D_Z(s)|^2(ut-m^2_{\tilde{\tau}_1}m^2_{\tilde{\tau}_2}). \qquad (51.69)$$

51.8.4 *Chargino and neutralino pair production*

51.8.4.1 $\tilde{\chi}_i^-\tilde{\chi}_j^0$ *production*

The subprocess cross section for $d\bar{u}\to\tilde{\chi}_i^-\tilde{\chi}_j^0$ depends on Lagrangian couplings

$$\mathcal{L}_{W\bar{u}d} = -\frac{g}{\sqrt{2}}\bar{u}\gamma_\mu P_L d W^{+\mu} \ + \text{h.c.}$$

,

$$\mathcal{L}_{W\tilde{\chi}_i^-\tilde{\chi}_j^0} = -g(-i)^{\theta_j}\overline{\tilde{\chi}^-}_i[X_i^j+Y_i^j\gamma_5]\gamma_\mu\tilde{\chi}_j^0 W^{-\mu} \ + \text{h.c.}$$

,

$$\mathcal{L}_{q\bar{q}\tilde{\chi}_i^-} = iA^d_{\tilde{\chi}_i^-}\tilde{u}_L^\dagger\overline{\tilde{\chi}_i^-}P_L d + iA^u_{\tilde{\chi}_i^-}\tilde{d}_L^\dagger\overline{\tilde{\chi}_i^c}P_L u \ + \text{h.c.}$$

and

$$\mathcal{L}_{q\bar{q}\tilde{\chi}_j^0} = iA^q_{\tilde{\chi}_j^0}\tilde{q}_L^\dagger\overline{\tilde{\chi}^0}_j P_L q \ + \text{h.c.}$$

. Contributing diagrams include W exchange and also $\tilde{d}_L$ and $\tilde{u}_L$ squark exchange. The X_i^j and Y_i^j couplings are new, and again convention-dependent: the cross section formulae works if the interaction Lagrangian is written in the above form, so that the couplings can be suitably extracted. The term $\theta_j = 0$ (1) if $m_{\tilde{\chi}_j^0} > 0$ (< 0); it comes about because the neutralino field must be re-defined by a $-i\gamma_5$ transformation if its mass eigenvalue is negative [13]. The subprocess cross section is given in terms of dot products of four momenta, where particle labels are used to denote their four-momenta; note that all mass terms in the cross section formulae are positive definite, so that the signs of mass eigenstates have been absorbed into the Lagrangian couplings, as for instance in Ref. [13]. We then have

$$\frac{d\sigma}{dt}(d\bar{u}\to\tilde{\chi}_i^-\tilde{\chi}_j^0) = \frac{1}{192\pi s^2}$$
$$\left[T_W + T_{\tilde{d}_L} + T_{\tilde{u}_L} + T_{W\tilde{d}_L} + T_{W\tilde{u}_L} + T_{\tilde{d}_L\tilde{u}_L}\right] \qquad (51.70)$$

where

$$T_W = 8g^4|D_W(s)|^2\left\{[X_i^{j2}+Y_i^{j2}](\tilde{\chi}_j^0\cdot d\tilde{\chi}_i^-\cdot\bar{u}+\tilde{\chi}_j^0\cdot\bar{u}\tilde{\chi}_i^-\cdot d)\right.$$
$$+ 2(X_i^jY_i^j)(\tilde{\chi}_j^0\cdot d\tilde{\chi}_i^-\cdot\bar{u}-\tilde{\chi}_j^0\cdot\bar{u}\tilde{\chi}_i^-\cdot d)$$
$$\left.+ [X_i^{j2}-Y_i^{j2}]m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\}, \qquad (51.71)$$

$$T_{\tilde{d}_L} = \frac{4|A^u_{\tilde{\chi}_i^-}|^2|A^d_{\tilde{\chi}_j^0}|^2}{[(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}]^2}\ d\cdot\tilde{\chi}_j^0\tilde{\chi}_i^-\cdot\bar{u}, \qquad (51.72)$$

$$T_{\tilde{u}_L} = \frac{4|A^d_{\tilde{\chi}_i^-}|^2|A^u_{\tilde{\chi}_j^0}|^2}{[(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}]^2}\ \bar{u}\cdot\tilde{\chi}_j^0\tilde{\chi}_i^-\cdot d \qquad (51.73)$$

$$T_{W\tilde{d}_L} = \frac{-\sqrt{2}g^2 Re[A^{d*}_{\tilde{\chi}_j^0}A^u_{\tilde{\chi}_i^-}(-i)^{\theta_j}](s-M_W^2)|D_W(s)|^2}{(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}}$$
$$\times\left\{8(X_i^j+Y_i^j)\tilde{\chi}_j^0\cdot d\bar{u}\cdot\tilde{\chi}_i^- + 4(X_i^j-Y_i^j)m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\} \qquad (51.74)$$

$$T_{W\tilde{u}_L} = \frac{\sqrt{2}g^2 Re[A^{d*}_{\tilde{\chi}_i^-}A^u_{\tilde{\chi}_j^0}(-i)^{\theta_j}](s-M_W^2)|D_W(s)|^2}{(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}}$$
$$\times\left\{8(X_i^j-Y_i^j)\tilde{\chi}_j^0\cdot\bar{u}d\cdot\tilde{\chi}_i^- + 4(X_i^j+Y_i^j)m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\} \qquad (51.75)$$

and

$$T_{\tilde{d}_L\tilde{u}_L} = -\frac{4Re[A^d_{\tilde{\chi}_j^0}A^{u*}_{\tilde{\chi}_i^-}A^{d*}_{\tilde{\chi}_i^-}A^u_{\tilde{\chi}_j^0}]m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}}{[(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}][(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}]}. \qquad (51.76)$$

51.8.4.2 *Chargino pair production*

The subprocess cross section for $d\bar{d}\to\tilde{\chi}_i^-\tilde{\chi}_i^+$ $(i=1,2)$ depends on Lagrangian couplings $\mathcal{L} = e\overline{\tilde{\chi}_i^-}\gamma_\mu\tilde{\chi}_i^- A^\mu - e\cot\theta_W\overline{\tilde{\chi}_i^-}\gamma_\mu(x_i - y_i\gamma_5)\tilde{\chi}_i^- Z^\mu$ and also $\mathcal{L}\ni iA^d_{\tilde{\chi}_i^-}\tilde{u}_L^\dagger\overline{\tilde{\chi}_i^-}P_L d + iA^u_{\tilde{\chi}_i^-}\tilde{d}_L^\dagger\overline{\tilde{\chi}_i^{-c}}P_L u + \text{h.c.}$. Contributing diagrams include s-channel γ, Z^0 exchange and t-channel $\tilde{u}_L$ exchange [16, 17]. The couplings x_i and y_i are again new and as usual convention-dependent.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(d\bar{d}\to\tilde{\chi}_i^-\tilde{\chi}_i^+) =$$
$$\frac{1}{192\pi s^2}\left[T_\gamma + T_Z + T_{\tilde{u}_L} + T_{\gamma Z} + T_{\gamma\tilde{u}_L} + T_{Z\tilde{u}_L}\right] \qquad (51.77)$$

where

$$T_\gamma = \frac{32e^4q_d^2}{s^2}\left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\right] \qquad (51.78)$$

$$T_Z = 32e^4 \cot^2\theta_W |D_Z(s)|^2$$
$$\left\{(\alpha_d^2+\beta_d^2)(x_i^2+y_i^2)\left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-} d\cdot\bar{d}\right]\right.$$
$$\left. \mp 4\alpha_d\beta_d x_i y_i\left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- - d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+\right] - 2y_i^2(\alpha_d^2+\beta_d^2)m^2_{\tilde{\chi}_i^-} d\cdot\bar{d}\right\}, \tag{51.79}$$

$$T_{\tilde{u}_L} = \frac{4|A^d_{\tilde{\chi}_i^-}|^4}{[(d-\tilde{\chi}_i^-)^2 - m^2_{\tilde{u}_L}]^2}\; d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ \tag{51.80}$$

$$T_{\gamma Z} = \frac{64e^4\cot\theta_W q_d(s-M_Z^2)|D_Z(s)|^2}{s}\times$$
$$\left\{\alpha_d x_i\left(d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-} d\cdot\bar{d}\right)\right.$$
$$\left.\pm\beta_d y_i\left(d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ - d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^-\right)\right\} \tag{51.81}$$

$$T_{\gamma\tilde{u}_L} = \mp\frac{8e^2 q_d}{s}\frac{|A^d_{\tilde{\chi}_i^-}|^2}{[(d-\tilde{\chi}_i^-)^2 - m^2_{\tilde{u}_L}]}\left\{2\bar{d}\cdot\tilde{\chi}_i^+ d\cdot\tilde{\chi}_i^- + m^2_{\tilde{\chi}_i^-} d\cdot\bar{d}\right\} \tag{51.82}$$

and

$$T_{Z\tilde{u}_L} = \mp 8e^2\cot\theta_W |D_Z(s)|^2 \frac{|A^d_{\tilde{\chi}_i^-}|^2(s-M_Z^2)}{[(d-\tilde{\chi}_i^-)^2 - m^2_{\tilde{u}_L}]}(\alpha_d-\beta_d)$$
$$\times\left\{2(x_i\mp y_i)d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}(x_i\pm y_i)d\cdot\bar{d}\right\} \tag{51.83}$$

using the upper of the sign choices.

The cross section for $u\bar{u}\to\tilde{\chi}_i^+\tilde{\chi}_i^-$ can be obtained from the above by replacing $\alpha_d\to\alpha_u$, $\beta_d\to\beta_u$, $q_d\to q_u$, $\tilde{u}_L\to\tilde{d}_L$, $A^d_{\tilde{\chi}_i^-}\to A^u_{\tilde{\chi}_i^-}$, $d\to\bar{u}$, $\bar{d}\to u$ and adopting the lower of the sign choices everywhere.

The cross section for $q\bar{q}\to\tilde{\chi}_1^-\tilde{\chi}_2^+$, $\tilde{\chi}_1^+\tilde{\chi}_2^-$ can occur via Z and $\tilde{q}_L$ exchange. It is usually much smaller than $\tilde{\chi}^-_{1,2}\tilde{\chi}^+_{1,2}$ production, so the cross section will not be presented here. It can be found in Appendix A of Ref. [13].

51.8.4.3 *Neutralino pair production*

Neutralino pair production via $q\bar{q}$ fusion takes place via s-channel Z exchange plus t- and u-channel left- and right- squark exchange (5 diagrams) [17, 18]. The Lagrangian couplings (see previous footnote*) needed include terms given above plus terms of the form $\mathcal{L} = W_{ij}\overline{\tilde{\chi}^0}_i\gamma_\mu(\gamma_5)^{\theta_i+\theta_j+1}\tilde{\chi}_j^0 Z^\mu$. The couplings W_{ij} depend only on the *higgsino* components of the neutralinos i and j. The subprocess cross section is given by:

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\chi}_i^0\tilde{\chi}_j^0) = \frac{1}{192\pi s^2}\left[T_Z + T_{\tilde{q}_L} + T_{\tilde{q}_R} + T_{Z\tilde{q}_L} + T_{Z\tilde{q}_R}\right] \tag{51.84}$$

where

$$T_Z = 128e^2|W_{ij}|^2(\alpha_q^2+\beta_q^2)|D_Z(s)|^2$$
$$\left[q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 + q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right], \tag{51.85}$$

$$T_{\tilde{q}_L} = 4|A^q_{\tilde{\chi}_i^0}|^2|A^q_{\tilde{\chi}_j^0}|^2\left\{\frac{q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}]^2} + \frac{q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]^2}\right.$$
$$\left. - \eta_i\eta_j\frac{m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}][(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]}\right\} \tag{51.86}$$

$$T_{\tilde{q}_R} = 4|B^q_{\tilde{\chi}_i^0}|^2|B^q_{\tilde{\chi}_j^0}|^2\left\{\frac{q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}]^2} + \frac{q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]^2}\right.$$
$$\left. - \eta_i\eta_j\frac{m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}][(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]}\right\} \tag{51.87}$$

$$T_{Z\tilde{q}_L} = 16e(\alpha_q-\beta_q)(s-M_Z^2)|D_Z(s)|^2$$
$$\left\{\frac{Re(W_{ij}A^{q*}_{\tilde{\chi}_i^0}A^q_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}]}\left[2q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right.$$
$$\left. + \eta_i\eta_j\frac{Re(W_{ij}A^q_{\tilde{\chi}_i^0}A^{q*}_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]}\left[2q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right\} \tag{51.88}$$

$$T_{Z\tilde{q}_R} = 16e(\alpha_q+\beta_q)(s-M_Z^2)|D_Z(s)|^2$$
$$\left\{\frac{Re(W_{ij}B^{q*}_{\tilde{\chi}_i^0}B^q_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}]}\left[2q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right.$$
$$\left. - \frac{Re(W_{ij}B^q_{\tilde{\chi}_i^0}B^{q*}_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]}\left[2q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right\}. \tag{51.89}$$

As before, $\eta_i = \pm 1$ corresponding to whether the neutralino mass eigenvalue is positive or negative. When $i = j$ in the above formula, one must remember to integrate over just 2π steradians of solid angle to avoid double counting in the total cross section.

51.9 Universal extra dimensions

In the Universal Extra Dimension (UED) model of Ref. [19] (see Ref. [20] for a review of models with extra spacetime dimensions), the Standard Model is embedded in a five dimensional theory, where the fifth dimension is compactified on an S_1/Z_2 orbifold. Each SM chirality state is then the zero mode of an infinite tower of Kaluza-Klein excitations labeled by $n = 0-\infty$. A KK parity is usually assumed to hold, where each state is assigned KK-parity $P = (-1)^n$. If the compactification scale is around a TeV, then the $n = 1$ (or even higher) KK modes may be accessible to collider searches.

Of interest for hadron colliders are the production of massive $n \geq 1$ quark or gluon pairs. These production cross sections have been calculated in Ref. [21, 22]. We list here results for the $n = 1$ case only with $M_1 = 1/R$ (R is the compactification radius) and s, t and u are the usual Mandelstam variables; more general formulae can be found in Ref. [22]. The superscript $*$ stands for any KK excited state, while $\bullet$ stands for left chirality states and $\circ$ stands for right chirality states.

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}T \tag{51.90}$$

where

$$T(q\bar{q}\to g^*g^*) = \frac{2g_s^4}{27}\left[M_1^2\left(-\frac{4s^3}{t'^2u'^2} + \frac{57s}{t'u'} - \frac{108}{s}\right)\right.$$
$$\left. + \frac{20s^2}{t'u'} - 93 + \frac{108t'u'}{s^2}\right] \tag{51.91}$$

and

$$T(gg\to g^*g^*) =$$
$$\frac{9g_s^4}{27}\left[3M_1^4\frac{s^2+t'^2+u'^2}{t'^2u'^2} - 3M_1^2\frac{s^2+t'^2+u'^2}{st'u'} + 1\right.$$
$$\left. + \frac{(s^2+t'^2+u'^2)^3}{4s^2t'^2u'^2} - \frac{t'u'}{s^2}\right] \tag{51.92}$$

where $t' = t - M_1^2$ and $u' = u - M_1^2$.

Also,

$$T(q\bar{q}\to q_1^{*\prime}\bar{q}_1^{*\prime}) = \frac{4g_s^4}{9}\left[\frac{2M_1^2}{s} + \frac{t'^2+u'^2}{s^2}\right],$$

$$T(q\bar{q}\to q_1^*\bar{q}_1^*)=\frac{g_2^4}{9}\left[2M_1^2\left(\frac{4}{s}+\frac{s}{t'^2}-\frac{1}{t'}\right)\right.$$
$$\left.+\frac{23}{6}+\frac{2s^2}{t'^2}+\frac{8s}{3t'}+\frac{6t'}{s}+\frac{8t'^2}{s^2}\right],$$
$$T(qq\to q_1^*q_1^*)=\frac{g_s^4}{27}\left[M_1^2\left(6\frac{t'}{u'^2}+6\frac{u'}{t'^2}-\frac{s}{t'u'}\right)\right.$$
$$\left.+2\left(3\frac{t'^2}{u'^2}+3\frac{u'^2}{t'^2}+4\frac{s^2}{t'u'}-5\right)\right],$$
$$T(gg\to q_1^*\bar{q}_1^*)=g_s^4\left[M_1^4\frac{-4}{t'u'}\left(\frac{s^2}{6t'u'}-\frac{3}{8}\right)\right.$$
$$\left.+M_1^2\frac{4}{s}\left(\frac{s^2}{6t'u'}-\frac{3}{8}\right)+\frac{s^2}{6t'u'}-\frac{17}{24}+\frac{3t'u'}{4s^2}\right],$$
$$T(gq\to g^*q_1^*)=\frac{-g_s^4}{3}\left[\frac{5s^2}{12t'^2}+\frac{s^3}{t'^2u'}+\frac{11su'}{6t'^2}+\frac{5u'^2}{12t'^2}+\frac{u'^3}{st'^2}\right],$$
$$T(q\bar{q}'\to q_1^*\bar{q}_1^{*\prime})=\frac{g_s^4}{18}\left[4M_1^4\frac{s}{t'^2}+5+4\frac{s^2}{t'^2}+8\frac{s}{t'}\right],$$
$$T(qq'\to q_1^*q_1^{*\prime})=\frac{2g_s^4}{9}\left[-M_1^2\frac{s}{t'^2}+\frac{1}{4}+\frac{s^2}{t'^2}\right],$$
$$T(qq\to q_1^\bullet q_1^\circ)=$$
$$\frac{g_s^4}{9}\left[M_1^2\left(\frac{2s^3}{t'^2u'^2}-\frac{4s}{t'u'}\right)+2\frac{s^4}{t'^2u'^2}-8\frac{s^2}{t'u'}+5\right],$$
$$T(q\bar{q}'\to q_1^\bullet\bar{q}_1^{\prime\circ})=\frac{g_s^4}{9}\left[2M_1^2\left(\frac{1}{t'}+\frac{u'}{t'^2}\right)+\frac{5}{2}+\frac{4u'}{t'}+\frac{2u'^2}{t'^2}\right],$$

and

$$T(qq'\to q_1^\bullet q_1^{\prime\circ})=\frac{g_s^4}{9}\left[-2M_1^2\left(\frac{1}{t'}+\frac{u'}{t'^2}\right)+\frac{1}{2}+\frac{2u'^2}{t'^2}\right].$$

51.10 Large extra dimensions

In the ADD theory [23] with large extra dimensions (LED), the SM particles are confined to a 3-brane, while gravity propagates in the bulk. It is assumed that the n extra dimensions are compactified on an n-dimensional torus of volume $(2\pi r)^n$, so that the fundamental $4+n$ dimensional Planck scale M_* is related to the usual 4-dimensional Planck scale M_{Pl} by $M_{Pl}^2=M_*^{n+2}(2\pi r)^n$. If $M_*\sim 1$ TeV, then the M_W-M_{Pl} hierarchy problem is just due to gravity propagating in the large extra dimensions.

In these theories, the KK-excited graviton states $G_{\mu\nu}^n$ for $n=1-\infty$ can be produced at collider experiments. The graviton couplings to matter are suppressed by $1/M_{Pl}$, so that graviton emission cross sections $d\sigma/dt\sim 1/M_{Pl}^2$. However, the mass splittings between the excited graviton states can be tiny, so the graviton eigenstates are usually approximated by a continuum distribution. A summation (integration) over all allowed graviton emissions ends up cancelling the $1/M_{Pl}^2$ factor, so that observable cross section rates can be attained. Some fundamental production formulae for a KK graviton (denoted G) of mass m at hadron colliders include the subprocesses

$$\frac{d\sigma_m}{dt}(f\bar{f}\to\gamma G)=\frac{\alpha Q_f^2}{16N_f}\frac{1}{sM_{Pl}^2}F_1(\frac{t}{s},\frac{m^2}{s}),\qquad(51.93)$$

where Q_f is the charge of fermion f and N_f is the number of QCD colors of f. Also,

$$\frac{d\sigma_m}{dt}(q\bar{q}\to gG)=\frac{\alpha_s}{36}\frac{1}{sM_{Pl}^2}F_1(\frac{t}{s},\frac{m^2}{s}),\qquad(51.94)$$

$$\frac{d\sigma_m}{dt}(qg\to qG)=\frac{\alpha_s}{96}\frac{1}{sM_{Pl}^2}F_2(\frac{t}{s},\frac{m^2}{s}),\qquad(51.95)$$

$$\frac{d\sigma_m}{dt}(gg\to gG)=\frac{3\alpha_s}{16}\frac{1}{sM_{Pl}^2}F_3(\frac{t}{s},\frac{m^2}{s}),\qquad(51.96)$$

where

$$F_1(x,y)=\frac{1}{x(y-1-x)}\left[-4x(1+x)(1+2x+2x^2)+\right.$$
$$\left.y(1+6x+18x^2+16x^3)-6y^2x(1+2x)+y^3(1+4x)\right]\qquad(51.97)$$

$$F_2(x,y)=-(y-1-x)F_1\left(\frac{x}{y-1-x},\frac{y}{y-1-x}\right)\qquad(51.98)$$

and

$$F_3(x,y)=\frac{1}{x(y-1-x)}\left[1+2x+3x^2+2x^3+x^4\right.$$
$$\left.-2y(1+x^3)+3y^2(1+x^2)-2y^3(1+x)+y^4\right].\qquad(51.99)$$

These formulae must then be multiplied by the graviton density of states formula
$dN=S_{n-1}\frac{M_{Pl}^2}{M_*^{n+2}}m^{n-1}dm$ to gain the cross section

$$\frac{d^2\sigma}{dtdm}=S_{n-1}\frac{M_{Pl}^2}{M_*^{n+2}}m^{n-1}\frac{d\sigma_m}{dt}\qquad(51.100)$$

where $S_n=\frac{(2\pi)^{n/2}}{\Gamma(n/2)}$ is the surface area of an n-dimensional sphere of unit radius.

Virtual graviton processes can also be searched for at colliders. For instance, in Ref. [24] the cross section for Drell-Yan production of lepton pairs via gluon fusion was calculated, where it is found that, in the center-of-mass system

$$\frac{d\sigma}{dz}(gg\to\ell^+\ell^-)=\frac{\lambda^2s^3}{64\pi M_*^8}(1-z^2)(1+z^2)\qquad(51.101)$$

where $z=\cos\theta$ and λ is a model-dependent coupling constant ~ 1. Formulae for Drell-Yan production via $q\bar{q}$ fusion can also be found in Refs. [24, 25].

51.11 Warped extra dimensions

In the Randall-Sundrum model [26] of warped extra dimensions, the arena for physics is a 5-d anti-deSitter (AdS_5) spacetime, for which a non-factorizable metric exists with a metric warp factor $e^{-2\sigma(\phi)}$. It is assumed that two opposite tension 3-branes exist within AdS_5 at the two ends of an S_1/Z_2 orbifold parameterized by co-ordinate ϕ which runs from $0-\pi$. The 4-D solution of the Einstein equations yields $\sigma(\phi)=kr_c|\phi|$, where r_c is the compactification radius of the extra dimension and $k\sim M_{Pl}$. The 4-D effective action allows one to identify $\overline{M}_{Pl}^2=\frac{M^3}{k}(1-e^{-2kr_c\pi})$, where M is the 5-D Planck scale. Physical particles on the TeV scale (SM) brane have mass $m=e^{-kr_c\pi}m_0$, where m_0 is a fundamental mass of order the Planck scale. Thus, the weak scale-Planck scale hierarchy occurs due to the existence of the exponential warp factor if $kr_c\sim 12$.

In the simplest versions of the RS model, the TeV-scale brane contains only SM particles plus a tower of KK gravitons. The RS gravitons have mass $m_n=kx_ne^{-kr_c\pi}$, where the x_i are roots of Bessel functions $J_1(x_n)=0$, with $x_1\simeq 3.83$, $x_2\simeq 7.02$ etc. While the RS zero-mode graviton couplings suppressed by $1/\overline{M}_{Pl}$ and are thus inconsequential for collider searches, the $n=1$ and higher modes have couplings suppressed instead by $\Lambda_\pi=e^{-kr_c\pi}\overline{M}_{Pl}\sim TeV$. The $n=1$ RS graviton should have width $\Gamma_1=\rho m_1x_1^2(k/\overline{M}_{Pl})^2$, where ρ is a constant depending on how many decay modes are open. The formulae for dilepton production via virtual RS graviton exchange can be gained from the above formulae for the ADD scenario via the replacement [27]

$$\frac{\lambda}{M_*^4}\to\frac{i^2}{8\Lambda_\pi^2}\sum_{n=1}^{\infty}\frac{1}{s-m_n^2+im_n\Gamma_n}.\qquad(51.102)$$

52. Neutrino Cross Section Measurements

Revised August 2021 by G.P. Zeller (FNAL).

Neutrino cross sections are an essential ingredient in all neutrino experiments. Interest in neutrino scattering has increased due to the need for such information in the interpretation of neutrino oscillation data [1] and given that uncertainties in neutrino-nucleus scattering remain a dominate source of systematic uncertainty in many neutrino oscillation measurements, for example [2]. Historically, neutrino scattering results on both charged current (CC) and neutral current (NC) channels have been collected over many decades using a variety of targets, analysis techniques, and detector technologies. With the advent of intense neutrino sources constructed for neutrino oscillation investigations, experiments are now remeasuring such interaction cross sections with a renewed appreciation for nuclear effects[1] and the need for more precise neutrino flux estimations. This work summarizes accelerator-based neutrino cross section measurements performed in the $\sim 0.1-300$ GeV range with an emphasis on inclusive, quasi-elastic (pionless), and pion production processes, areas where we have the most experimental input at present (Table 52.1). For a more comprehensive discussion of neutrino cross sections, including neutrino-electron elastic scattering and lower energy neutrino measurements, the reader is directed to a review of this subject [3]. Here, we survey existing experimental data on neutrino interactions and do not attempt to provide a census of the associated theoretical calculations [4], which are both critical and plentiful. Companion electron-nucleus scattering data are additionally playing an increased role in neutrino event generator development through such efforts as the e4ν collaboration.

Table 52.1: List of beam properties, nuclear targets, and run durations for modern accelerator-based neutrino experiments studying neutrino scattering.

Experiment	beam	$\langle E_\nu \rangle$, $\langle E_{\overline{\nu}} \rangle$ GeV	neutrino target(s)	run period
ArgoNeuT	$\nu, \overline{\nu}$	4.3, 3.6	Ar	2009 – 2010
ICARUS (at CNGS)	ν	20.0	Ar	2010 – 2012
ICARUS (at FNAL)	ν	0.8	Ar	2021 –
K2K	ν	1.3	CH, H_2O	2003 – 2004
MicroBooNE	ν	0.8	Ar	2015 – 2020
MINERvA	$\nu, \overline{\nu}$	3.5 (LE), 5.5 (ME)	He, C, CH, H_2O, Fe, Pb	2009 – 2019
MiniBooNE	$\nu, \overline{\nu}$	0.8, 0.7	CH_2	2002 – 2019
MINOS	$\nu, \overline{\nu}$	3.5, 6.1	Fe	2004 – 2016
NOMAD	$\nu, \overline{\nu}$	23.4, 19.7	C–based	1995 – 1998
NOvA	$\nu, \overline{\nu}$	2.0, 2.0	CH_2	2010 –
SciBooNE	$\nu, \overline{\nu}$	0.8, 0.7	CH	2007 – 2008
T2K	ν, $\overline{\nu}$	0.6, 0.6	CH, H_2O, Fe	2010 –

52.1 Inclusive Scattering

Over the years, many experiments have measured the total inclusive charged current cross section for neutrino ($\nu_\mu N \to \mu^- X$) and antineutrino ($\overline{\nu}_\mu N \to \mu^+ X$) scattering covering a broad range of neutrino energies. As can be seen in Fig. 52.1, the inclusive cross section approaches a linear dependence on neutrino energy. This behavior is expected for point-like scattering of neutrinos from quarks, an assumption which breaks down at lower energies. Modern measurements of such inclusive scattering cross sections and their target nuclei are summarized in Table 52.2.

To provide a more complete picture, single and double differential cross sections for such inclusive scattering processes have also been reported. These include measurements on iron from NuTeV [5] and on a variety of nuclear targets from ArgoNeuT [6,7], MicroBooNE [8], MINERvA [9–11], NINJA [12], and T2K [13,14]. More recently, MINERvA has provided measurements in terms of longitudinal and transverse muon momenta [10, 11], MicroBooNE has measured the first double differential cross sections in argon [8], and T2K has provided the first measurement of the antineutrino inclusive cross section at low energy [15] (Fig. 52.1).

At high energy, the inclusive cross section is dominated by deep inelastic scattering (DIS). Several neutrino experiments have measured DIS cross sections for specific targets and final states, for example, MINERvA has measured ratios of muon neutrino inclusive and DIS cross sections on a variety of nuclear targets including lead, iron, and carbon [16, 17]. The reader is referred to a recent review of measurements in the shallow and deep inelastic scattering regions [18]. Other experiments have measured opposite-sign dimuon production, the most recent being from CHORUS [19], NOMAD [20], and NuTeV [21].

The aforementioned measurements have all been performed using beams of muon neutrinos and antineutrinos. For the first time, measurements of inclusive electron neutrino cross sections have also been reported, most recently by MicroBooNE [22] and T2K [23–25].

Table 52.2: Published measurements of neutrino and antineutrino CC inclusive cross sections from modern accelerator-based neutrino experiments.

experiment	measurement	target
ArgoNeuT	ν_μ [6,7], $\overline{\nu}_\mu$ [7]	Ar
MicroBooNE	ν_μ [8,26], ν_e [22]	Ar
MINERνA	ν_μ [9–11, 16, 17, 27], $\overline{\nu}_\mu$ [27], $\overline{\nu}_\mu/\nu_\mu$ [28]	CH, C/CH, Fe/CH, Pb/CH
MINOS	ν_μ [29], $\overline{\nu}_\mu$ [29]	Fe
NINJA	ν_μ [12], $\overline{\nu}_\mu$ [12]	H_2O
NOMAD	ν_μ [30]	C
SciBooNE	ν_μ [31]	CH
T2K	ν_μ [13, 14, 32–34], ν_e [23–25], $\overline{\nu}_\mu/\nu_\mu$ [15]	CH, H_2O, Fe

At lower neutrino energies, the inclusive cross section is an additionally complex combination of quasi-elastic scattering and pion production processes, two areas we discuss next.

52.2 Quasi-elastic scattering

Quasi-elastic (QE) scattering is the dominant neutrino interaction for neutrino energies less than $\sim$ 1 GeV and represents a large fraction of the signal samples in many neutrino oscillation experiments, which is why this process has received considerable attention in recent years. Historically, neutrino (antineutrino) quasi-elastic scattering refers to the process, $\nu_\mu n \to \mu^- p$ ($\overline{\nu}_\mu p \to \mu^+ n$), where a charged lepton and single nucleon are ejected in the elastic interaction of a neutrino (or antineutrino) with a nucleon in the target material. This is the final state one would strictly observe, for example, in scattering off of a *free* nucleon target. There were many early measurements of neutrino QE scattering that span back to the 1970's [3]. In many of these initial measurements, bubble chamber experiments employed light targets (hydrogen or deuterium) and required both the detection of the final state muon and single nucleon[2]; thus the final state was clear and elastic kinematic conditions could be verified. The situation is more complicated, of course, for heavier nuclear targets used in modern neutrino experiments. In this case, nuclear effects can impact the size and shape of the cross section as well as the final state composition, kinematics, and topology. Due to intranuclear hadron rescattering and the effects of correlations between target nucleons, additional particles may be ejected in the final state; hence, a QE interaction on a nuclear target does not necessarily imply the ejection of a lepton and a *single* nucleon. One therefore needs to take care in defining what one means by neutrino QE scattering when scattering off targets heavier than hydrogen or deuterium. Because of this, modern experiments tend to instead report cross sections for processes involving pionless (e.g., nucleon-only) final states, often referred to as CC 0π or QE-like reactions in recent literature. Such measurements are

[1] Nuclear effects refer to kinematic and final state effects which impact neutrino scattering off nuclei. Such effects can be significant and are particularly relevant given that modern neutrino experiments make use of nuclear targets to increase their event yields.

[2] In the case of deuterium, many experiments additionally observed the spectator proton.

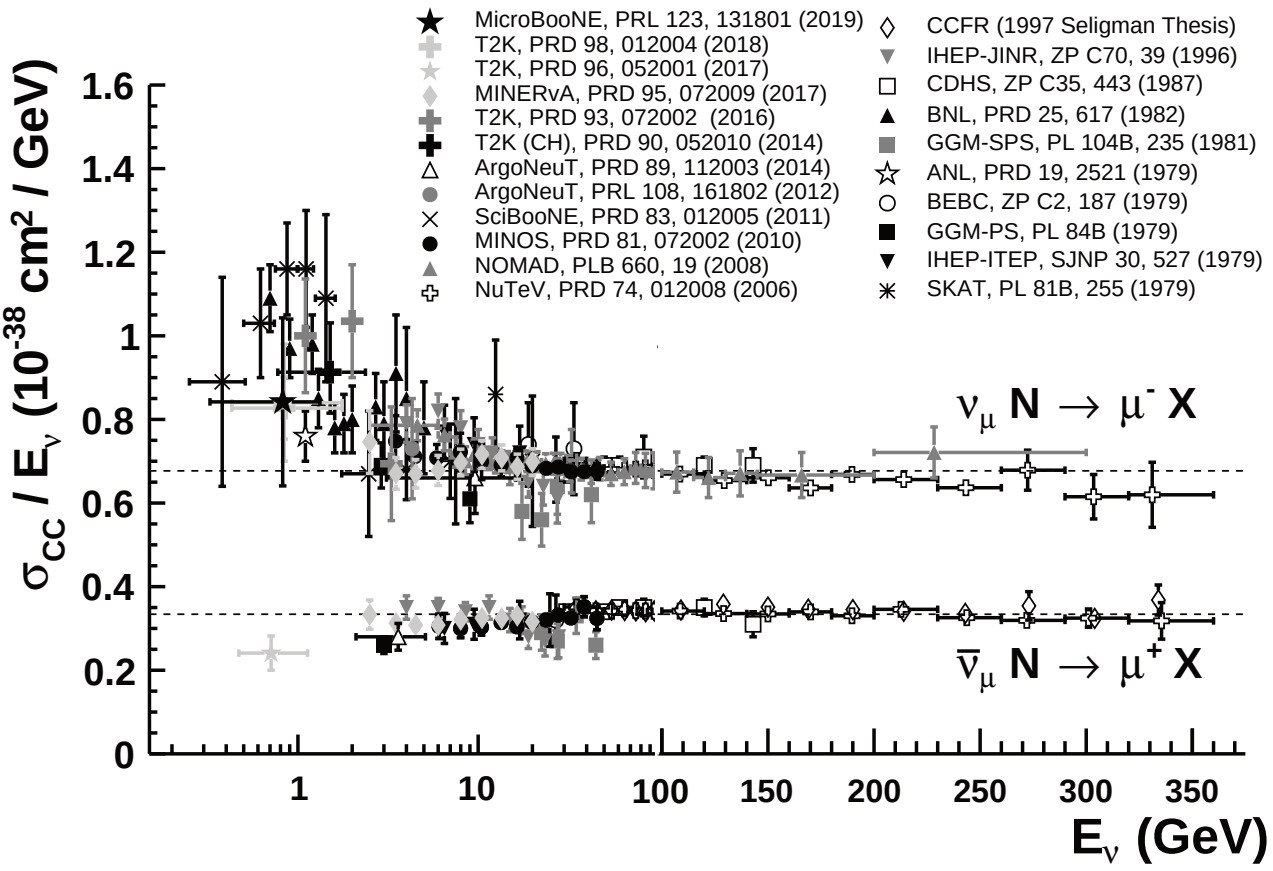

Figure 52.1: Measurements of per nucleon ν_μ and $\overline{\nu}_\mu$ CC inclusive scattering cross sections divided by neutrino energy as a function of neutrino energy. Note the transition between logarithmic and linear scales occurring at 100 GeV. Neutrino cross sections are typically twice as large as their corresponding antineutrino counterparts, although this difference can be larger at lower energies. NC cross sections (not shown) are generally smaller compared to their CC counterpart.

summarized in Table 52.3. Many modern experiments have also recently opted to report nucleon-only cross sections as a function of observed final state particle kinematics [35–48]. Such measurements can be more difficult to directly compare between experiments but have the advantage of being much less model-dependent and provide more stringent tests of the theory than historical cross sections as a function of derived quantities such as neutrino energy (E_ν) or 4-momentum transfer (Q^2). More recent work has been done to develop a means to directly compare experimental measurements produced in these less model-dependent forms [49].

The topic of neutrino QE scattering began drawing considerable attention following the first double differential cross section measurements of this process that revealed a significantly larger cross section than originally anticipated, predominantly in the backwards muon scattering region [40, 41]. Such an enhancement was observed many years prior in transverse electron-nucleus scattering [68] and was attributed to the presence of correlations between nucleons in the target nucleus. As a result, the impact of such nuclear effects on neutrino QE scattering has recently become the subject of intense experimental and theoretical scrutiny with implications on event rates, nucleon emission, neutrino energy reconstruction, and neutrino versus antineutrino cross sections. The reader is referred to reviews of the situation in [4, 69, 70]. To help drive further progress in understanding the underlying nuclear contributions, pionless (e.g., nucleon-only) cross sections have been reported for the first time in the form of double-differential distributions by MiniBooNE [40, 41], MINERvA [35–37, 55], and T2K [42–46]. Such double-differential cross sections in terms of final state particle kinematics reduce the model-dependence of the reported data, provide the most robust measurements available, and allow a more rigorous two-dimensional test of the underlying nuclear theory. MINERvA and T2K have been especially prolific in recent years in probing this interaction process (Table 52.3). Neutrino experiments have also launched dedicated studies of the hadronic side of these interactions, including ArgoNeuT [50, 71], MicroBooNE [47, 48], MINERvA [54], and T2K [67]. MINERvA has been the first modern experiment to measure neutron emission in antineutrino interactions [72]. T2K has probed ratios of oxygen to carbon [45] and asymmetries between neutrino and antineutrino scattering [46] to glean more information on the nature of the underlying nuclear effects. In addition, the exploration of transverse kinematic variables and momentum imbalances in pionless neutrino scattering is allowing better constraints on the various nuclear contributions to the cross section. Such scrutiny includes recent evaluations from MINERvA [35, 36, 38, 39] and T2K [67]. With the MiniBooNE results having first revealed these additional complexities in neutrino-nucleus QE scattering, measurements from multiple neutrino experiments, on multiple targets, and using a variety of kinematic information have been crucial in gaining a better handle on the underlying nuclear physics impacting neutrino-nucleus interactions. What we once thought was "simple" QE scattering is in fact not so simple.

In addition to such charged current investigations, measurements of the neutral current counterpart of this channel have also been performed. The most recent NC elastic scattering cross section measurements include those from BNL E734 [73], MiniBooNE [59, 60], Super-K [63], and T2K [66]. A number of measurements of the Cabibbo-suppressed antineutrino QE hyperon production cross section have additionally been reported [74, 75], although not in recent years.

Table 52.3: Published modern measurements of neutrino CC and NC scattering cross sections with nucleon-only final states.

experiment	measurement	target
ArgoNeuT	2p [50]	Ar
K2K	M_A [51]	H_2O
MicroBooNE	$\frac{d\sigma}{dp_\mu}$ $\frac{d\sigma}{dp_p}$ $\frac{d\sigma}{d\cos\theta_\mu}$ $\frac{d\sigma}{d\cos\theta_p}$ [47, 48]	Ar
MINERνA	$\frac{d^2\sigma}{dp_T dp_{\|\|}}$ [35–37], $\frac{d\sigma}{d\delta p_{Tx}}$ $\frac{d\sigma}{d\delta p_{Ty}}$ [38], $\frac{d\sigma}{dp_n}$ $\frac{d\sigma}{d\delta\alpha_T}$ [39]	CH,Fe,Pb
	$\frac{d\sigma}{dQ^2}$ [52, 53], 1p [54], $\frac{d^2\sigma}{dE_{avail}dq_3}$ [55], $\frac{d\sigma}{dQ^2}$ [56], ν_e [57]	
MiniBooNE	$\frac{d^2\sigma}{dT_\mu d\theta_\mu}$ [40, 41], M_A [58], NC [59, 60]	CH_2
MINOS	M_A [61]	Fe
NOMAD	M_A, $\sigma(E_\nu)$ [62]	C
Super-K	NC [63]	H_2O
T2K	$\frac{d^2\sigma}{dT_\mu d\theta_\mu}$ [42–46], $\sigma(E_\nu)$ [64], M_A [65], NC [66], $\frac{d\sigma}{d\delta p_T}$ $\frac{d\sigma}{d\delta\alpha_T}$ [67], O/C [45]	CH,H_2O

52.3 Pion Production

In addition to such elastic scattering processes, neutrinos can also inelastically scatter producing a nucleon excited state (Δ, N^*). Such baryonic resonances quickly decay, most often to a nucleon and single-pion final state. Historically, experiments have measured various exclusive final states associated with these reactions, the majority of which have been on hydrogen and deuterium targets [3]. There have been several recent re-analyses of this data to better understand the consistency between data sets [76], nucleon form factors [77], and non-resonant contributions [78]. Also, modern measurements of neutrino-induced pion production have since been performed on a variety of nuclear targets (Table 52.4).

Table 52.4: Summary of modern measurements of NC and CC scattering cross sections involving a single pion or multiple pions in the final state.

experiment	$\pi^\pm$	π^0	target
ArgoNeuT	CC [79, 80]	NC [81]	Ar
K2K	CC[82, 83]	CC [84], NC [85]	CH, H_2O
MicroBooNE	–	CC [86]	Ar
MINERνA	CC [87–92]	CC [88, 93–95], NC [96]	CH
MiniBooNE	CC [97, 98]	CC [99], NC [100, 101]	CH_2
MINOS	–	NC [102]	Fe
NOMAD	–	NC [103]	C
NOvA	–	NC [104]	C
SciBooNE	CC [105]	NC [106, 107]	CH
T2K	CC [108–111]	–	CH, H_2O

In addition to resonance production processes, neutrinos can also coherently scatter off of the entire nucleus and produce a distinctly forward-scattered single pion final state. Both CC ($\nu_\mu\, A \to \mu^-\, A\, \pi^+$, $\overline{\nu}_\mu\, A \to \mu^+\, A\, \pi^-$) and NC ($\nu_\mu\, A \to \nu_\mu\, A\pi^0, \overline{\nu}_\mu\, A \to \overline{\nu}_\mu\, A\pi^0$) processes are possible in this case. Even though the level of coherent pion production is small compared to their resonant counterpart, observations exist across a broad energy range and on multiple nuclear targets [112]. More recently, several modern neutrino experiments have either measured or set limits on coherent pion production cross sections including ArgoNeuT [79], K2K [83], MINERvA [89, 91], MiniBooNE [101], MINOS [102], NOMAD [103], NOvA [104], SciBooNE [105, 107], and T2K [83].

As with inclusive and quasi-elastic scattering, a new appreciation for the significance of nuclear effects has also surfaced in pion production physics, again due to the use of heavy nuclear targets in modern neutrino experiments. Many experiments have been careful to report cross sections for various detected final states, thereby not correcting for large and uncertain nuclear effects (e.g., pion rescattering, charge exchange, and absorption) which can introduce significant sources of uncertainty and model dependence. Providing the most comprehensive survey of neutrino single-pion production to date, MiniBooNE has published a total of 16 single- and double-differential cross sections for both the final state muon (in the case of CC scattering) and pions in these interactions; thus, providing the first measurements of such final state kinematic distributions [97–100]. At similar neutrino energies, T2K has provided new data [108] including the first measurement of the Adler angles in neutrino-nucleus scattering [110] and the first exploration of transverse kinematic imbalances in pion production processes [111]. MINERvA has produced a similar accompaniment of measurements at higher neutrino energies [88, 90, 92, 94]. Importantly, MINERvA has been working towards an improved nuclear model [95] and one that can potentially describe all of the pion reaction channels simultaneously, an issue that many experiments have struggled with up until now [88]. ArgoNeuT [80, 81] and MicroBooNE [86] have since been adding new information on single pion production in argon. Regardless of the interaction channel or target material, differential cross section measurements in terms of observed final state particle kinematics are preferred for their reduced model dependence and for the additional kinematic information they provide. Such a new direction has been the focus of modern measurements as opposed to the reporting of more model-dependent, historical cross sections as a function of E_ν or Q^2. Together with similar results for other interaction channels, a better understanding and modeling of nuclear effects will be possible moving forward. MINERvA [113] has already taken a large step in this direction by explicitly tuning the physics in existing neutrino event generators to best fit the experimental data on pion production.

It should be noted that baryonic resonances can also decay to multi-pion, other mesonic (K, η, ρ, etc.), and even photon final states. Experimental results for these channels are typically sparse or non-existent [3]; however, photon production processes can comprise an important background for $\nu_\mu \to \nu_e$ appearance searches in some detectors and thus have become the focus of recent experimental investigations, most notably in NOMAD [114] and T2K [115, 116]. There have also been several recent measurements of kaon final states produced in neutrino NC and CC scattering in MINERvA [117–119] that are providing needed background constraints for certain nucleon decay searches.

52.4 Outlook

Neutrino experiments continue to produce critical neutrino scattering measurements on nuclei as they accumulate increased statistics and pursue new ways of reporting their measurements. Analysis of a broad energy range of data from MINERvA is providing some of the most detailed analysis of nuclear effects in neutrino interactions by examining multiple nuclei in a single experiment. Data from ArgoNeuT and MicroBooNE (and soon also ICARUS and SBND) are probing deeper into complex neutrino final states using the superior capabilities of liquid argon time projection chambers, while the T2K and NOvA near detectors continue to collect high statistics samples in intense neutrino beams. Together with dedicated discussions between experiments on how best to report neutrino cross section measurements [120] and with accompanying work being advanced by theorists to further improve nuclear model calculations [4], we are starting to significantly advance our understanding of neutrino-nucleus scattering.

52.5 Acknowledgments

The author thanks Anne Schukraft (Fermilab) for help in preparing the plots and content of this review.

53. Plots of Cross Sections and Related Quantities

Updated in 2021. See various sections for details.

53.1 Pseudorapidity Distributions in pp and $\bar{p}p$ Interactions

Revised August 2013 by D.R. Ward (Cavendish Lab.).

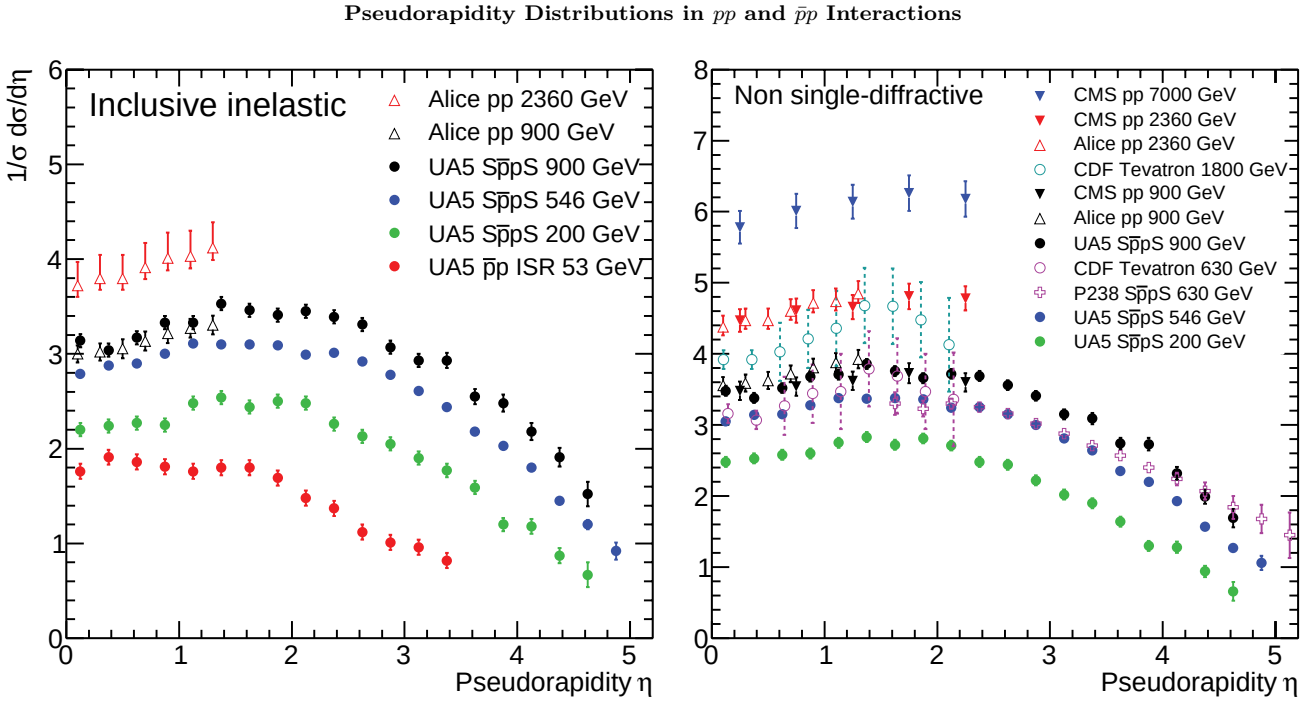

Figure 53.1: Charged particle pseudorapidity distributions in $p\overline{p}$ collisions for 53 GeV $\leq \sqrt{s} \leq$ 1800 GeV. UA5 data from the S$p\overline{p}$S are taken from [1], and from the ISR from [2]. The UA5 data are shown for both the full inelastic cross-section and with singly diffractive events excluded. Additional non single-diffractive measurements are available from CDF at the Tevatron [3] and from P238 at the S$p\overline{p}$S [4]. These may be compared with both inclusive and non single-diffractive measurements in pp collisions at the LHC from ALICE [5] and for non single-diffractive interactions from CMS [6, 7]. (Courtesy of D.R. Ward, Cambridge Univ., 2013)

53.2 Average Hadron Multiplicities in Hadronic e^+e^- Annihilation Events

Revised August 2021 by O. Biebel (Ludwig-Maximilians U.).

Table 53.1: Average hadron multiplicities per hadronic e^+e^- annihilation event at $\sqrt{s} \approx 10$, 29–35, 91, and 130–200 GeV. The rates given include decay products from resonances with $c\tau < 10$ cm, and include the corresponding anti-particle state. Correlations of the systematic uncertainties were considered for the calculation of the averages. Quoted errors are not increased by scale factor S.

Particle	$\sqrt{s} \approx 10$ GeV	$\sqrt{s} = 29$–35 GeV	$\sqrt{s} = 91$ GeV	$\sqrt{s} = 130$–200 GeV	References

(a)$\sigma_{\rm had} = 3.33 \pm 0.05 \pm 0.21$ nb (**CLEO**: [98]) has been used in converting the measured cross sections to average hadron multiplicities.
(b) B($D_s \to \eta\pi,\ \eta'\pi$) was used (RPP 1994).

(c) Comprises both charged and neutral B meson states.
(d) The Standard Model B($Z \to b\bar{b}$) = 0.217 was used.
(e) $x_p = p/p_{\rm beam} > 0.1$ only.
(f) Both charge states.
(g) B($D^*(2010)^+ \to D^0\pi^+$) × B($D^0 \to K^-\pi^+$) has been used (RPP 2000).
(h) B($D_s^* \to D_S^+\gamma$), B($D_s^+ \to \phi\pi^+$), B($\phi \to K^+K^-$) have been used (RPP 1998).
(i) Any charge state (*i.e.*, B_d^*, B_u^*, or B_s^*).
(j) B($Z \to$ hadrons) = 0.699 was used (RPP 1994).
(k) Any charge state (*i.e.*, B_d^{**}, B_u^{**}, or B_s^{**}).
(ℓ) Assumes B($D_{s1}^+ \to D^{*+}K^0 + D^{*0}K^+$) = 100% and B($D_{s2}^+ \to D^0K^+$) = 45%.
(m) The value was derived from the cross section of $\Lambda_c^+ \to p\pi K$ using (a) and assuming the branching fraction to be (5.0 ± 1.3)% (RPP 2004).

53.3 σ and R in e^+e^- Collisions

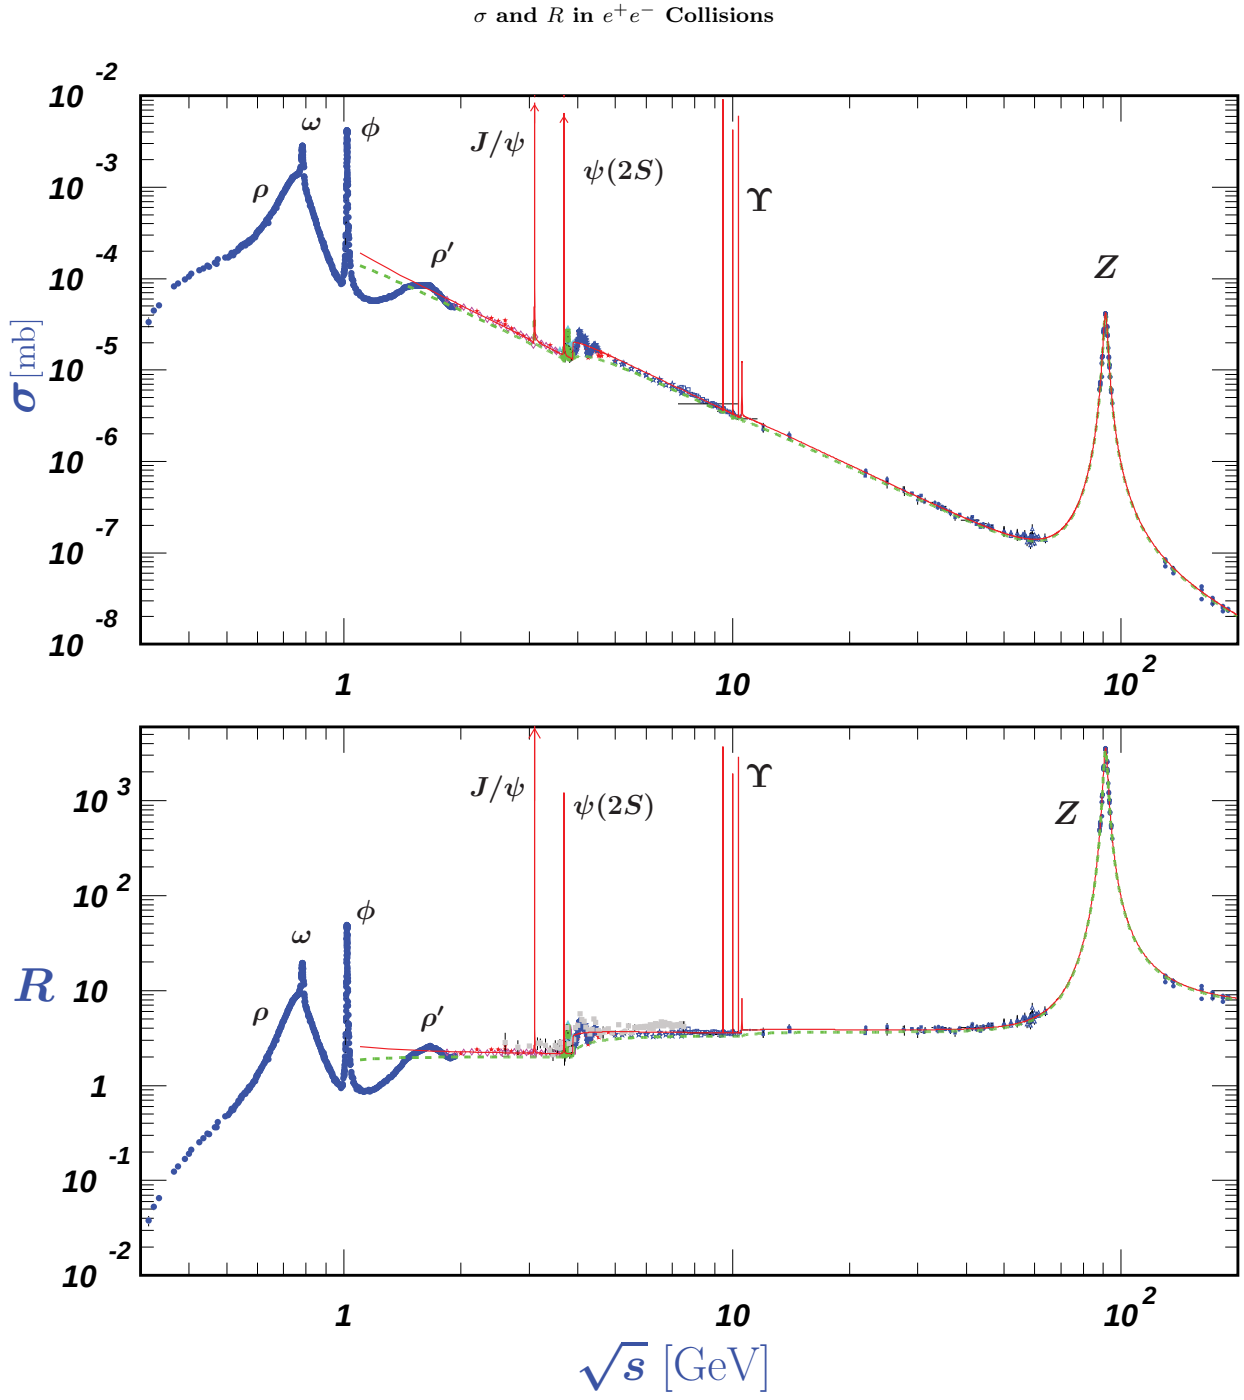

Figure 53.2: World data on the total cross section of $e^+e^- \to hadrons$ and the ratio $R(s) = \sigma(e^+e^- \to hadrons, s)/\sigma(e^+e^- \to \mu^+\mu^-, s)$. $\sigma(e^+e^- \to hadrons, s)$ is the experimental cross section corrected for initial state radiation and electron-positron vertex loops, $\sigma(e^+e^- \to \mu^+\mu^-, s) = 4\pi\alpha^2(s)/3s$. Data errors are total below 2 GeV and statistical above 2 GeV. The curves are an educative guide: the broken one (green) is a naive quark-parton model prediction, and the solid one (red) is 3-loop pQCD prediction (see "Quantum Chromodynamics" section of this *Review*, Eq. (9.7) or, for more details [99], Breit-Wigner parameterizations of J/ψ, $\psi(2S)$, and $\Upsilon(nS), n = 1, 2, 3, 4$ are also shown. The full list of references to the original data and the details of the R ratio extraction from them can be found in [100]. Corresponding computer-readable data files are available at http://pdg.lbl.gov/current/xsect/. (Courtesy of the COMPAS (Protvino) and HEPDATA (Durham) Groups, August 2021. Corrections by P. Janot (CERN) and M. Schmitt (Northwestern U.))

R in Light-Flavor, Charm, and Beauty Threshold Regions

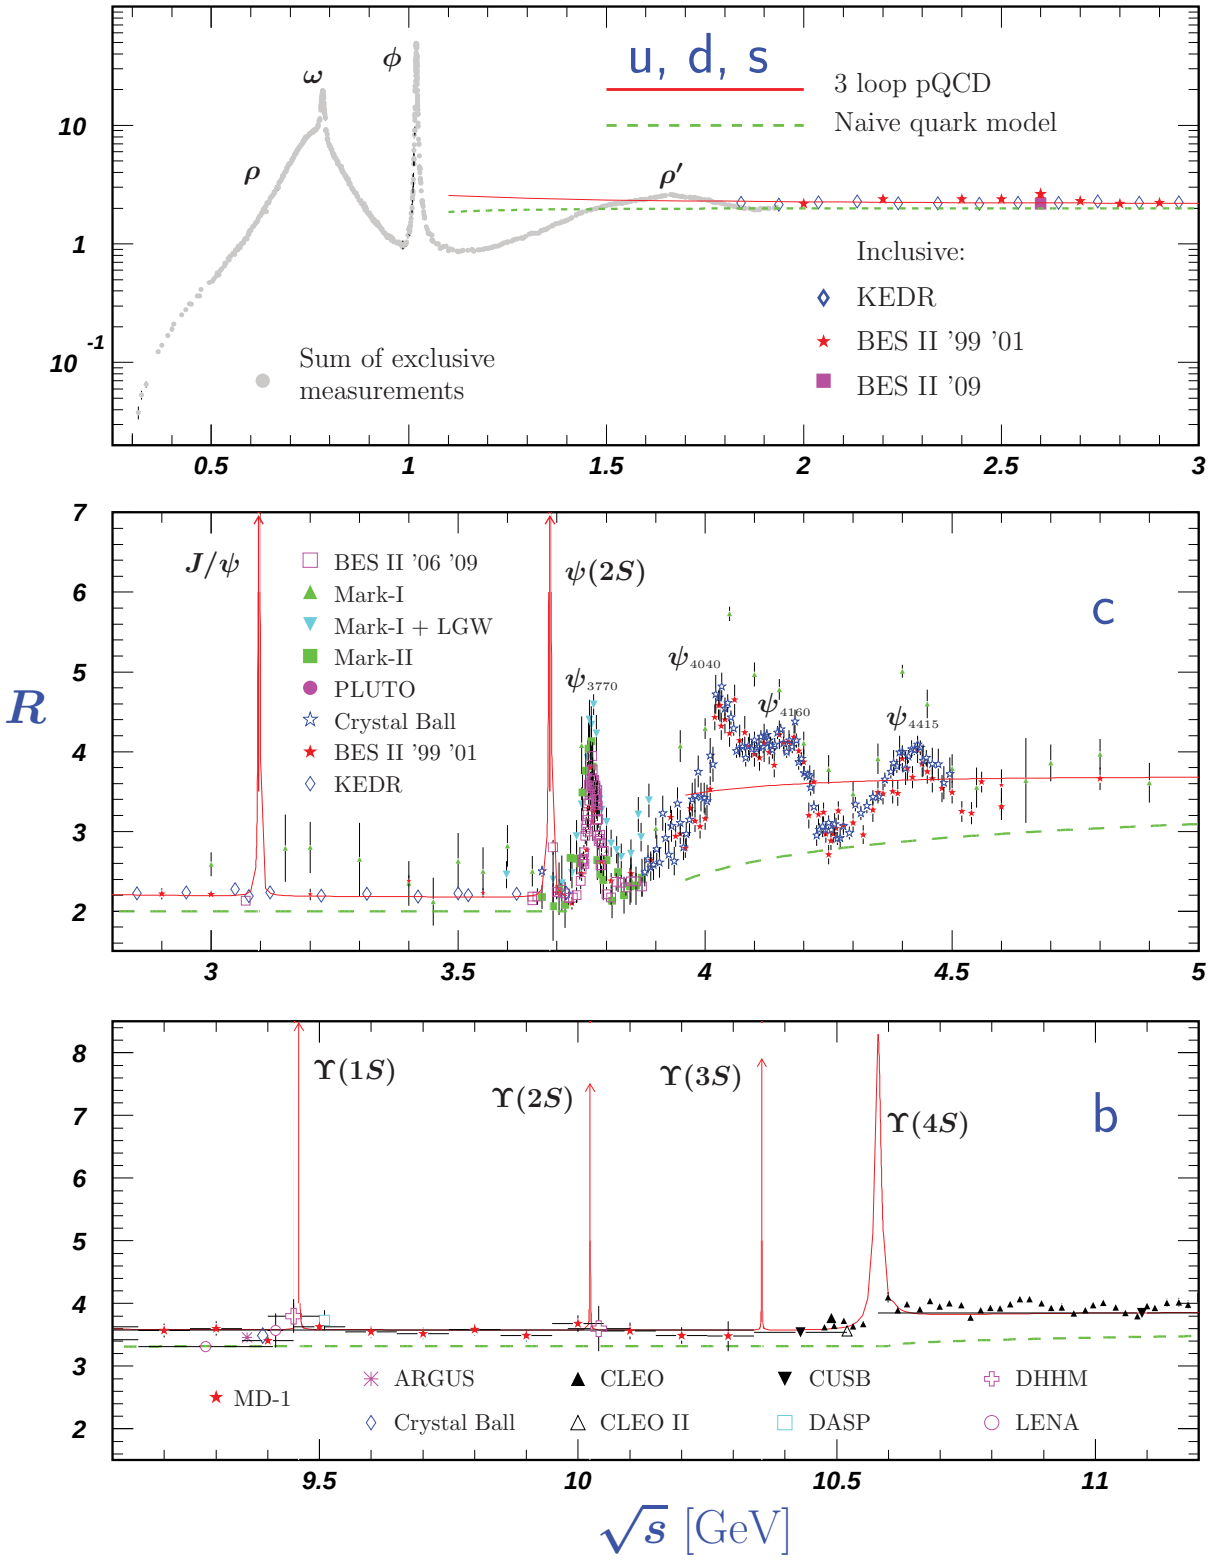

Figure 53.3: R in the light-flavor, charm, and beauty threshold regions. Data errors are total below 2 GeV and statistical above 2 GeV. The curves are the same as in Fig. 53.2. **Note:** CLEO data above $\Upsilon(4S)$ were not fully corrected for radiative effects, and we retain them on the plot only for illustrative purposes with a normalization factor of 0.8. The full list of references to the original data and the details of the R ratio extraction from them can be found in [100]. The computer-readable data are available at http://pdg.lbl.gov/current/xsect/. (Courtesy of the COMPAS (Protvino) and HEPDATA (Durham) Groups, August 2021.)

53.4 Annihilation Cross Section Near M_Z

Courtesy of M. Grünewald and the LEP Electroweak Working Group, 2007.

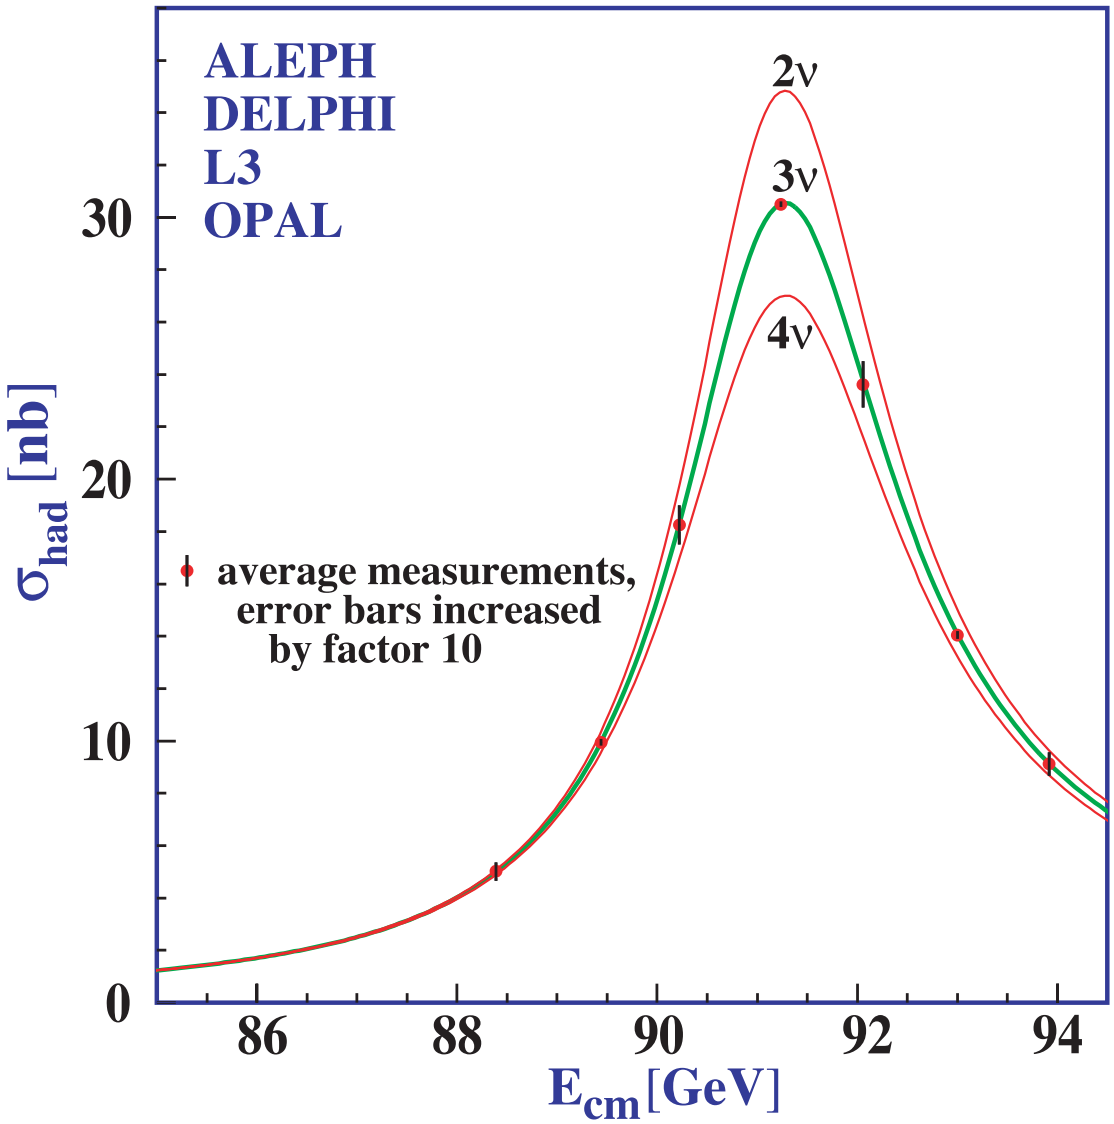

Figure 53.4: Combined data from the ALEPH, DELPHI, L3, and OPAL Collaborations for the cross section in e^+e^- annihilation into hadronic final states as a function of the center-of-mass energy near the Z pole. The curves show the predictions of the Standard Model with two, three, and four species of light neutrinos. The asymmetry of the curve is produced by initial-state radiation. Note that the error bars have been increased by a factor ten for display purposes. References: ALEPH [101], DELPHI [102], L3 [103], OPAL [104], Combination [105],

53.5 Total Hadronic Cross Sections

Revised August 2021 by COMPAS Group (NRC KI – IHEP, Protvino).

There are a significant number of physical quantities extracted from experimental data that are related to the physics of hadronic interactions. Depending on the magnitude of the transverse momenta of particles in the final states, the interactions are either classified as "hard" or "soft". In hard processes, the transverse momenta are comparable in magnitude with the momenta of the initial particles, while in soft processes they are vanishingly small compared to the initial momenta. Soft processes reveal characteristic interference pattern of the scattered states, and are often referred to as diffractive processes. The set of experimentally measured quantities related to diffractive processes include total and elastic cross sections, differential cross sections of elastic scattering and diffraction dissociation processes, as well as secondary quantities such as the slopes of differential cross sections and the ratio of real parts of the scattering amplitude to its imaginary parts (ρ parameter). In this section, plots of total and elastic cross section for various processes are presented. They include the data from purely hadronic collisions such as pp and πp, as well as γp, γd, and $\gamma\gamma$[a]

One of the most important basic notions and tools in general theoretical framework related to the diffractive processes is the notion of the Regge poles, or Reggeons, generalizing a simple one-particle exchange (of Yukawa type) by virtual particles of fixed spin to exchanges by states with "running spin" dependent on the transferred momenta [106, 107]. The simplest case of the one-Reggeon exchange amplitude is given by the amplitude (at high c.m. energy $\sqrt{s}$ and fixed (small) transferred momentum squared, t): $T(s,t) = \beta(t)s^{\alpha(t)}$ which qualitatively exhibits many typical features of generic diffractive processes (e.g. the growth of the interaction radius with energy). In practice the single-pole Reggeon model is insufficient for many diffractive processes but serves as a building block for more sophisticated schemes. Up to now no firm results concerning Regge trajectories $\alpha(t)$ and Regge residues $\beta(t)$ are obtained from the first principles of QCD. Therefore one has to rely on general principles of quantum field theory as a guide. These imply, in particular, that both $\alpha(t)$ and $\beta(t)$ are analytic functions with right cuts from some $t_0 > 0$ to positive infinity.

The theoretical requisite for analyzing diffractive phenomena is therefore represented by various model approaches. The more commonly discussed models in the literatures are:

- **Regge-eikonal approach** [108–115]: this approach automatically satisfies the s-channel unitarity condition and generalizes the impact parameter approximation to the relativistic case. The main element of the model is the Born amplitude defined by one or several leading "Pomeronic" Regge trajectories with intercepts higher than 1. To take into account the difference between C-conjugated processes (such as pp and $\bar{p}p$), a term with an Odderon Reggeon is also added, as well as, if one wishes to describe low (5 to 10 GeV) energies, a secondary Reggeon with low intercepts.
- **Regge pole models with minimal corrections due to two-Reggeon exchanges** [116–118]: in this model, contribution of the leading trajectory in the scattering amplitude is supplemented by a two-Reggeon exchange with an arbitrary coefficient chosen from the fitting details.
- **U-matrix (or "resonance") approach** [119,120]: the unitarity respecting approach with the scattering amplitude defined by a "U-matrix".
- **Direct functional modelling of the amplitudes with limited Regge trajectories** [121, 122]: this approach appeals to only very general (analytic) properties of the amplitudes leaving aside all dynamical assumptions and mostly aiming at the best phenomenological description of the data.
- **Quasi-classical approach** [123–125]: this model is based on the observation that diffractive processes deal with high quantum numbers, in particular, with large number of virtual quanta.

The ratio $\rho(s) = \mathrm{Re}T(s,0)/\mathrm{Im}T(s,0) = \cot\Phi(s,0)$, where $\Phi(s,0)$ is the phase of the forward scattering amplitude, $T(s,0) = |T(s,0)|\exp(i\Phi(s,0))$, is accessible due to Coulomb-nuclear interference (CNI). There are several different ways to deal with CNI in the literature [126–130]. The value ρ is important for measurements of the total cross-sections as well as for discrimination of different models [131,132]. The phase $\Phi(s,0)$ starts from π at low energies, evolves further down to $\pi/2$, achieves a shallow minimum and then slowly rise up to $\pi/2$ at asymptotic energies.

The total cross-sections results shown in this review exhibit a common feature: starting from a certain energy (unique for each initial state) the cross-sections begin a slow but steady rise which continue up to several tens of TeV. The current data show the upper bound for total hadronic cross-section is well below the Froissart-Martin asymptotic bound [133,134], more than 20000 mb at the LHC energies [135].

For readers who are interested in examples of both total and elastic cross section parametrizations and fits, see previous edition of the *Plots of Cross Sections and Related Quantities* review [136]. For the cross section plots shown in the following pages, the example fits are using parametrizations as described in [136] with the fit range starting at about $\sqrt{s} = 5$ GeV.

[a] In spite of its electromagnetic nature the photon interacts with hadron targets as an effective hadron (via transmutation of γ into virtual vector mesons $\rho^0, \omega, \phi, \ldots$).

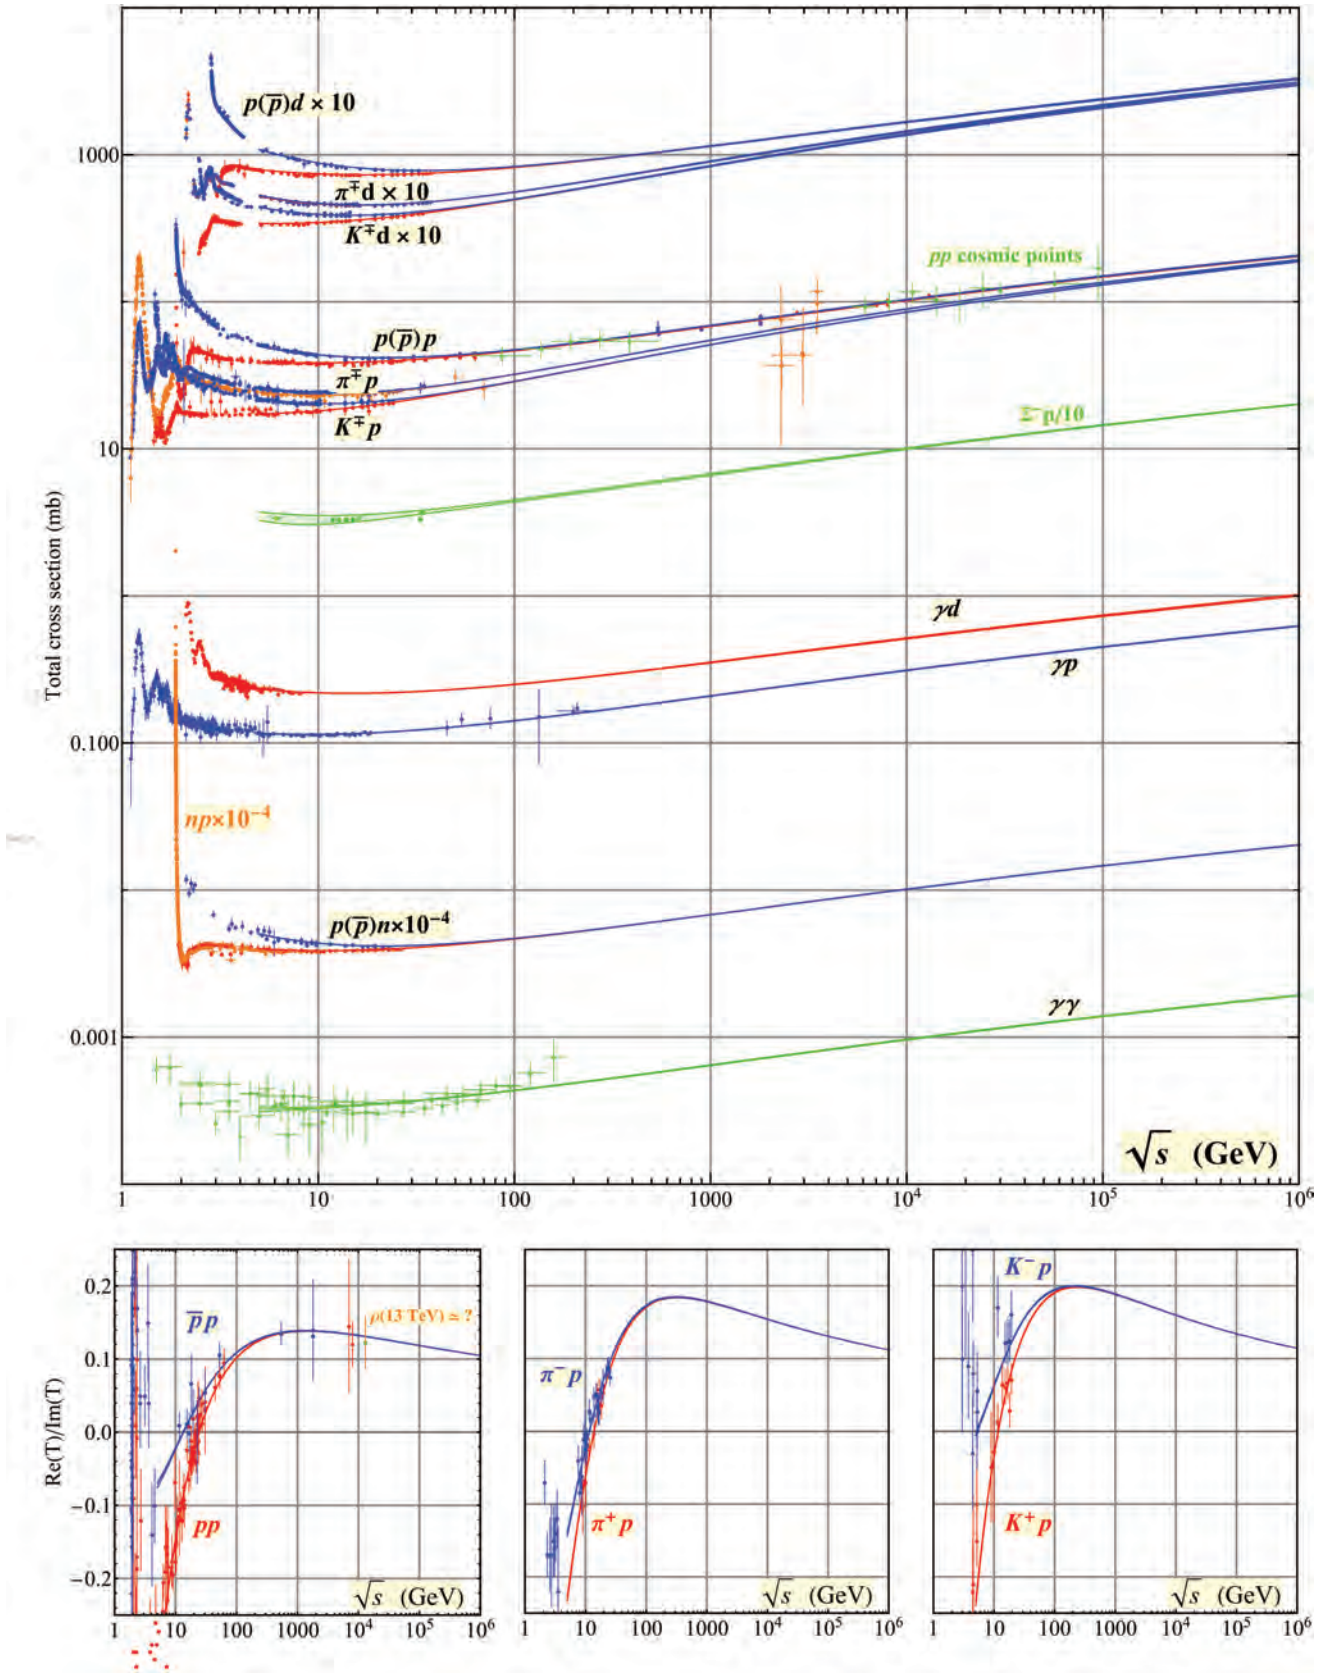

Figure 53.5: Summary of hadronic, γp, γd, and $\gamma\gamma$ total cross sections (top), and ratio of the real to imaginary parts of the forward hadronic amplitudes (bottom). 54. Mass and Width of the W Boson

Revised May 2022 by M. Grünewald (University Coll. Dublin) and A. Gurtu (CERN; TIFR Mumbai).

Precision determination of the W mass is of great importance in testing the internal consistency of the Standard Model. From the time of its discovery in 1983, the W boson has been studied and its mass determined in $p\bar{p}$ and e^+e^- interactions; it is currently studied in pp interactions at the LHC. The mass and width definition used here corresponds to a Breit-Wigner with mass-dependent width.

Production of on-shell W bosons at hadron colliders is tagged by the high p_T charged lepton from its leptonic decay modes. Owing to the unknown parton-parton effective energy and missing energy in the longitudinal direction, the hadron collider experiments reconstruct the transverse mass of the W boson, and derive the W mass from comparing the transverse mass distribution with Monte Carlo predictions as a function of the mass m_W. The transverse momentum of the charged lepton itself and the transverse missing energy (arising from the neutrino in W decay) are also sensitive to the W mass and used in its determination. These analyses use the electron and muon decay modes of the W boson.

At the e^+e^- collider LEP, a precise knowledge of the beam energy enables one to determine the $e^+e^- \to W^+W^-$ cross section as a function of center of mass energy, as well as to reconstruct the W mass precisely from its decay products, even if one of them decays leptonically. Close to the W^+W^- production threshold ($\sqrt{s} = 161$ GeV), the dependence of the W-pair production cross section on m_W is large, and this was used to determine m_W. At higher centre-of-mass energies (172 to 209 GeV) this dependence is much weaker, thus W bosons were directly reconstructed and the mass determined as the invariant mass of the decay products, improving the resolution with a kinematic fit.

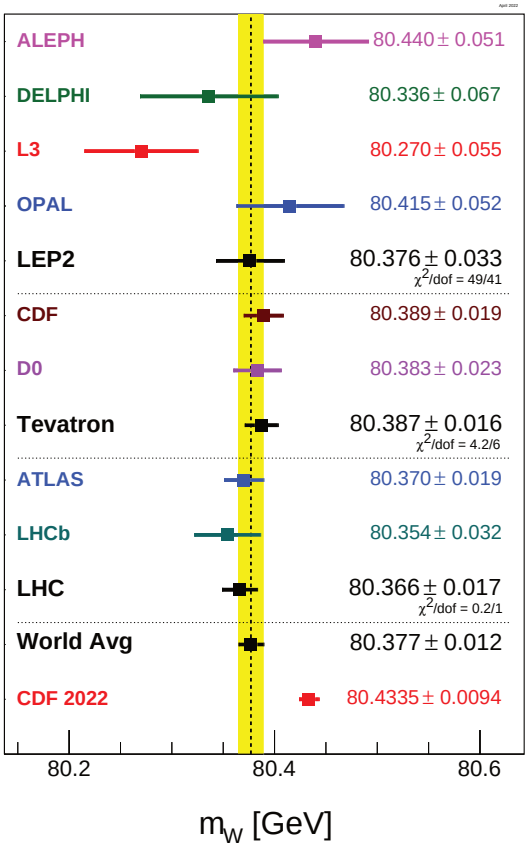

Figure 54.1: Measurements of the W boson mass by the LEP, Tevatron and LHC experiments. The pre-2022 CDF result, used in the world average, is superseded by the new CDF 2022 result.

In order to compute the LEP average W mass, each experiment provided its measured W mass for the $q\bar{q}q\bar{q}$ and $q\bar{q}\ell\nu$, $\ell = e, \mu, \tau$ channels at each center-of-mass energy, along with a detailed break-up of uncertainty contributions: statistical, uncorrelated, partially correlated and fully correlated systematics [1]. These results have been combined to obtain a LEP average W mass of $m_W = 80.376 \pm 0.033$ GeV. Errors on m_W due to uncertainties in the LEP beam energy (9 MeV), and possible effect of color reconnection (CR) and Bose-Einstein correlations (BEC) between quarks from different W bosons (8 MeV) are included. The mass difference between $q\bar{q}q\bar{q}$ and $q\bar{q}\ell\nu$ final states (due to possible CR and BEC effects) is -12 ± 45 MeV. In a similar manner, the results on the total width of the W boson obtained at LEP have been combined, resulting in an average of $\Gamma_W = 2.195 \pm 0.083$ GeV [1].

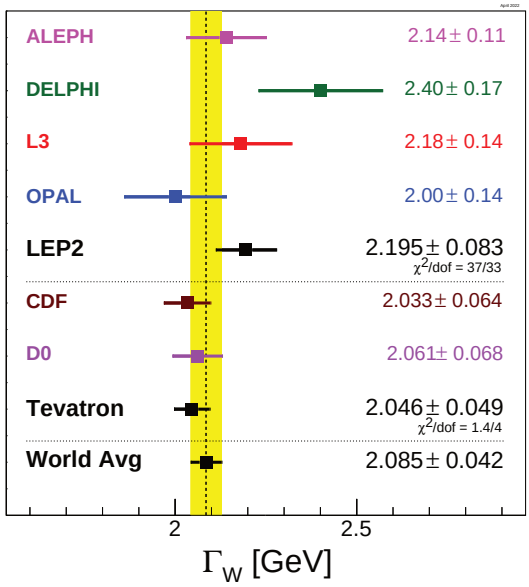

Figure 54.2: Measurements of the W-boson width by the LEP and Tevatron experiments.

The two Tevatron experiments CDF and D0 have also identified common systematic errors. Between the two experiments, uncertainties due to the parton distribution functions (PDF), radiative corrections, and choice of mass (width) in the width (mass) measurements are treated as correlated. An average W width of $\Gamma_W = 2.046 \pm 0.049$ GeV [2] is obtained. Errors of 20 MeV and 7 MeV accounting for PDF and radiative correction uncertainties in this width combination dominate the correlated uncertainties. The CDF and D0 measurements of 80.387 ± 0.019 GeV [3] and 80.375 ± 0.023 GeV [4], respectively, obtained with Run-II data, are the two single most precise determinations of the W boson mass at the Tevatron. Combining the results from Run-I and Run-II of the Tevatron using an improved treatment of correlations, following the procedure used in [5], the results are 80.389 ± 0.019 GeV for CDF and 80.383 ± 0.023 GeV for D0. A combination of all pre-2022 CDF and D0 results yields a Tevatron average of 80.387 ± 0.016 GeV [5], with common uncertainties of 10 MeV (PDF) and 4 MeV (radiative corrections).

Using pp collisions at $\sqrt{s} = 7$ TeV, the ATLAS collaboration has published the first measurement of the W boson mass at the LHC, $m_W = 80.370 \pm 0.019$ GeV [6], which is of similar precision as the best measurements of CDF and D0. The LHCb collaboration has measured the W boson mass in pp collisions at $\sqrt{s} = 13$ TeV at the LHC, $m_W = 80.354 \pm 0.032$ GeV [7]. Combining the results from ATLAS and LHCb using the BLUE procedure [8, 9] assuming a correlated uncertainty of 9 MeV (PDF), the LHC average is $m_W = 80.366 \pm 0.017$ GeV.

The results obtained by the experiments at the different accelerators are all in good agreement with each other. Assuming a correlated uncertainty of 7 MeV, a hadron collider average of the

Tevatron and LHC measurements of $m_W = 80.377 \pm 0.013$ GeV is obtained, and a world average of $m_W = 80.377 \pm 0.012$ GeV, combining with the LEP result assuming no correlation, again using the BLUE procedure for these averages.

The LEP, Tevatron and LHC results on mass and width are compared in Fig. 54.1 and Fig. 54.2. The Standard Model prediction from the electroweak fit, including Z-pole data and the measured masses of the top quark and of the Higgs boson, gives a W-boson mass of $m_W = 80.356 \pm 0.006$ GeV (see Section 10, Electroweak Model and Contraints on New Physics, J.Erler and A.Freitas, 2022, this review) and a W-boson width of $\Gamma_W = 2.091 \pm 0.001$ GeV [10], which are in good agreement with the measurements.

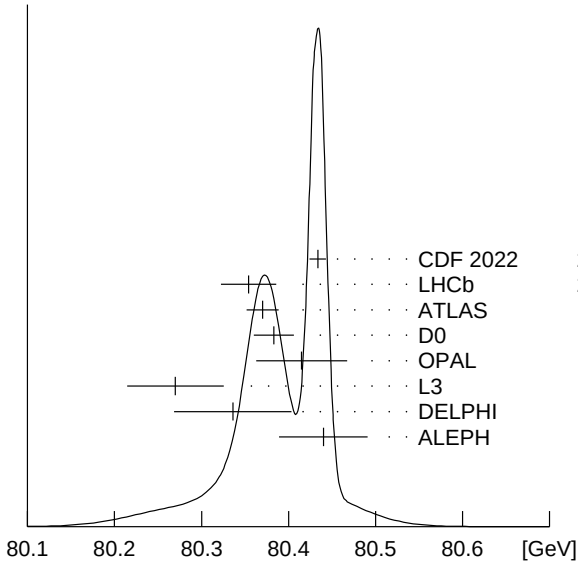

Figure 54.3: Ideogram showing the compatibility of all W-boson mass measurements, replacing the pre-2022 CDF result by the new CDF 2022 result.

In April 2022, after the cut-off of results for this review, the CDF collaboration published a measurement of the W mass based on their full Run-II dataset of 8.8 fb^{-1}, with much reduced uncertainty: $80,433.5 \pm 9.4$ MeV [11][1]. This new CDF Run-II result is of higher precision than our world average of 80.377 ± 0.012 GeV. However, the two determinations disagree significantly, as visible in Fig. 54.1. A probability ideogram comparing the results from Fig. 54.1 is shown in Fig. 54.3 (see Section 5.2 in the Introduction of this review on the construction of ideograms).

For calculating a new world average, replacing the old CDF Run-II result [3] by the new one [11], the uncertainties of all results need to be scaled by a factor of about two in order to achieve a χ^2 per degree of freedom of unity (see Section 5.2 in the Introduction of this review on the definition of the scale factor). The world average quoted above (80.377 ± 0.012 GeV) increases significantly in central value, by up to 40 MeV, while its scaled uncertainty increases by up to 6 MeV, with the exact changes depending on the assumptions made concerning correlated uncertainties. A detailed understanding of the results and their correlations is needed. Corresponding studies are currently being undertaken by the experiments.

[1] The new result includes the 2.2 fb^{-1} of data used for the previous CDF Run-II result of 80.387 ± 0.019 GeV [3]. Incorporating the improved understanding of PDFs and track reconstruction, the central value of the 2.2 fb^{-1} result is increased by 13.5 MeV to 80,400.5 MeV [11].

55. Z Boson

Revised August 2018 by M. Grünewald (University Coll. Dublin) and A. Gurtu (CERN; TIFR Mumbai).

Precision measurements at the Z-boson resonance using electron–positron colliding beams began in 1989 at the SLC and at LEP. During 1989–95, the four LEP experiments (ALEPH, DELPHI, L3, OPAL) made high-statistics studies of the production and decay properties of the Z. Although the SLD experiment at the SLC collected much lower statistics, it was able to match the precision of LEP experiments in determining the effective electroweak mixing angle $\sin^2\overline{\theta}_W$ and the rates of Z decay to b- and c-quarks, owing to availability of polarized electron beams, small beam size, and stable beam spot.

The Z-boson properties reported in this section may broadly be categorized as:

- The standard 'lineshape' parameters of the Z consisting of its mass, M_Z, its total width, Γ_Z, and its partial decay widths, Γ(hadrons), and $\Gamma(\ell\overline{\ell})$ where $\ell = e, \mu, \tau, \nu$;
- Z asymmetries in leptonic decays and extraction of Z couplings to charged and neutral leptons;
- The b- and c-quark-related partial widths and charge asymmetries which require special techniques;
- Determination of Z decay modes and the search for modes that violate known conservation laws;
- Average particle multiplicities in hadronic Z decay;
- Z anomalous couplings.

The effective vector and axial-vector coupling constants describing the Z-to-fermion coupling are also measured in $p\bar{p}$ and ep collisions at the Tevatron and at HERA. The corresponding cross-section formulae are given in Section 39 (Cross-section formulae for specific processes) and Section 16 (Structure Functions) in this *Review*. In this minireview, we concentrate on the measurements in e^+e^- collisions at LEP and SLC.

The standard 'lineshape' parameters of the Z are determined from an analysis of the production cross sections of these final states in e^+e^- collisions. The $Z \to \nu\overline{\nu}(\gamma)$ state is identified directly by detecting single photon production and indirectly by subtracting the visible partial widths from the total width. Inclusion in this analysis of the forward-backward asymmetry of charged leptons, $A_{FB}^{(0,\ell)}$, of the τ polarization, $P(\tau)$, and its forward-backward asymmetry, $P(\tau)^{fb}$, enables the separate determination of the effective vector ($\overline{g}_V$) and axial vector ($\overline{g}_A$) couplings of the Z to these leptons and the ratio ($\overline{g}_V/\overline{g}_A$), which is related to the effective electroweak mixing angle $\sin^2\overline{\theta}_W$ (see the "Electroweak Model and Constraints on New Physics" review).

Determination of the b- and c-quark-related partial widths and charge asymmetries involves tagging the b and c quarks for which various methods are employed: requiring the presence of a high momentum prompt lepton in the event with high transverse momentum with respect to the accompanying jet; impact parameter and lifetime tagging using precision vertex measurement with high-resolution detectors; application of neural-network techniques to classify events as b or non-b on a statistical basis using event–shape variables; and using the presence of a charmed meson (D/D^*) or a kaon as a tag.

55.1 Z-parameter determination

LEP was run at energy points on and around the Z mass (88–94 GeV) constituting an energy 'scan'. The shape of the cross-section variation around the Z peak can be described by a Breit-Wigner *ansatz* with an energy-dependent total width [1–3]. The **three** main properties of this distribution, viz., the **position** of the peak, the **width** of the distribution, and the **height** of the peak, determine respectively the values of M_Z, Γ_Z, and $\Gamma(e^+e^-) \times \Gamma(f\overline{f})$, where $\Gamma(e^+e^-)$ and $\Gamma(f\overline{f})$ are the electron and fermion partial widths of the Z. The quantitative determination of these parameters is done by writing analytic expressions for these cross sections in terms of the parameters, and fitting the calculated cross sections to the measured ones by varying these parameters, taking properly into account all the errors. Single-photon exchange (σ^0_γ) and γ-Z interference ($\sigma^0_{\gamma Z}$) are included, and the large (∼25 %) initial-state radiation (ISR) effects are taken into account by convoluting the analytic expressions over a 'Radiator Function' [1–5] $H(s, s')$. Thus for the process $e^+e^- \to f\overline{f}$:

$$\sigma_f(s) = \int H(s,s')\ \sigma^0_f(s')\ ds' \tag{55.1}$$

$$\sigma^0_f(s) = \sigma^0_Z + \sigma^0_\gamma + \sigma^0_{\gamma Z} \tag{55.2}$$

$$\sigma^0_Z = \frac{12\pi}{M_Z^2}\ \frac{\Gamma(e^+e^-)\Gamma(f\overline{f})}{\Gamma_Z^2}\ \frac{s\ \Gamma_Z^2}{(s-M_Z^2)^2\ +\ s^2\Gamma_Z^2/M_Z^2} \tag{55.3}$$

$$\sigma^0_\gamma = \frac{4\pi\alpha^2(s)}{3s}\ Q_f^2 N_c^f \tag{55.4}$$

$$\sigma^0_{\gamma Z} = -\ \frac{2\sqrt{2}\alpha(s)}{3}\ (Q_f G_F N_c^f \mathcal{G}_V^e \mathcal{G}_V^f) \times \frac{(s-M_Z^2)M_Z^2}{(s-M_Z^2)^2 + s^2\Gamma_Z^2/M_Z^2} \tag{55.5}$$

where Q_f is the charge of the fermion, $N_c^f = 3$ for quarks and 1 for leptons, and $\mathcal{G}_V^f$ is the vector coupling of the Z to the fermion-antifermion pair $f\overline{f}$.

Since $\sigma^0_{\gamma Z}$ is expected to be much less than σ^0_Z, the LEP Collaborations have generally calculated the interference term in the framework of the Standard Model. This fixing of $\sigma^0_{\gamma Z}$ leads to a tighter constraint on M_Z, and consequently a smaller error on its fitted value. It is possible to relax this constraint and carry out the fit within the S-matrix framework, which is briefly described in the next section.

In the above framework, the QED radiative corrections have been explicitly taken into account by convoluting over the ISR and allowing the electromagnetic coupling constant to run [6]: $\alpha(s) = \alpha/(1-\Delta\alpha)$. On the other hand, weak radiative corrections that depend upon the assumptions of the electroweak theory and on the values of $M_{\rm top}$ and $M_{\rm Higgs}$ are accounted for by **absorbing them into the couplings**, which are then called the *effective* couplings $\mathcal{G}_V$ and $\mathcal{G}_A$ (or alternatively the effective parameters of the $\star$ scheme of Kennedy and Lynn [7].)

$\mathcal{G}_V^f$ and $\mathcal{G}_A^f$ are complex numbers with small imaginary parts. As experimental data does not allow simultaneous extraction of both real and imaginary parts of the effective couplings, the convention $g_A^f = \mathrm{Re}(\mathcal{G}_A^f)$ and $g_V^f = \mathrm{Re}(\mathcal{G}_V^f)$ is used and the imaginary parts are added in the fitting code [4].

Defining

$$A_f = 2\frac{g_V^f \cdot g_A^f}{(g_V^f)^2 + (g_A^f)^2} \tag{55.6}$$

the lowest-order expressions for the various lepton-related asymmetries on the Z pole are [8–10] $A_{FB}^{(0,\ell)} = (3/4)A_eA_f$, $P(\tau) = -A_\tau$, $P(\tau)^{fb} = -(3/4)A_e$, $A_{LR} = A_e$. The full analysis takes into account the energy-dependence of the asymmetries. Experimentally A_{LR} is defined as $(\sigma_L - \sigma_R)/(\sigma_L + \sigma_R)$, where $\sigma_{L(R)}$ are the $e^+e^- \to Z$ production cross sections with left- (right)-handed electrons.

The definition of the partial decay width of the Z to $f\overline{f}$ includes the effects of QED and QCD final-state corrections, as well as the contribution due to the imaginary parts of the couplings:

$$\Gamma(f\overline{f}) = \frac{G_F M_Z^3}{6\sqrt{2}\pi}\ N_c^f\,(\left|\mathcal{G}_A^f\right|^2 R_A^f + \left|\mathcal{G}_V^f\right|^2 R_V^f) + \Delta_{ew/\mathrm{QCD}} \tag{55.7}$$

where R_V^f and R_A^f are radiator factors to account for final state QED and QCD corrections, as well as effects due to nonzero fermion masses, and $\Delta_{ew/\mathrm{QCD}}$ represents the non-factorizable electroweak/QCD corrections.

55.2 S-matrix approach to the Z

While most experimental analyses of LEP/SLC data have followed the 'Breit-Wigner' approach, an alternative S-matrix-based

analysis is also possible. The Z, like all unstable particles, is associated with a complex pole in the S matrix. The pole position is process-independent and gauge-invariant. The mass, $\overline{M}_Z$, and width, $\overline{\Gamma}_Z$, can be defined in terms of the pole in the energy plane via [11–14]

$$\overline{s} = \overline{M}_Z^2 - i\overline{M}_Z\overline{\Gamma}_Z \tag{55.8}$$

leading to the relations

$$\begin{aligned}\overline{M}_Z &= M_Z/\sqrt{1+\Gamma_Z^2/M_Z^2} \\ &\approx M_Z \ - 34.1 \text{ MeV} \end{aligned} \tag{55.9}$$

$$\begin{aligned}\overline{\Gamma}_Z &= \Gamma_Z/\sqrt{1+\Gamma_Z^2/M_Z^2} \\ &\approx \Gamma_Z \ - 0.9 \text{ MeV} \ . \end{aligned} \tag{55.10}$$

The LEP collaborations [15] have analyzed their data using the S–matrix approach as defined in Eq. (55.8), in addition to the conventional one. They observe a downward shift in the Z mass as expected.

55.3 Handling the large-angle e^+e^- final state

Unlike other $f\overline{f}$ decay final states of the Z, the e^+e^- final state has a contribution not only from the s-channel but also from the t-channel and s-t interference. The full amplitude is not amenable to fast calculation, which is essential if one has to carry out minimization fits within reasonable computer time. The usual procedure is to calculate the non-s channel part of the cross section separately using the Standard Model programs ALIBABA [16] or TOPAZ0 [17], with the measured value of $M_{\rm top}$, and $M_{\rm Higgs} = 150$ GeV, and add it to the s-channel cross section calculated as for other channels. This leads to two additional sources of error in the analysis: firstly, the theoretical calculation in ALIBABA itself is known to be accurate to $\sim 0.5\%$, and secondly, there is uncertainty due to the error on $M_{\rm top}$ and the unknown value of $M_{\rm Higgs}$ (100–1000 GeV). These errors are propagated into the analysis by including them in the systematic error on the e^+e^- final state. As these errors are common to the four LEP experiments, this is taken into account when performing the LEP average.

55.4 Errors due to uncertainty in LEP energy determination

The systematic errors related to the LEP energy measurement, see [18–23], can be classified as:

- The absolute energy scale error;
- Energy-point-to-energy-point errors due to the nonlinear response of the magnets to the exciting currents;
- Energy-point-to-energy-point errors due to possible higher-order effects in the relationship between the dipole field and beam energy;
- Energy reproducibility errors due to various unknown uncertainties in temperatures, tidal effects, corrector settings, RF status, *etc.*

Precise energy calibration was done outside normal data-taking using the resonant depolarization technique. Run-time energies were determined every 10 minutes by measuring the relevant machine parameters and using a model which takes into account all the known effects, including leakage currents produced by trains in the Geneva area and the tidal effects due to gravitational forces of the Sun and the Moon. The LEP Energy Working Group has provided a covariance matrix from the determination of LEP energies for the different running periods during 1993–1995 [18].

55.5 Choice of fit parameters

The LEP Collaborations have chosen the following primary set of parameters for fitting:

$$M_Z, \Gamma_Z, \sigma^0_{\rm hadron}, R(\text{lepton}), A_{FB}^{(0,\ell)},$$

where

$$\begin{aligned} R(\text{lepton}) &= \Gamma(\text{hadrons})/\Gamma(\text{lepton}), \sigma^0_{\rm hadron} \\ &= 12\pi\Gamma(e^+e^-)\Gamma(\text{hadrons})/M_Z^2\Gamma_Z^2. \end{aligned}$$

With a knowledge of these fitted parameters and their covariance matrix, any other parameter can be derived. The main advantage of these parameters is that they form a physics motivated set of parameters with much reduced correlations.

Thus, the most general fit carried out to cross section and asymmetry data determines the **nine parameters**: M_Z, Γ_Z, $\sigma^0_{\rm hadron}$, $R(e)$, $R(\mu)$, $R(\tau)$, $A_{FB}^{(0,e)}$, $A_{FB}^{(0,\mu)}$, $A_{FB}^{(0,\tau)}$. Assumption of lepton universality leads to a **five-parameter fit** determining M_Z, Γ_Z, $\sigma^0_{\rm hadron}$, $R(\text{lepton})$, $A_{FB}^{(0,\ell)}$.

55.6 Combining results from LEP and SLC experiments

With a steady increase in statistics over the years and improved understanding of the common systematic errors between LEP experiments, the procedures for combining results have evolved continuously [24]. The Line Shape Sub-group of the LEP Electroweak Working Group investigated the effects of these common errors, and devised a combination procedure for the precise determination of the Z parameters from LEP experiments. Using these procedures, this note also gives the results after combining the final parameter sets from the four experiments, and these are the results quoted as the fit results in the Z listings below. Transformation of variables leads to values of derived parameters like partial decay widths and branching ratios to hadrons and leptons. Finally, transforming the LEP combined nine parameter set to (M_Z, Γ_Z, $\sigma^\circ_{\rm hadron}$, g_A^f, g_V^f, $f = e, \mu, \tau$) using the average values of lepton asymmetry parameters (A_e, A_μ, A_τ) as constraints, leads to the best fitted values of the vector and axial-vector couplings (g_V, g_A) of the charged leptons to the Z.

Brief remarks on the handling of common errors and their magnitudes are given below. The identified common errors are those coming from

(a) LEP energy-calibration uncertainties, and

(b) the theoretical uncertainties in (i) the luminosity determination using small angle Bhabha scattering, (ii) estimating the non-s channel contribution to large angle Bhabha scattering, (iii) the calculation of QED radiative effects, and (iv) the parametrization of the cross section in terms of the parameter set used.

55.7 Common LEP energy errors

All the collaborations incorporate in their fit the full LEP energy error matrix as provided by the LEP energy group for their intersection region [18]. The effect of these errors is separated out from that of other errors by carrying out fits with energy errors scaled up and down by $\sim 10\%$ and redoing the fits. From the observed changes in the overall error matrix, the covariance matrix of the common energy errors is determined. Common LEP energy errors lead to uncertainties on M_Z, Γ_Z, and $\sigma^\circ_{\rm hadron}$ of 1.7, 1.2 MeV, and 0.011 nb, respectively.

55.8 Common luminosity errors

BHLUMI 4.04 [25] is used by all LEP collaborations for small-angle Bhabha scattering leading to a common uncertainty in their measured cross sections of 0.061% [26]. BHLUMI does not include a correction for production of light fermion pairs. OPAL explicitly corrects for this effect and reduces their luminosity uncertainty to 0.054%, which is taken fully correlated with the other experiments. The other three experiments among themselves have a common uncertainty of 0.061%.

55.9 Common non-s channel uncertainties

The same standard model programs ALIBABA [16] and TOPAZ0 [17] are used to calculate the non-s channel contribution to the large angle Bhabha scattering [27]. As this contribution is a function of the Z mass, which itself is a variable in the fit, it is parameterized as a function of M_Z by each collaboration to properly track this contribution as M_Z varies in the fit. The common errors on R_e and $A_{FB}^{(0,e)}$ are 0.024 and 0.0014 respectively, and are correlated between them.

55.10 Common theoretical uncertainties: QED

There are large initial-state photon and fermion pair radiation effects near the Z resonance, for which the best currently available evaluations include contributions up to $\mathcal{O}(\alpha^3)$. To estimate the

remaining uncertainties, different schemes are incorporated in the standard model programs ZFITTER [5], TOPAZ0 [17], and MIZA [28]. Comparing the different options leads to error estimates of 0.3 and 0.2 MeV on M_Z and Γ_Z respectively, and of 0.02% on $\sigma^\circ_{\rm hadron}$.

55.11 Common theoretical uncertainties: parametrization of lineshape and asymmetries

To estimate uncertainties arising from ambiguities in the model-independent parametrization of the differential cross-section near the Z resonance, results from TOPAZ0 and ZFITTER were compared by using ZFITTER to fit the cross sections and asymmetries calculated using TOPAZ0. The resulting uncertainties on M_Z, Γ_Z, $\sigma^\circ_{\rm hadron}$, R(lepton), and $A_{FB}^{(0,\ell)}$ are 0.1 MeV, 0.1 MeV, 0.001 nb, 0.004, and 0.0001 respectively.

Thus, the overall theoretical errors on M_Z, Γ_Z, $\sigma^\circ_{\rm hadron}$ are 0.3 MeV, 0.2 MeV, and 0.008 nb respectively; on each R(lepton) is 0.004 and on each $A_{FB}^{(0,\ell)}$ is 0.0001. Within the set of three R(lepton)'s and the set of three $A_{FB}^{(0,\ell)}$'s, the respective errors are fully correlated.

All the theory-related errors mentioned above utilize Standard Model programs which need the Higgs mass and running electromagnetic coupling constant as inputs; uncertainties on these inputs will also lead to common errors. All LEP collaborations used the same set of inputs for Standard Model calculations: $M_Z = 91.187$ GeV, the Fermi constant $G_F = (1.16637 \pm 0.00001) \times 10^{-5}$ GeV^{-2} [29], $\alpha^{(5)}(M_Z) = 1/128.877 \pm 0.090$ [30], $\alpha_s(M_Z) = 0.119$ [31], $M_{\rm top} = 174.3 \pm 5.1$ GeV [31] and $M_{\rm Higgs} = 150$ GeV. The only observable effect, on M_Z, is due to the variation of $M_{\rm Higgs}$ between 100–1000 GeV (due to the variation of the γ/Z interference term which is taken from the Standard Model): M_Z changes by +0.23 MeV per unit change in $\log_{10} M_{\rm Higgs}/{\rm GeV}$, which is not an error but a correction to be applied once $M_{\rm Higgs}$ is determined. The effect is much smaller than the error on M_Z ($\pm$2.1 MeV).

55.12 Methodology of combining the LEP experimental results

The LEP experimental results actually used for combination are slightly modified from those published by the experiments (which are given in the Listings below). This has been done in order to facilitate the procedure by making the inputs more consistent. These modified results are given explicitly in [24]. The main differences compared to the published results are (a) consistent use of ZFITTER 6.23 and TOPAZ0 (the published ALEPH results used ZFITTER 6.10); (b) use of the combined energy-error matrix, which makes a difference of 0.1 MeV on the M_Z and Γ_Z for L3 only as at that intersection the RF modeling uncertainties are the largest.

Thus, nine-parameter sets from all four experiments with their covariance matrices are used together with all the common errors correlations. A grand covariance matrix, V, is constructed and a combined nine-parameter set is obtained by minimizing $\chi^2 = \Delta^T V^{-1} \Delta$, where Δ is the vector of residuals of the combined parameter set to the results of individual experiments. Imposing lepton universality in the combination results in the combined five-parameter set.

55.13 Study of $Z \to b\bar{b}$ and $Z \to c\bar{c}$

In the sector of c- and b-physics, the LEP experiments have measured the ratios of partial widths $R_b = \Gamma(Z \to b\bar{b})/\Gamma(Z \to$ hadrons), and $R_c = \Gamma(Z \to c\bar{c})/\Gamma(Z \to$ hadrons), and the forward-backward (charge) asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. The SLD experiment at SLC has measured the ratios R_c and R_b and, utilizing the polarization of the electron beam, was able to obtain the final state coupling parameters A_b and A_c from a measurement of the left-right forward-backward asymmetry of $b-$ and $c-$quarks. The high precision measurement of R_c at SLD was made possible owing to the small beam size and very stable beam spot at SLC, coupled with a highly precise CCD pixel detector. Several of the analyses have also determined other quantities, in particular the semileptonic branching ratios, B($b \to \ell^-$), B($b \to c \to \ell^+$), and B($c \to \ell^+$), the average time-integrated $B^0\overline{B}^0$ mixing parameter $\overline{\chi}$ and the probabilities for a c–quark to fragment into a D^+, a D_s, a D^{*+} , or a charmed baryon. The latter measurements do not concern properties of the Z boson, and hence they do not appear in the Listing below. However, for completeness, we will report at the end of this minireview their values as obtained fitting the data contained in the Z section. All these quantities are correlated with the electroweak parameters, and since the mixture of b hadrons is different from the one at the $\Upsilon(4S)$, their values might differ from those measured at the $\Upsilon(4S)$.

All the above quantities are correlated to each other since:

- Several analyses (for example the lepton fits) determine more than one parameter simultaneously;
- Some of the electroweak parameters depend explicitly on the values of other parameters (for example R_b depends on R_c);
- Common tagging and analysis techniques produce common systematic uncertainties.

The LEP Electroweak Heavy Flavour Working Group has developed [32] a procedure for combining the measurements taking into account known sources of correlation. The combining procedure determines fourteen parameters: the six parameters of interest in the electroweak sector, R_b, R_c, $A_{FB}^{b\bar{b}}$, $A_{FB}^{c\bar{c}}$, A_b and A_c and, in addition, B($b \to \ell^-$), B($b \to c \to \ell^+$), B($c \to \ell^+$), $\overline{\chi}$, $f(D^+)$, $f(D_s)$, $f(c_{\rm baryon})$ and $P(c \to D^{*+}) \times {\rm B}(D^{*+} \to \pi^+ D^0)$, to take into account their correlations with the electroweak parameters. Before the fit both the peak and off-peak asymmetries are translated to the common energy $\sqrt{s} = 91.26$ GeV using the predicted energy-dependence from ZFITTER [5].

55.14 Summary of the measurements and of the various kinds of analysis

The measurements of R_b and R_c fall into two classes. In the first, named single-tag measurement, a method for selecting b and c events is applied and the number of tagged events is counted. A second technique, named double-tag measurement, has the advantage that the tagging efficiency is directly derived from the data thereby reducing the systematic error on the measurement.

The measurements in the b- and c-sector can be essentially grouped in the following categories:

- Lifetime (and lepton) double-tagging measurements of R_b. These are the most precise measurements of R_b and obviously dominate the combined result. The main sources of systematics come from the charm contamination and from estimating the hemisphere b-tagging efficiency correlation;
- Analyses with $D/D^{*\pm}$ to measure R_c. These measurements make use of several different tagging techniques (inclusive/exclusive double tag, exclusive double tag, reconstruction of all weakly decaying charmed states) and no assumptions are made on the energy-dependence of charm fragmentation;
- A measurement of R_c using single leptons and assuming B($b \to c \to \ell^+$);
- Lepton fits which use hadronic events with one or more leptons in the final state to measure the asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. Each analysis usually gives several other electroweak parameters. The dominant sources of systematics are due to lepton identification, to other semileptonic branching ratios and to the modeling of the semileptonic decay;
- Measurements of $A_{FB}^{b\bar{b}}$ using lifetime tagged events with a hemisphere charge measurement. These measurements dominate the combined result;
- Analyses with $D/D^{*\pm}$ to measure $A_{FB}^{c\bar{c}}$ or simultaneously $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$;
- Measurements of A_b and A_c from SLD, using several tagging methods (lepton, kaon, D/D^*, and vertex mass). These quantities are directly extracted from a measurement of the left–right forward–backward asymmetry in $c\bar{c}$ and $b\bar{b}$ production using a polarized electron beam.

55.15 Averaging procedure

All the measurements are provided by the LEP and SLD Collaborations in the form of tables with a detailed breakdown of

the systematic errors of each measurement and its dependence on other electroweak parameters.

The averaging proceeds via the following steps:

- Define and propagate a consistent set of external inputs such as branching ratios, hadron lifetimes, fragmentation models *etc.* All the measurements are checked to ensure that all use a common set of assumptions (for instance, since the QCD corrections for the forward–backward asymmetries are strongly dependent on the experimental conditions, the data are corrected before combining);
- Form the full (statistical and systematic) covariance matrix of the measurements. The systematic correlations between different analyses are calculated from the detailed error breakdown in the measurement tables. The correlations relating several measurements made by the same analysis are also used;
- Take into account any explicit dependence of a measurement on the other electroweak parameters. As an example of this dependence, we illustrate the case of the double-tag measurement of R_b, where c-quarks constitute the main background. The normalization of the charm contribution is not usually fixed by the data and the measurement of R_b depends on the assumed value of R_c, which can be written as:

$$R_b = R_b^{\rm meas} + a(R_c)\frac{(R_c - R_c^{\rm used})}{R_c} \ , \qquad (55.11)$$

  where $R_b^{\rm meas}$ is the result of the analysis which assumed a value of $R_c = R_c^{\rm used}$ and $a(R_c)$ is the constant which gives the dependence on R_c;
- Perform a χ^2 minimization with respect to the combined electroweak parameters.

After the fit the average peak asymmetries $A_{FB}^{c\bar{c}}$ and $A_{FB}^{b\bar{b}}$ are corrected for the energy shift from 91.26 GeV to M_Z and for QED (initial state radiation), γ exchange, and γZ interference effects, to obtain the corresponding pole asymmetries $A_{FB}^{0,c}$ and $A_{FB}^{0,b}$.

This averaging procedure, using the fourteen parameters described above, and applied to the data contained in the Z particle listing below, gives the following results (where the last 8 parameters do not depend directly on the Z):

$$\begin{aligned}
R_b^0 &= 0.21629 \pm 0.00066 \\
R_c^0 &= 0.1721 \pm 0.0030 \\
A_{FB}^{0,b} &= 0.0992 \pm 0.0016 \\
A_{FB}^{0,c} &= 0.0707 \pm 0.0035 \\
A_b &= 0.923 \pm 0.020 \\
A_c &= 0.670 \pm 0.027 \\
\\
B(b \to \ell^-) &= 0.1071 \pm 0.0022 \\
{\rm B}(b \to c \to \ell^+) &= 0.0801 \pm 0.0018 \\
B(c \to \ell^+) &= 0.0969 \pm 0.0031 \\
\overline{\chi} &= 0.1250 \pm 0.0039 \\
f(D^+) &= 0.235 \pm 0.016 \\
f(D_s) &= 0.126 \pm 0.026 \\
f(c_{\rm baryon}) &= 0.093 \pm 0.022 \\
P(c \to D^{*+}) \times {\rm B}(D^{*+} \to \pi^+ D^0) &= 0.1622 \pm 0.0048 \qquad (55.12)
\end{aligned}$$

Among the non–electroweak observables, the B semileptonic branching fraction $B(b \to \ell^-)$ is of special interest, since the dominant error source on this quantity is the dependence on the semileptonic decay model for $b \to \ell^-$, with $\Delta B(b \to \ell^-)_{b\to\ell^- {\rm model}} = 0.0012$. Extensive studies have been made to understand the size of this error. Among the electroweak quantities, the quark asymmetries with leptons depend also on the semileptonic decay model, while the asymmetries using other methods usually do not. The fit implicitely requires that the different methods give consistent results and this effectively constrains the decay model, and thus reduces in principle the error from this source in the fit result.

To obtain a conservative estimate of the modelling error, the above fit has been repeated removing all asymmetry measurements. The results of the fit on B–decay related observables are [24]: $B(b \to \ell^-) = 0.1069 \pm 0.0022$, with $\Delta B(b \to \ell^-)_{b\to\ell^- {\rm model}} = 0.0013$, $B(b \to c \to \ell^+) = 0.0802 \pm 0.0019$ and $\overline{\chi} = 0.1259 \pm 0.0042$.

56. Muon Anomalous Magnetic Moment

Revised August 2021 by A. Höcker (CERN) and W.J. Marciano (BNL).

The Dirac equation predicts a muon magnetic moment, $\vec{M} = g_\mu \frac{e}{2m_\mu}\vec{S}$, with gyromagnetic ratio $g_\mu = 2$. Quantum loop effects lead to a small calculable deviation from $g_\mu = 2$, parameterized by the magnetic anomaly[1]

$$a_\mu \equiv \frac{g_\mu - 2}{2} \ . \tag{56.1}$$

That quantity can be accurately measured and, within the Standard Model (SM) framework, precisely predicted. Hence, comparison of experiment and theory tests the SM at its quantum loop level. A deviation in $a_\mu^{\rm exp}$ from the SM expectation would signal effects of new physics, with current sensitivity reaching up to mass scales of $\mathcal{O}$(TeV) [1]. For recent thorough muon $g-2$ reviews, see e.g. Refs. [2–4].

The E821 experiment at Brookhaven National Lab (BNL) studied the precession of μ^+ and μ^- in a constant external magnetic field as they circulated in a confining storage ring. It found[2] [6]

$$\begin{aligned} a_{\mu^+}^{\rm exp,BNL} &= 116\,592\,040(60)(50) \times 10^{-11} \ , \\ a_{\mu^-}^{\rm exp,BNL} &= 116\,592\,150(80)(30) \times 10^{-11} \ , \end{aligned} \tag{56.2}$$

where the first errors are statistical and the second systematic. Assuming CPT invariance and taking into account correlations between systematic uncertainties, one finds for their average [5,6]

$$a_\mu^{\rm exp,BNL} = 116\,592\,089(54)(33) \times 10^{-11} \ . \tag{56.3}$$

These results represent about a factor of 14 improvement over the classic CERN experiments of the 1970's [7].

Further improvement of the measurement by a factor of four by setting up the E821 storage ring at the Fermilab National Accelerator Laboratory (FNAL), and utilizing a cleaner and more intense muon beam and improved detectors [8] is in progress. A first analysis with positive muons based on a fraction of the data found [9]

$$a_{\mu^+}^{\rm exp,FNAL} = 116\,592\,040(51)(19) \times 10^{-11} \ . \tag{56.4}$$

The FNAL result is consistent with the BNL measurement and has comparable statistical as well as improved systematic precision. Their average assuming CPT invariance reads [9]

$$a_\mu^{\rm exp} = 116\,592\,061(41) \times 10^{-11} \ , \tag{56.5}$$

providing a relative precision of 0.35 parts per million.

Another muon $g-2$ experiment with similar sensitivity but using an alternative zero-electric-field technique with a low-emittance and low-momentum muon beam is currently under construction at J-PARC in Japan [10].

The SM prediction $a_\mu^{\rm SM}$ is generally divided into three parts (see Fig. 56.1 for representative Feynman diagrams)

$$a_\mu^{\rm SM} = a_\mu^{\rm QED} + a_\mu^{\rm EW} + a_\mu^{\rm Had} \ . \tag{56.6}$$

In the following discussion we use the numerical estimates provided by the Muon $g-2$ Theory Initiative White Paper [4].

The QED part includes all photonic and leptonic (e, μ, τ) loops starting with the classic $\alpha/2\pi$ Schwinger contribution [11]. It has been computed through five loops [4, 12, 13]

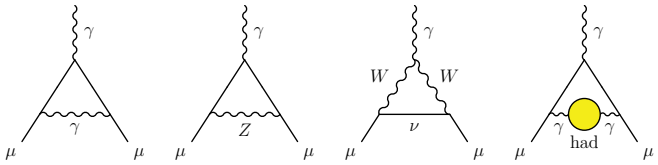

Figure 56.1: Representative diagrams contributing to $a_\mu^{\rm SM}$. From left to right: first order QED (Schwinger term), lowest-order weak, lowest-order hadronic.

$$\begin{aligned} a_\mu^{\rm QED} =& \frac{\alpha}{2\pi} + 0.765\,857\,420(13)\left(\frac{\alpha}{\pi}\right)^2 + 24.050\,509\,85(23)\left(\frac{\alpha}{\pi}\right)^3 \\ &+ 130.8782(60)\left(\frac{\alpha}{\pi}\right)^4 + 751.0(9)\left(\frac{\alpha}{\pi}\right)^5 + \cdots \end{aligned} \tag{56.7}$$

with little change in the coefficients since our last update of this review. Employing $\alpha^{-1} = 137.035\,999\,046(27)$, obtained from the precise measurements of $h/m_{\rm Cs}$ [14], the Rydberg constant, and $m_{\rm Cs}/m_e$ leads to[3] [12]

$$a_\mu^{\rm QED} = 116\,584\,718.93(0.10) \times 10^{-11} \ , \tag{56.8}$$

where the small error results mainly from the uncertainties in the estimate of the six loop contribution and in α.

Loop contributions involving heavy $W^\pm, Z$ or Higgs particles are collectively labeled as $a_\mu^{\rm EW}$. They are suppressed by at least a factor of $(\alpha/\pi)\cdot(m_\mu^2/m_W^2) \simeq 4 \times 10^{-9}$. At 1-loop order [18]

$$\begin{aligned} &a_\mu^{\rm EW}[\text{1-loop}] = \\ &\frac{G_\mu m_\mu^2}{8\sqrt{2}\pi^2}\left[\frac{5}{3} + \frac{1}{3}\left(1 - 4\sin^2\theta_{\rm W}\right)^2 + \mathcal{O}\left(\frac{m_\mu^2}{M_W^2}\right) + \mathcal{O}\left(\frac{m_\mu^2}{m_H^2}\right)\right] \\ &= 194.8 \times 10^{-11} \ , \end{aligned} \tag{56.9}$$

for $\sin^2\theta_{\rm W} \equiv 1 - M_W^2/M_Z^2 \simeq 0.223$, and where $G_\mu \simeq 1.166 \times 10^{-5}$ GeV^{-2} is the Fermi coupling constant. Two-loop corrections are relatively large and negative [19]. For a Higgs boson mass of 125 GeV it amounts to $a_\mu^{\rm EW}[\text{2-loop}] = -41.2(1.0) \times 10^{-11}$ [19], where the uncertainty stems from quark triangle loops. The 3-loop leading logarithms are negligible, $\mathcal{O}(10^{-12})$ [19, 20]. Overall one finds

$$a_\mu^{\rm EW} = 153.6(1.0) \times 10^{-11} \ . \tag{56.10}$$

A recent complete 2-loop numerical evaluation of the electroweak correction [21] when adjusted for appropriate light quark masses confirmed the result in Eq. (56.10).

Hadronic (quark and gluon) loop contributions to $a_\mu^{\rm SM}$ give rise to its main uncertainty. One traditionally relies on a data-driven dispersion relation approach to evaluate the lowest-order $\mathcal{O}(\alpha^2)$ hadronic vacuum polarization contribution $a_\mu^{\rm Had}$[LO] from corresponding cross section measurements [22]

$$a_\mu^{\rm Had}[\text{LO}] = \frac{1}{3}\left(\frac{\alpha}{\pi}\right)^2 \int_{m_\pi^2}^{\infty} ds\, \frac{K(s)}{s} R^{(0)}(s) \, , \tag{56.11}$$

[1] Also referred to as *anomalous magnetic moment* despite being dimensionless.

[2] The results reported by the experiment have been updated in Eqs. (56.2) and (56.3) to the newest value for the absolute muon-to-proton magnetic ratio $\lambda = 3.183\,345\,142(71)$ [5]. The change induced in $a_\mu^{\rm exp}$ with respect to the value of $\lambda = 3.183\,345\,39(10)$ used in Ref. [6] amounts to $+10 \times 10^{-11}$.

[3] A recent measurement using Rb-87 atoms [15] resulted in $\alpha^{-1} = 137.035\,999\,206(11)$, which exhibits a larger than 5σ discrepancy with the Cs-133 based result. Using this value in Eq. (56.7) leads to a reduction of $a_\mu^{\rm QED}$ by 0.14×10^{-11}, which is larger than the quoted uncertainty in Eq. (56.8), but still negligible compared to other uncertainties affecting $a_\mu^{\rm SM}$. This discrepancy impacts, however, the SM prediction of the magnetic anomaly of the electron [13, 16], which differs by respectively -2.4σ and $+1.6\sigma$ from the experimental value [17], depending on whether the Cs-133 or Rb-87 based α value is used.

where $K(s)$ is a QED kernel function [23], and where $R^{(0)}(s)$ denotes the ratio of the bare[4] cross section for e^+e^- annihilation into hadrons to the pointlike muon-pair cross section at center-of-mass energy $\sqrt{s}$. The function $K(s) \sim 1/s$ in Eq. (56.11) emphasizes the low-energy part of the integral so that $a_\mu^{\rm Had}$[LO] is dominated by the $\rho(770) \to \pi^+\pi^-$ resonance.

The analysis of Eq. (56.11) results in the representative value [4, 24–29]

$$a_\mu^{\rm Had}[\rm LO] = 6\,931(40) \times 10^{-11}\,, \qquad (56.12)$$

whose error is dominated by systematic uncertainties in the $e^+e^- \to$ hadrons cross-section data, and also includes a small uncertainty due to perturbative QCD, which is used at intermediate and large energies in the dispersion integral to predict the contribution from the quark-antiquark continuum. The experimental precision is currently limited by a discrepancy between the most precise $\pi^+\pi^-$ data from the BABAR and KLOE experiments [26, 28].

Alternatively, one can use precise vector spectral functions from $\tau \to \nu_\tau +$ hadrons decays [30] that can be related to isovector $e^+e^- \to$ hadrons cross sections by isospin symmetry. Analyses replaced e^+e^- data in the two-pion and four-pion channels by the corresponding isospin- transformed τ data, and applied isospin-violating corrections [31]. Owing to the progress in the precision of the e^+e^- data, the τ data are now less precise and less reliable due to additional theoretical uncertainties, so that recent $a_\mu^{\rm Had}$[LO] evaluations ignored them.

Progress has been achieved on the evaluation of $a_\mu^{\rm Had}$[LO] using lattice QCD, which allows to directly compute the real part of the two-point correlation function without invoking the resonances occurring on the imaginary axis [32–34]. The required sub-percent precision represents a challenge requiring to master systematic and extrapolation uncertainties. A combination of recent lattice QCD evaluations [35, 36] gives [4]

$$a_\mu^{\rm Had}[\rm LO] = 7\,116(184) \times 10^{-11}\,, \qquad (56.13)$$

with an uncertainty that is not yet competitive with the data-driven approach. Another recent lattice QCD calculation with much reduced uncertainty found [37]

$$a_\mu^{\rm Had}[\rm LO] = 7\,075(55) \times 10^{-11}\,, \qquad (56.14)$$

whose error is dominated by systematic uncertainties. It exhibits a 2.1σ tension with the data-driven result, growing up to 3.7σ for the modified observable $a_{\mu,\rm win}$ that has favourable properties for computation on the lattice[5] [36, 37, 39]. Because of the complexity and challenges of such a calculation, it is critical that it is confronted with independent lattice results of comparable precision [36, 39, 40].

Higher order hadronic loop contributions are also obtained from dispersion relations using the same $e^+e^- \to$ hadrons data but with different integration kernels [41]. Recent evaluations found $a_\mu^{\rm Had,Disp}[\rm NLO] = (-98.3 \pm 0.7) \times 10^{-11}$ [4, 29] and $a_\mu^{\rm Had,Disp}[\rm NNLO] = (12.4 \pm 0.1) \times 10^{-11}$ [42]. In the case of hadronic light-by-light scattering contributions, which enter at NLO, recent studies [3, 4, 43, 44] based on short-distance QCD, dispersion relations and lattice QCD calculations lead to the improved prediction $a_\mu^{\rm Had,LBL}[\rm NLO] = 92(18) \times 10^{-11}$ [4].[6] One thus finds for the sum of the three higher order hadronic terms

$$a_\mu^{\rm Had}[\rm N(N)LO] = 6(18) \times 10^{-11}\,, \qquad (56.15)$$

where the error is dominated by the hadronic light-by-light scattering uncertainty.

Adding Eqs. (56.8), (56.10), (56.12) and (56.15) gives the representative SM prediction

$$a_\mu^{\rm SM} = 116\,591\,810(1)(40)(18) \times 10^{-11}\,, \qquad (56.16)$$

whose errors are due to the electroweak, lowest-order hadronic, and higher-order hadronic contributions, respectively. The difference between experiment and theory

$$\Delta a_\mu = a_\mu^{\rm exp} - a_\mu^{\rm SM} = 251(41)(43) \times 10^{-11}\,, \qquad (56.17)$$

where the errors are from experiment and theory prediction (with all errors combined in quadrature, taking into account a small anticorrelation [4] between the data-driven lowest and higher order contributions), represents an interesting but not yet conclusive discrepancy of 4.2σ.[7] The new FNAL measurement has increased the discrepancy with the SM prediction (56.16) from previously 3.7σ. Figure 56.2 represents the difference between experimental and predicted a_μ values based on the most recent data-driven and lattice QCD based evaluations of $a_\mu^{\rm Had}$[LO].

A leading candidate explanation for the deviation observed in Δa_μ has been supersymmetry particle loop contributions. Such a scenario is quite natural, since generically, supersymmetric models predict [1] an additional contribution to $a_\mu^{\rm SM}$

$$a_\mu^{\rm SUSY} \simeq \pm 130 \times 10^{-11} \cdot \left(\frac{100\ {\rm GeV}}{m_{\rm SUSY}}\right)^2 \tan\beta\,, \qquad (56.18)$$

where $m_{\rm SUSY}$ is a representative supersymmetric mass scale, $\tan\beta \simeq$ 3–40 a potential enhancement factor, and ± 1 corresponds to the sign of the μ term in the supersymmetric Lagrangian. Supersymmetric particles in the mass range 100–500 GeV could be

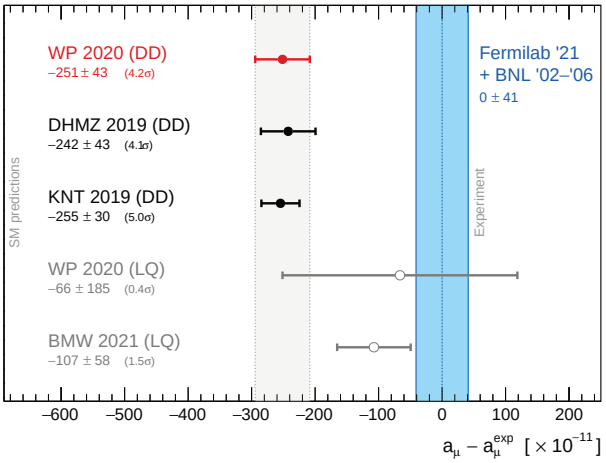

Figure 56.2: Compilation of recent results for a_μ (in units of 10^{-11}), subtracted by the central value of the experimental average (56.3). The light blue vertical band indicates the total experimental uncertainty. The SM predictions shown differ only in the value used for the $a_\mu^{\rm Had}$[LO] contribution. They are taken from: WP 2020 [4] (Eq. (56.16), also indicated by the light grey vertical band), DHMZ 2019 [28], KNT 2019 [29], all three based on the data-driven (DD) $a_\mu^{\rm Had}$[LO] evaluation, and the lattice QCD (LQ) based evaluations WP 2020 [4, 35, 36] and BMW 2021 [37]. Note that the quoted errors in the figure do not include the uncertainty on the subtracted experimental value. To obtain for each theory calculation a result equivalent to Eq. (56.17), the errors from theory and experiment must be added in quadrature.

[4] The bare cross section is defined as the measured cross section corrected for initial-state radiation, electron-vertex loop contributions and vacuum-polarization effects in the photon propagator. However, QED effects in the hadron vertex and final state, as photon radiation, are included.

[5] A dispersive approach similar to that for $a_\mu^{\rm Had}$[LO] is used to determine the hadronic contribution to the running of the electromagnetic fine structure constant at the Z-boson mass $\Delta\alpha_{\rm had}(m_Z)$, which is a critical ingredient of the global electroweak fit. One may therfore ask if the goodness of that fit would break down were $a_\mu^{\rm Had}$[LO] in Eq. (56.12) be brought in compatibility with the result (56.14). However, the difference in the relevant integration kernels (whereas 73% of the contribution to $a_\mu^{\rm Had}$[LO] stems from the $\pi^+\pi^-$ channel, it is only 13% in the case of $\Delta\alpha_{\rm had}(m_Z)$) allows to absorb large effects in $a_\mu^{\rm Had}$[LO] without creating a significant tension in the electroweak fit. Detailed discussions are available in the literature [38].

[6] A very recent lattice QCD based calculation of $a_\mu^{\rm Had,LBL}$[NLO] [45], not included in [4], gives a consistent result with [4, 44] using a different approach.

[7] The probabilistic interpretation of the discrepancy requires caution due to the systematic nature of the $a_\mu^{\rm SM}$ uncertainty.

the source of the deviation Δa_μ. If so, those particles should be directly observable at the Large Hadron Collider at CERN. So far, there is however no direct evidence in support of the supersymmetry interpretation.

New physics effects [1] other than supersymmetry could also explain a non-vanishing Δa_μ. A popular scenario involves the "dark photon", a relatively light hypothetical vector boson from the dark matter sector that couples to our world of particle physics through mixing with the ordinary photon [46–48]. As a result, it couples to ordinary charged particles with strength $\varepsilon \cdot e$ and gives rise to an additional muon magnetic anomaly contribution

$$a_\mu^{\text{dark photon}} = \frac{\alpha}{2\pi}\varepsilon^2 F(m_V/m_\mu)\,, \qquad (56.19)$$

where $F(x) = \int_0^1 2z(1-z)^2/[(1-z)^2 + x^2 z]\,dz$. For values of $\varepsilon \sim 1\text{–}2 \times 10^{-3}$ and $m_V \sim 10\text{–}100\,\text{MeV}$, the dark photon, which was originally motivated by cosmology, can provide a viable solution to the muon $g-2$ discrepancy. However, experimental constraints appear to rule out the simplest model in which the dark photon has equal couplings to electrons and muons and decays primarily to e^+e^- pairs [49] or invisible dark particles [50] that give rise to missing event energy. One can expand the dark photon scenario into a more complete theory in which several new particles contribute to the muon $g-2$. Direct searches for a dark photon, therefore, continue to be well motivated, but with primary guidance coming from astrophysics [51].

Recent popular solutions to the muon anomaly discrepancy have also focused on loop contributions induced by relatively light scalar or pseudo scalar particle appendages from physics beyond the SM [52, 53].

57. Muon Decay Parameters

Revised August 2021 by W. Fetscher (ETH Zurich) and H.-J. Gerber (ETH Zurich).

57.1 Introduction:

All measurements in direct muon decay, $\mu^- \to e^- + 2$ neutrals, and its inverse, $\nu_\mu + e^- \to \mu^-$ + neutral, are successfully described by the "V-A interaction," which is a particular case of a local, derivative-free, lepton-number-conserving, four-fermion interaction [1]. As shown below, within this framework, the Standard Model assumptions, such as the V-A form and the nature of the neutrals (ν_μ and $\bar{\nu}_e$), and hence the doublet assignments $(\nu_e\, e^-)_L$ and $(\nu_\mu\, \mu^-)_L$, have been determined from experiments [2,3]. All considerations on muon decay are valid for the leptonic tau decays $\tau^- \to \ell^- + \nu_\tau + \bar{\nu}_\ell$ with the replacements $m_\mu \to m_\tau$, $m_e \to m_{ell}$, $\ell^- = e^-, \mu^-$.

57.2 Parameters:

The differential decay probability to obtain an $e^\pm$ with (reduced) energy between x and $x + \mathrm{d}x$, emitted in the direction $\widehat{\boldsymbol{x}}_3$ at an angle between ϑ and $\vartheta + \mathrm{d}\vartheta$ with respect to the muon polarization vector $\boldsymbol{P}_\mu$, and with its spin parallel to the arbitrary direction $\widehat{\boldsymbol{\zeta}}$, neglecting radiative corrections, is given by

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} = \frac{m_\mu}{4\pi^3}\, W_{e\mu}^4\, G_\mathrm{F}^2\, \sqrt{x^2 - x^{2}_{0}} \times \left(F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta F_\mathrm{AS}(x)\right) \times \left[1 + \widehat{\boldsymbol{\zeta}} \cdot \boldsymbol{P}_e(x,\vartheta)\right] \,. \tag{57.1}$$

Here, $W_{e\mu} = \max(E_e) = (m_\mu^2 + m_e^2)/2m_\mu$ is the maximum $e^\pm$ energy, $x = E_e/W_{e\mu}$ is the reduced energy, $x_0 = m_e/W_{e\mu} = 9.67 \times 10^{-3}$, and $P_\mu = |\boldsymbol{P}_\mu|$ is the degree of muon polarization. $\widehat{\boldsymbol{\zeta}}$ is the direction in which a perfect polarization-sensitive electron detector is most sensitive. The isotropic part of the spectrum, $F_\mathrm{IS}(x)$, the anisotropic part $F_\mathrm{AS}(x)$, and the electron polarization, $\boldsymbol{P}_e(x,\vartheta)$, may be parametrized by the Michel parameter ρ [1], by η [4], by ξ and δ [5,6], *etc.* These are bilinear combinations of the coupling constants $g^\gamma_{\varepsilon\mu}$, which occur in the matrix element (given below).

If the masses of the neutrinos as well as x_0^2 are neglected, the energy and angular distribution of the electron in the rest frame of a muon ($\mu^\pm$) measured by a polarization insensitive detector, is given by

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} \sim x^2 \cdot \left\{3(1-x) + \frac{2\rho}{3}(4x-3) + 3\eta\, x_0(1-x)/x \pm P_\mu \cdot \xi \cdot \cos\vartheta \left[1 - x + \frac{2\delta}{3}(4x-3)\right]\right\} \,. \tag{57.2}$$

Here, ϑ is the angle between the electron momentum and the muon spin, and $x \equiv 2E_e/m_\mu$. For the Standard Model coupling, we obtain $\rho = \xi\delta = 3/4$, $\xi = 1$, $\eta = 0$ and the differential decay rate is

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} = \frac{G_\mathrm{F}^2 m_\mu^5}{192\pi^3}\, [3 - 2x \pm P_\mu \cos\vartheta(2x-1)] \cdot x^2 \,. \tag{57.3}$$

The coefficient in front of the square bracket is the total decay rate.

If only the neutrino masses are neglected, and if the $e^\pm$ polarization is detected, then the functions in Eq. (57.1) become

$$F_\mathrm{IS}(x) = x\,(1-x) + \tfrac{2}{9}\,\rho\,(4x^2 - 3x - x_0^2) + \eta \cdot x_0\,(1-x) \tag{57.4a}$$

$$F_\mathrm{AS}(x) = \tfrac{1}{3}\,\xi\,\sqrt{x^2 - x_0^2} \times \left[(1-x) + \tfrac{2}{3}\delta\left\{(4x-3) + \left(\sqrt{1-x_0^2} - 1\right)\right\}\right] \tag{57.4b}$$

$$\boldsymbol{P}_e(x,\vartheta) = P_{\mathrm{T}_1} \cdot \widehat{\boldsymbol{x}}_1 + P_{\mathrm{T}_2} \cdot \widehat{\boldsymbol{x}}_2 + P_\mathrm{L} \cdot \widehat{\boldsymbol{x}}_3 \tag{57.4c}$$

Here $\widehat{\boldsymbol{x}}_1$, $\widehat{\boldsymbol{x}}_2$, and $\widehat{\boldsymbol{x}}_3$ are orthogonal unit vectors defined as follows:

$\widehat{\boldsymbol{x}}_3$	is along the e momentum $\boldsymbol{p}_e$
$\dfrac{\widehat{\boldsymbol{x}}_3 \times \boldsymbol{P}_\mu}{\lvert\widehat{\boldsymbol{x}}_3 \times \boldsymbol{P}_\mu\rvert} = \widehat{\boldsymbol{x}}_2$	is transverse to $\boldsymbol{p}_e$ and perpendicular to "the decay plane"
$\widehat{\boldsymbol{x}}_2 \times \widehat{\boldsymbol{x}}_3 = \widehat{\boldsymbol{x}}_1$	is transverse to $\boldsymbol{p}_e$ and in the decay plane

The components of $\boldsymbol{P}_e$ then are given by

$$P_{\mathrm{T}_1}(x,\vartheta) = P_\mu \sin\vartheta \cdot F_{\mathrm{T}_1}(x) / \left\{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)\right\} \tag{57.5a}$$

$$P_{\mathrm{T}_2}(x,\vartheta) = P_\mu \sin\vartheta \cdot F_{\mathrm{T}_2}(x) / \left\{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)\right\} \tag{57.5b}$$

$$P_\mathrm{L}(x,\vartheta) = \frac{\pm F_\mathrm{IP}(x) + P_\mu \cos\vartheta \cdot F_\mathrm{AP}(x)}{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)} \quad , \tag{57.5c}$$

where

$$F_{\mathrm{T}_1}(x) = \tfrac{1}{12}\left\{-2\left[\xi'' + 12\left(\rho - \tfrac{3}{4}\right)\right](1-x)x_0 - 3\,\eta\left(x^2 - x_0^2\right) + \eta''\left(-3x^2 + 4x - x_0^2\right)\right\} \tag{57.6a}$$

$$F_{\mathrm{T}_2}(x) = \tfrac{1}{3}\,\sqrt{x^2 - x_0^2} \cdot \left\{3\,\frac{\alpha'}{A}(1-x) + 2\,\frac{\beta'}{A}\sqrt{1-x_0^2}\right\} \tag{57.6b}$$

$$F_\mathrm{IP}(x) = \tfrac{1}{54}\sqrt{x^2 - x_0^2} \cdot \left\{9\,\xi'\left(-2x + 2 + \sqrt{1-x_0^2}\right) + 4\,\xi\left(\delta - \tfrac{3}{4}\right)\left(4x - 4 + \sqrt{1-x_0^2}\right)\right\} \tag{57.6c}$$

$$F_\mathrm{AP}(x) = \tfrac{1}{6}\left\{\xi''\left(2x^2 - x - x_0^2\right) + 4\left(\rho - \tfrac{3}{4}\right)\left(4x^2 - 3x - x_0^2\right) + 2\,\eta''(1-x)\,x_0\right\}. \tag{57.6d}$$

For the experimental values of the parameters ρ, ξ, ξ', ξ'', δ, η, η'', α/A, β/A, α'/A, β'/A, which are not all independent, see the Data Listings below. Experiments in the past have also been analyzed using the parameters a, b, c, a', b', c', α/A, β/A, α'/A, β'/A (and $\eta = (\alpha - 2\beta)/2A$), as defined by Kinoshita and Sirlin [5,6]. They serve as a model-independent summary of all possible measurements on the decay electron (see Listings below). The relations between the two sets of parameters are

$$\rho - \tfrac{3}{4} = \tfrac{3}{4}\,(-a + 2\,c)/A \tag{57.7a}$$

$$\eta = (\alpha - 2\beta)/A \tag{57.7b}$$

$$\eta'' = (3\,\alpha + 2\,\beta)/A \tag{57.7c}$$

$$\delta - \tfrac{3}{4} = \tfrac{9}{4} \cdot \frac{(a' - 2\,c')\,/A}{1 - [a + 3\,a' + 4\,(b + b') + 6\,c - 14\,c']\,/A} \tag{57.7d}$$

$$1 - \xi\,\frac{\delta}{\rho} = 4\,\frac{[(b + b') + 2\,(c - c')]\,/A}{1 - (a - 2\,c)/A} \tag{57.7e}$$

$$1 - \xi = \left[\left(a + a'\right) + 4\left(b + b'\right) + 6\left(c + c'\right)\right]/A \tag{57.7f}$$

$$1 - \xi'' = (-2\,a + 20\,c)/A \tag{57.7g}$$

$$\text{with} \qquad A = a + 4\,b + 6\,c \tag{57.7h}$$

The differential decay probability to obtain a *left-handed* ν_e with (reduced) energy between y and $y + dy$, neglecting radiative corrections as well as the masses of the electron and of the neutrinos, is given by [7]

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}y} = \frac{m_\mu^5 G_\mathrm{F}^2}{16\,\pi^3} \cdot Q_L^{\nu_e} \cdot y^2 \left\{(1-y) - \omega_L \cdot \left(y - \tfrac{3}{4}\right)\right\} \,. \tag{57.8}$$

Here, $y = 2\ E_{\nu_e}/m_\mu$. $Q_L^{\nu_e}$ and ω_L are parameters. ω_L is the neutrino analog of the spectral shape parameter ρ of Michel. Since in the Standard Model, $Q_L^{\nu_e} = 1$, $\omega_L = 0$, the measurement of $\mathrm{d}\Gamma/\mathrm{d}y$ has allowed a null-test of the Standard Model (see Listings below).

Table 57.1: Coupling constants $g^\gamma_{\varepsilon\mu}$ and some combinations of them. Ninety-percent confidence level experimental limits. The limits on $|g^S_{LL}|$ and $|g^V_{LL}|$ are from [8–10], and the others from a general analysis of muon decay measurements. Top three rows: [11], fourth row: [12], next three rows: [13], last row: [14]. The experimental uncertainty on the muon polarization in pion decay is included. Note that, by definition, $|g^S_{\varepsilon\mu}| \leq 2$, $|g^V_{\varepsilon\mu}| \leq 1$ and $|g^T_{\varepsilon\mu}| \leq 1/\sqrt{3}$.

$\lvert g^S_{RR}\rvert < 0.035$	$\lvert g^V_{RR}\rvert < 0.017$	$\lvert g^T_{RR}\rvert \equiv 0$
$\lvert g^S_{LR}\rvert < 0.050$	$\lvert g^V_{LR}\rvert < 0.023$	$\lvert g^T_{LR}\rvert < 0.015$
$\lvert g^S_{RL}\rvert < 0.420$	$\lvert g^V_{RL}\rvert < 0.105$	$\lvert g^T_{RL}\rvert < 0.105$
$\lvert g^S_{LL}\rvert < 0.550$	$\lvert g^V_{LL}\rvert > 0.960$	$\lvert g^T_{LL}\rvert \equiv 0$
$\lvert g^S_{LR} + 6\,g^T_{LR}\rvert < 0.143$	$\lvert g^S_{RL} + 6\,g^T_{RL}\rvert < 0.418$	
$\lvert g^S_{LR} + 2\,g^T_{LR}\rvert < 0.108$	$\lvert g^S_{RL} + 2\,g^T_{RL}\rvert < 0.417$	
$\lvert g^S_{LR} - 2\,g^T_{LR}\rvert < 0.070$	$\lvert g^S_{RL} - 2\,g^T_{RL}\rvert < 0.418$	
$Q_{RR} + Q_{LR} < 8.2{\times}10^{-4}$		

57.3 Matrix element:

All results in direct muon decay (energy spectra of the electron and of the neutrinos, polarizations, and angular distributions), and in inverse muon decay (the reaction cross section) at energies well below $m_W c^2$, may be parametrized in terms of amplitudes $g^\gamma_{\varepsilon\mu}$ and the Fermi coupling constant G_F, using the matrix element

$$\frac{4G_\mathrm{F}}{\sqrt{2}} \sum_{\substack{\gamma=S,V,T\\ \varepsilon,\mu=R,L}} g^\gamma_{\varepsilon\mu}\, \langle \bar{e}_\varepsilon | \Gamma^\gamma | (\nu_e)_n \rangle\, \langle (\bar{\nu}_\mu)_m | \Gamma_\gamma | \mu_\mu \rangle \tag{57.9}$$

We use the notation of Fetscher *et al.* [2], who in turn use the sign conventions and definitions of Scheck [15]. Here, $\gamma = S, V, T$ indicates a scalar, vector, or tensor interaction; and $\varepsilon, \mu = R, L$ indicate a right- or left-handed chirality of the electron or muon. The chiralities n and m of the ν_e and $\bar{\nu}_\mu$ are then determined by the values of γ, ε, and μ. The particles are represented by fields of definite chirality [16].

As shown by Langacker and London [17], explicit lepton-number nonconservation still leads to a matrix element equivalent to Eq. (57.9). They conclude that it is not possible, even in principle, to test lepton-number conservation in (leptonic) muon decay if the final neutrinos are massless and are not observed.

The ten complex amplitudes $g^\gamma_{\varepsilon\mu}$ (g^T_{RR} and g^T_{LL} are identically zero) and G_F constitute 19 independent (real) parameters to be determined by experiment. The Standard Model interaction corresponds to one single amplitude g^V_{LL} being unity and all the others being zero.

The (direct) muon decay experiments are compatible with an arbitrary mix of the scalar and vector amplitudes g^S_{LL} and g^V_{LL} – in the extreme even with purely scalar $g^S_{LL} = 2$, $g^V_{LL} = 0$. The decision in favour of the Standard Model comes from the quantitative observation of inverse muon decay, which would be forbidden for pure g^S_{LL} [2].

57.4 Experimental determination of $V{-}A$:

In order to determine the amplitudes $g^\gamma_{\varepsilon\mu}$ uniquely from experiment, the following set of equations, where the left-hand sides represent experimental results, has to be solved.

$$a = 16\left(|g^V_{RL}|^2 + |g^V_{LR}|^2\right) + \left|g^S_{RL} + 6\,g^T_{RL}\right|^2 + \left|g^S_{LR} + 6\,g^T_{LR}\right|^2 \tag{57.10a}$$

$$a' = 16\left(|g^V_{RL}|^2 - |g^V_{LR}|^2\right) + \left|g^S_{RL} + 6\,g^T_{RL}\right|^2 - \left|g^S_{LR} + 6\,g^T_{LR}\right|^2 \tag{57.10b}$$

$$\alpha = 8\,\mathrm{Re}\left\{g^V_{RL}\left(g^{S*}_{LR} + 6\,g^{T*}_{LR}\right) + g^V_{LR}\left(g^{S*}_{RL} + 6\,g^{T*}_{RL}\right)\right\} \tag{57.10c}$$

$$\alpha' = 8\,\mathrm{Im}\left\{-g^V_{RL}\left(g^{S*}_{LR} + 6\,g^{T*}_{LR}\right) + g^V_{LR}\left(g^{S*}_{RL} + 6\,g^{T*}_{RL}\right)\right\} \tag{57.10d}$$

$$b = 4\left(|g^V_{RR}|^2 + |g^V_{LL}|^2\right) + |g^S_{RR}|^2 + |g^S_{LL}|^2 \tag{57.10e}$$

$$b' = 4\left(|g^V_{RR}|^2 - |g^V_{LL}|^2\right) + |g^S_{RR}|^2 - |g^S_{LL}|^2 \tag{57.10f}$$

$$c = \tfrac{1}{2}\left\{|g^S_{RL} - 2\,g^T_{RL}|^2 + |g^S_{LR} - 2\,g^T_{LR}|^2\right\} \tag{57.10g}$$

$$c' = \tfrac{1}{2}\left\{|g^S_{RL} - 2\,g^T_{RL}|^2 - |g^S_{LR} - 2\,g^T_{LR}|^2\right\} \tag{57.10h}$$

and

$$Q_L^{\nu_e} = 1 - \left\{\tfrac{1}{4}|g^S_{LR}|^2 + \tfrac{1}{4}|g^S_{LL}|^2 + |g^V_{RR}|^2 + |g^V_{RL}|^2 + 3\,|g^T_{LR}|^2\right\}$$

$$\omega_L = \tfrac{3}{4}\,\frac{|g^S_{RR}|^2 + 4\,|g^V_{LR}|^2 + |g^S_{RL} + 2\,g^T_{LR}|^2}{|g^S_{RL}|^2 + |g^S_{RR}|^2 + 4\,|g^V_{LL}|^2 + 4\,|g^V_{LR}|^2 + 12\,|g^T_{RL}|^2}\,. \tag{57.10i}$$

It has been noted earlier by C. Jarlskog [18], that certain experiments observing the decay electron are especially informative if they yield the V-A values. The complete solution is now found as follows. Fetscher *et al.* [2] introduced four probabilities $Q_{\varepsilon\mu}(\varepsilon, \mu = R, L)$ for the decay of a μ-handed muon into an ε-handed electron, and showed that there exist upper bounds on Q_{RR}, Q_{LR}, and Q_{RL}, and a lower bound on Q_{LL}. These probabilities are given in terms of the $g^\gamma_{\varepsilon\mu}$'s by

$$Q_{\varepsilon\mu} = \tfrac{1}{4}|g^S_{\varepsilon\mu}|^2 + |g^V_{\varepsilon\mu}|^2 + 3\,(1 - \delta_{\varepsilon\mu})|g^T_{\varepsilon\mu}|^2 \tag{57.11}$$

where $\delta_{\varepsilon\mu} = 1$ for $\varepsilon = \mu$, and $\delta_{\varepsilon\mu} = 0$ for $\varepsilon \neq \mu$. They are related to the parameters $a,\ b,\ c,\ a', b'$, and c' by

$$Q_{RR} = 2\,(b + b')/A \tag{57.12a}$$

$$Q_{LR} = \left[(a - a') + 6\,(c - c')\right]/2A \tag{57.12b}$$

$$Q_{RL} = \left[(a + a') + 6\,(c + c')\right]/2A \tag{57.12c}$$

$$Q_{LL} = 2\,(b - b')/A \tag{57.12d}$$

with $A = 16$. In the Standard Model, $Q_{LL} = 1$ and the others are zero.

Since the upper bounds on Q_{RR}, Q_{LR}, and Q_{RL} are found to be small, and since the helicity of the ν_μ in pion decay is known from experiment [19, 20] to very high precision to be -1 [21], the cross section S of *inverse* muon decay, normalized to the V-A value, yields [2]

$$|g^S_{LL}|^2 \leq 4(1 - S) \tag{57.13a}$$

and

$$|g^V_{LL}|^2 = S\,. \tag{57.13b}$$

Thus the Standard Model assumption of a pure V-A leptonic charged weak interaction of e and μ is derived (within errors) from experiments at energies far below the mass of the $W^\pm$: Eq. (57.13 b) gives a lower limit for V-A, and Eqs. (57.12 a, b, c)

and (57.13 a) give upper limits for the other four-fermion interactions. The existence of such upper limits may also be seen from $Q_{RR}+Q_{RL}=(1-\xi')/2$ (e^+ longitudinal polarization) and $Q_{RR}+Q_{LR}=\frac{1}{2}(1+\xi/3-16\,\xi\delta/9)$ (decay asymmetry). Table 57.1 gives the current experimental limits on the magnitudes of the $g^{\gamma}_{\varepsilon\mu}$'s. More stringent limits on the six coupling constants g^S_{LR}, g^V_{LR}, g^T_{LR}, g^S_{RL}, g^V_{RL}, and g^T_{RL} have been derived from upper limits on the neutrino mass [22]. Limits on the "charge retention" coordinates, as used in the older literature (*e.g.*, Ref. [23]), are given by Burkard *et al.* [24].

58. τ Branching Fractions

Revised February 2022 by Sw. Banerjee (Louisville U.) and A. Lusiani (SNS, Pisa; INFN, Pisa).

58.1 τ Branching Fractions

The τ Listings contains 244 entries that correspond to either a τ partial decay fraction into a specific decay mode (branching fraction) or a ratio of two τ partial decay fractions (branching ratio). Experimental information provides values for 147 of these quantities, upper limits for 61 branching fractions to Lepton Family number, Lepton number, or Baryon number violating modes, and 36 additional upper limits for other modes. A total of 170 measurements of τ branching fraction and branching ratio measurements is used for a global fit that determines 129 quantities.

58.2 The constrained fit to τ branching fractions

The τ branching fractions fit uses the reported values, uncertanties and statistical correlations of the τ branching fractions and branching ratios measurements. Asymmetric uncertainties are symmetrized as $\sigma^2_{\rm symm} = (\sigma^2_+ + \sigma^2_-)/2$. Additionally, the most precise experimental inputs are treated according to how they depend on external parameters on the basis of their documentation [1]. The τ measurements may depend on parameters such as the τ pair production cross-section in e^+e^- annihilations at the $\Upsilon(4S)$ peak. In some cases, measurements reported in different papers by the same collaboration may depend on common parameters like the estimate of the integrated luminosity or of particle identification efficiencies. For all the significant detected dependencies, the τ measurements and their uncertainties are updated to account for the updated values of the external parameters. The dependencies on common systematic effects are also determined in size and sign, and all the common systematic dependencies of different measurements are used together with the published statistical and systematic uncertainties and correlations in order to compute a single all-inclusive variance and covariance matrix of the experimental inputs of the fit.

The fit procedure parameters correspond to τ quantities that are fit to the experimental measurements while respecting relations described by a series of constraint equations. All the experimental inputs and all the constraint equations are reported in the τ Listings section that follows this review. With respect to the 2016, 2017 and 2018 editions, the fit uses one more experimental measurement, published by the BaBar collaboration in 2018, on $\mathcal{B}(\tau \to K^-K^0\nu_\tau)$ [2]. If only a few measurements are correlated, the correlation coefficients are listed in the footnote for each measurement (see for example $\Gamma(\text{particle}^- \geq 0\,\text{neutrals} \geq 0\,K^0\nu_\tau$ ("1-prong"))$/\Gamma_{\rm total}$). If a large number of measurements are correlated, then the full correlation matrix is listed in the footnote to the measurement that first appears in the τ Listings. Footnotes to the other measurements refer to the first one. For example, the large correlation matrices for the branching fraction or ratio measurements contained in Refs. [3] [4] are listed in Footnotes to the $\Gamma(e^-\overline{\nu}_e\nu_\tau)/\Gamma_{\rm total}$ and $\Gamma(h^-\nu_\tau)/\Gamma_{\rm total}$ measurements respectively. The constraints between the τ branching fractions and ratios include coefficients that correspond to physical quantities, like for instance the branching fractions of the η and ω mesons. All quantities are taken from the 2018 edition of the Review of Particle Physics. Their uncertainties are neglected in the fit.

We obtain the branching fraction of $\tau \to a_1^-(\to \pi^-\gamma)\nu_\tau$ using the ALEPH estimate for $\mathcal{B}(a_1^- \to \pi^-\gamma)$ [3], which uses the measurement of $\Gamma(a_1^- \to \pi^-\gamma)$ [5]. In the fit, we assume that $\mathcal{B}(\tau^- \to a_1^-\nu_\tau)$ is equal to $\mathcal{B}(\tau \to \pi^-\pi^-\pi^+\nu_\tau$ (ex. K^0, ω)) + $\mathcal{B}(\tau \to \pi^- 2\pi^0\nu_\tau$ (ex. K^0)), neglecting the observed but negligible branching fractions to other modes, including $\mathcal{B}(a_1^- \to \pi^-\gamma)$.

In some cases, constraints describe approximate relations that nevertheless hold within the present experimental precision. For instance, the constraint $\mathcal{B}(\tau \to K^-K^-K^+\nu_\tau) = \mathcal{B}(\tau \to K^-\phi\nu_\tau) \times \mathrm{B}(\phi \to K^+K^-)$ is justified within the current experimental evidence.

In the fit, scale factors are applied to the published uncertainties of measurements only if significant inconsistency between different measurements remain after accounting for all relevant uncertainties and correlations. After examining the data and the fit pulls, it has been decided to apply just one scale factor of 5.4 on the measurements of $\mathcal{B}(\tau \to K^-K^-K^+\nu_\tau)$. The scale factor has been computed and applied according to the standard PDG procedure. Without the scale factor applied, the χ^2 probability of the fit is about 2%. On a per-measurement basis, the pull distribution in figure 58.1 indicates that just a few measurements have more than 3σ pulls. (The uncertainties to obtain the pulls are computed using the measurements variance matrix and the variance matrix of the result, accounting for the fact that the variance matrix of the result is obtained from the measurement variance with the fit.) The pull probability distribution in figure 58.2 is reasonably flat. With many measurements some entries on the tails of the normal distribution must be expected. There are 170 pulls, one per measurement. They are partially correlated, and the effective number of independent pulls is equal to the number of degrees of freedom of the fit, 125. Only the $\tau \to K^-K^-K^+\nu_\tau$ decay mode has a pull that is inconsistent at the level of more than 3σ even if considered as the largest pull in a set of 125. This confirms the choice of adopting just that one scale factor.

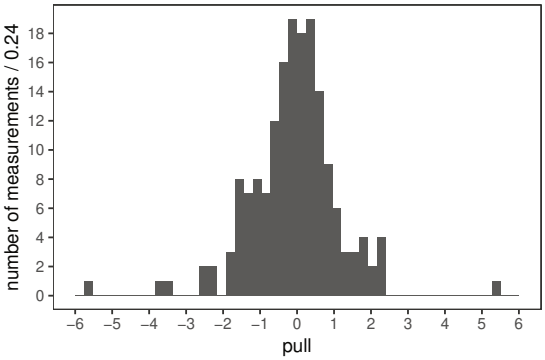

Figure 58.1: Pulls of individual measurements against the respective fitted quantity. No scale factor is used.

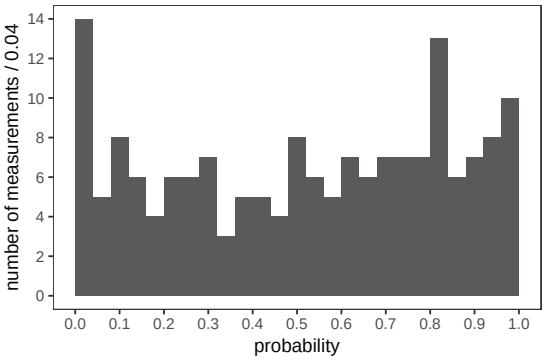

Figure 58.2: Probability of individual measurement pulls against the respective fitted quantity. No scale factor is used.

After scaling the error, the constrained fit has a χ^2 of 135 for 125 degrees of freedom, corresponding to a χ^2 probability of 26%. We use 170 measurements and 84 constraints on the branching fractions and ratios to determine 129 quantities, consisting of 112 branching fractions and 17 branching ratios. A total of 85 quantities have at least one measurement in the fit. The constraints include the unitarity constraint on the sum of all the exclusive τ decay modes, $\mathcal{B}_{\rm all} = 1$. If the unitarity constraint is released, the fit result for $\mathcal{B}_{\rm all}$ is consistent with unitarity with $1 - \mathcal{B}_{\rm all} = (0.00 \pm 0.10)\%$.

For the convenience of summarizing the fit results, we list in the following the values and uncertainties for a set of 46 "basis" decay modes, from which all remaining branching fractions and ratios can be obtained using the constraints. The basis decay modes are not intended to sum up to 1. Since some basis quantities represent multiple branching fractions that are related by constraint equations, they are properly weighted and the unitarity constraint

corresponds to a linear combination whose coefficients are listed in the following. The correlation matrix between the basis modes is reported in the τ Listings.

decay mode	fit result (%)	coefficient

$2\pi^-\pi^+3\pi^0\nu_\tau$ (ex. K^0, η, ω, f_1)	0.0014 ± 0.0027	1.0000
$3\pi^-2\pi^+\nu_\tau$ (ex. K^0, ω, f_1)	0.0775 ± 0.0030	1.0000
$K^-2\pi^-2\pi^+\nu_\tau$ (ex. K^0)	0.0001 ± 0.0001	1.0000
$2\pi^-\pi^+\omega\nu_\tau$ (ex. K^0)	0.0084 ± 0.0006	1.0000
$3\pi^-2\pi^+\pi^0\nu_\tau$ (ex. K^0, η, ω, f_1)	0.0038 ± 0.0009	1.0000
$K^-2\pi^-2\pi^+\pi^0\nu_\tau$ (ex. K^0)	0.0001 ± 0.0001	1.0000
$\pi^-f_1\nu_\tau$ ($f_1 \to 2\pi^-2\pi^+$)	0.0052 ± 0.0004	1.0000
$\pi^-2\pi^0\eta\nu_\tau$	0.0195 ± 0.0038	1.0000

In defining the fit constraints and in selecting the modes that sum up to one we made some assumptions and choices. We assume that some channels, like $\tau^- \to \pi^-K^+\pi^- \geq 0\pi^0\nu_\tau$ and $\tau^- \to \pi^+K^-K^- \geq 0\pi^0\nu_\tau$, have negligible branching fractions as expected from the Standard Model, even if the experimental limits for these branching fractions are not very stringent. The 95% confidence level upper limits are $\mathcal{B}(\tau^- \to \pi^-K^+\pi^- \geq 0\pi^0\nu_\tau) < 0.25\%$ and $\mathcal{B}(\tau^- \to \pi^+K^-K^- \geq 0\pi^0\nu_\tau) < 0.09\%$, values not so different from measured branching fractions for allowed 3-prong modes containing charged kaons. For decays to final states containing one neutral kaon we assume that the branching fraction with the K^0_L are the same as the corresponding one with a K^0_S. On decays with two neutral kaons we assume that the branching fractions with $K^0_LK^0_L$ are the same as the ones with $K^0_SK^0_S$.

58.3 BaBar and Belle measure on average lower branching fractions and ratios.

We compare the BaBar and Belle measurements with the results of a fit where all their measurements have been excluded. We find that that BaBar and Belle measure on average lower τ branching fractions and ratios than the other experiments. Figures 58.3 and 58.4 show histograms of the 28 normalized differences between the B-factory measurements and the respective non-B-factory fit results. The normalization is the uncertainty on the difference. The average normalized difference between the two sets of measurements is -0.8σ (-0.7σ for the 16 Belle measurements and -0.8σ for the 12 BaBar measurements).

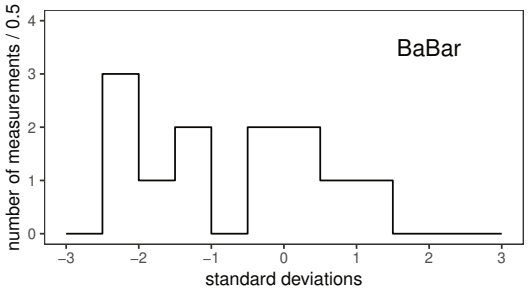

Figure 58.3: Distribution of the normalized difference between 12 measurements of branching fractions and ratios published by the BaBar collaboration and the respective averages computed using only non-B-factory measurements.

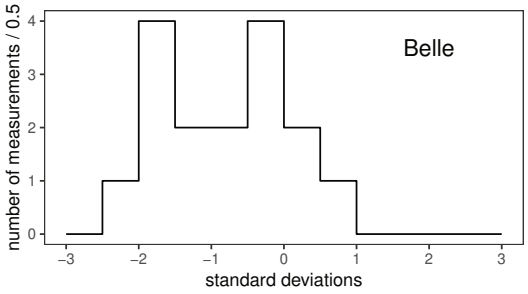

Figure 58.4: Distribution of the normalized difference between 16 measurements of branching fractions and ratios published by the Belle collaboration and the respective averages computed using only non-B-factory measurements.

58.4 Overconsistency of Leptonic Branching Fraction Measurements.

As observed in the previous editions of this review, measurements of the leptonic branching fractions are more consistent with each other than expected from the quoted errors on the individual measurements. The χ^2 is 0.34 for $\mathcal{B}_e$ and 0.08 for $\mathcal{B}_\mu$. Assuming normal errors, the probability of a smaller χ^2 is 1.3% for B_e and 0.08% for B_μ.

58.5 Technical implementation of the fit

The fit computes a set of quantities denoted with q_i by minimizing a χ^2 while respecting a series of equality constraints on the q_i. The χ^2 is computed using the measurements m_i and their covariance matrix E_{ij} as $\chi^2 = (m_i - A_{ik}q_k)^t E^{-1}_{ij}(m_j - A_{jl}q_l)$, where the model matrix A_{ij} is used to get the vector of the predicted measurements m'_i from the vector of the fit parameters q_j as $m'_i = A_{ij}q_j$. In this particular implementation the measurements are grouped by the quantity that they measure, and all quantities with at least one measurement correspond to a fit parameter. Therefore, the matrix A_{ij} has one row per measurement m_i and one column per fitted quantity q_j, with unity coefficients for the rows and column that identify a measurement m_i of the quantity q_j, respectively. The constraints are equations involving the fit parameters. The fit does not impose limitations on the functional form of the constraints. In summary, the fit requires:

$$\min\left[\chi^2(q_k)\right] = \min\left[(m_i - A_{ik}q_k)^t E^{-1}_{ij}(m_j - A_{jl}q_l)\right] \ , \quad (58.1)$$

$$\text{subjected to} \quad f_r(q_s) - c_r = 0 \ , \quad (58.2)$$

where the left term of Eq. 58.2 defines the constraint expressions. Using the method of Lagrange multipliers, a set of equations is

obtained by taking the derivatives with respect to the fitted quantities q_k and the Lagrange multipliers λ_r of the sum of the χ^2 and the constraint expressions multiplied by the Lagrange multipliers λ_r, one for each constraint:

$$\begin{aligned}\min\left[(A_{ik}q_k - m_i)^t E_{ij}^{-1}(A_{jl}q_l - m_j) + 2\lambda_r(f_r(q_s) - c_r)\right] = \\ = \min\left[\tilde{\chi}^2(q_k, \lambda_r)\right] \ , \\ (\partial/\partial q_k, \partial/\partial\lambda_r)\left[\tilde{\chi}^2(q_k, \lambda_r)\right] = 0 \ . \end{aligned} \tag{58.3}$$

Eq. 58.3 defines a set of equations for the vector of the unknowns (q_k, λ_r), some of which may be non-linear, in case of non-linear constraints. An iterative minimization procedure approximates at each step the non-linear constraint expressions by their first order Taylor expansion around the current values of the fitted quantities, $\bar{q}_s$:

$$f_r(q_s) - c_r = f_r(\bar{q}_s) + \left.\frac{\partial f_r(q_s)}{\partial q_s}\right|_{\bar{q}_s}(q_s - \bar{q}_s) - c_r \ ,$$

which can be written as

$$B_{rs}q_s - c'_r \ ,$$

where c'_r are the resulting constant known terms, independent of q_s at first order. After linearization, the differentiation by q_k and λ_r is trivial and leads to a set of linear equations

$$A^t_{ki}E^{-1}_{ij}A_{jl}q_l + B^t_{kr}\lambda_r = A^t_{ki}E^{-1}_{ij}m_j \ , \tag{58.4}$$

$$B_{rs}q_s = c'_r \ , \tag{58.5}$$

which can be expressed as

$$F_{ij}u_j = v_i \ , \tag{58.6}$$

where $u_j = (q_k, \lambda_r)$ and v_i is the vector of the known constant terms running over the index k and then r in the right terms of Eq. 58.4 and Eq. 58.5, respectively. Solving the equation set in Eq. 58.6 by matrix inversion gives the the fitted quantities and their variance and covariance matrix, using the measurements and their variance and covariance matrix. The fit procedure starts by computing the linear approximation of the non-linear constraint expressions around the quantities seed values. With an iterative procedure, the unknowns are updated at each step by solving the equations and the equations are then linearized around the updated values, until the variation of the fitted unknowns is reduced below a numerically small threshold.

59. τ-Lepton Decay Parameters

Revised February 2022 by A. Stahl (RWTH Aachen U.).

The purpose of the measurements of the decay parameters (also known as Michel parameters) of the τ is to determine the structure (spin and chirality) of the current mediating its decays.

59.1 Leptonic Decays:

The Michel parameters are extracted from the energy spectrum of the charged daughter lepton $\ell = e, \mu$ in the decays $\tau \to \ell\nu_\ell\nu_\tau$. Ignoring radiative corrections, neglecting terms of order $(m_\ell/m_\tau)^2$ and $\left(m_\tau/\sqrt{s}\right)^2$, and setting the neutrino masses to zero, the spectrum in the laboratory frame reads

$$\frac{d\Gamma}{dx} = \frac{G_{\tau\ell}^2\, m_\tau^5}{192\,\pi^3} \times \left\{ f_0\,(x) + \rho f_1\,(x) + \eta \frac{m_\ell}{m_\tau} f_2\,(x) - P_\tau\,[\xi g_1\,(x) + \xi\delta g_2\,(x)] \right\} \tag{59.1}$$

with

$$\begin{aligned} f_0(x) &= 2 - 6\,x^2 + 4\,x^3 \\ f_1(x) &= -\tfrac{4}{9} + 4x^2 - \tfrac{32}{9}x^3 \qquad g_1(x) = -\tfrac{2}{3} + 4x - 6x^2 + \tfrac{8}{3}x^3 \\ f_2(x) &= 12\,(1-x)^2 \qquad\qquad g_2(x) = \tfrac{4}{9} - \tfrac{16}{3}x + 12x^2 - \tfrac{64}{9}\,x^3\,. \end{aligned} \tag{59.2}$$

The quantity x is the fractional energy of the daughter lepton ℓ, *i.e.*, $x = E_\ell/E_{\ell,max} \approx E_\ell/(\sqrt{s}/2)$ and P_τ is the polarization of the tau leptons. The integrated decay width is given by

$$\Gamma = \frac{G_{\tau\ell}^2\, m_\tau^5}{192\,\pi^3} \left(1 + 4\,\eta\,\frac{m_\ell}{m_\tau}\right)\,. \tag{59.3}$$

The situation is similar to muon decays $\mu \to e\nu_e\nu_\mu$. The generalized matrix element with the couplings $g_{\varepsilon\mu}^\gamma$ and their relations to the Michel parameters ρ, η, ξ, and δ have been described in the "Note on Muon Decay Parameters". The Standard Model expectations are 3/4, 0, 1, and 3/4, respectively. For more details, see Ref. [1].

Additional Michel-parameters can be defined in radiative decays $\tau \to \ell\nu_\ell\nu_\tau\gamma$, see Ref. [2]. A first measurement is presented in Ref. [3]. The experimental precision does not provide a significant impact on the knowledge about the couplings, yet.

59.2 Hadronic Decays:

In the case of hadronic decays $\tau \to h\nu_\tau$, with $h = \pi$, ρ, or a_1, the ansatz is restricted to purely vectorial currents. The matrix element is

$$\frac{G_{\tau h}}{\sqrt{2}} \sum_{\lambda=R,L} g_\lambda \,\langle\, \overline{\Psi}_\omega(\nu_\tau) \mid \gamma^\mu \mid \Psi_\lambda(\tau) \,\rangle\;\; J_\mu^h \tag{59.4}$$

with the hadronic current J_μ^h. The neutrino chirality ω is uniquely determined from λ. The spectrum depends only on a single parameter ξ_h

$$\frac{d^n\Gamma}{dx_1 dx_2 \ldots dx_n} = f\,(\vec{x}) + \xi_h P_\tau\, g\,(\vec{x})\;\;, \tag{59.5}$$

with f and g being channel-dependent functions of the n observables $\vec{x} = (x_1, x_2, \ldots, x_n)$ (see Ref. [4]). The parameter ξ_h is related to the couplings through

$$\xi_h = |g_L|^2 - |g_R|^2\;. \tag{59.6}$$

ξ_h is the negative of the chirality of the τ neutrino in these decays. In the Standard Model, $\xi_h = 1$. Also included in the Data Listings for ξ_h are measurements of the neutrino helicity which coincide with ξ_h, if the neutrino is massless (ASNER 00 [5], ACKERSTAFF 97R [6], AKERS 95P [7], ALBRECHT 93C [8], and ALBRECHT 90I [9]).

59.3 Combination of Measurements:

The individual measurements are combined, taking into account the correlations between the parameters. In a first fit, universality between the two leptonic decays, and between all hadronic decays, is assumed. A second fit is made without these assumptions. The results of the two fits are provided as OUR FIT in the Data Listings below in the tables whose title includes "(e or mu)" or "(all hadronic modes)", and "(e)", "(mu)" *etc.*, respectively. The measurements show good agreement with the Standard Model. The χ^2 values with respect to the Standard model predictions are 24.1 for 41 degrees of freedom and 26.8 for 56 degrees of freedom, respectively. The correlations are reduced through this combination to less than 20%, with the exception of ρ and η which are correlated by +23%, for the fit with universality and by +70% for $\tau \to \mu\nu_\mu\nu_\tau$.

59.4 Model-independent Analysis:

From the Michel parameters, limits can be derived on the couplings $g_{\varepsilon\lambda}^\kappa$ without further model assumptions. In the Standard model $g_{LL}^V = 1$ (leptonic decays), and $g_L = 1$ (hadronic decays) and all other couplings vanish. First, the partial decay widths have to be compared to the Standard Model predictions to derive limits on the normalization of the couplings $A_x = G_{\tau x}^2/G_F^2$ with Fermi's constant G_F:

$$\begin{aligned} A_e &= 1.0022 \pm 0.0041\;, \\ A_\mu &= 0.983 \pm 0.017\;, \\ A_\pi &= 0.9957 \pm 0.0049\;. \end{aligned} \tag{59.7}$$

Then limits on the couplings (95% CL) can be extracted (see Ref. [10] and Ref. [11]). Without the assumption of universality, the limits given in Table 59.1 are derived.

Table 59.1: Coupling constants $g_{\varepsilon\mu}^\gamma$. 95% confidence level experimental limits. The limits include the quoted values of A_e, A_μ, and A_π and assume $A_\rho = A_{a_1} = 1$.

$\tau \to e\nu_e\nu_\tau$		
$\lvert g_{RR}^S\rvert < 0.70$	$\lvert g_{RR}^V\rvert < 0.17$	$\lvert g_{RR}^T\rvert \equiv 0$
$\lvert g_{LR}^S\rvert < 0.99$	$\lvert g_{LR}^V\rvert < 0.13$	$\lvert g_{LR}^T\rvert < 0.082$
$\lvert g_{RL}^S\rvert < 2.01$	$\lvert g_{RL}^V\rvert < 0.52$	$\lvert g_{RL}^T\rvert < 0.51$
$\lvert g_{LL}^S\rvert < 2.01$	$\lvert g_{LL}^V\rvert < 1.004$	$\lvert g_{LL}^T\rvert \equiv 0$
$\tau \to \mu\nu_\mu\nu_\tau$		
$\lvert g_{RR}^S\rvert < 0.72$	$\lvert g_{RR}^V\rvert < 0.18$	$\lvert g_{RR}^T\rvert \equiv 0$
$\lvert g_{LR}^S\rvert < 0.95$	$\lvert g_{LR}^V\rvert < 0.12$	$\lvert g_{LR}^T\rvert < 0.079$
$\lvert g_{RL}^S\rvert < 2.01$	$\lvert g_{RL}^V\rvert < 0.52$	$\lvert g_{RL}^T\rvert < 0.51$
$\lvert g_{LL}^S\rvert < 2.01$	$\lvert g_{LL}^V\rvert < 1.006$	$\lvert g_{LL}^T\rvert \equiv 0$
$\tau \to \pi\nu_\tau$		
$\lvert g_R^V\rvert < 0.15$	$\lvert g_L^V\rvert > 0.984$	
$\tau \to \rho\nu_\tau$		
$\lvert g_R^V\rvert < 0.10$	$\lvert g_L^V\rvert > 0.995$	
$\tau \to a_1\nu_\tau$		
$\lvert g_R^V\rvert < 0.16$	$\lvert g_L^V\rvert > 0.987$	

59.5 Model-dependent Interpretation:

More stringent limits can be derived assuming specific models. For example, in the framework of a two Higgs doublet model, the measurements correspond to a limit of $m_{H^\pm} > 2.0$ GeV $\times \tan\beta$ on the mass of the charged Higgs boson, or a limit of 500 GeV on the mass of the second W boson in left-right symmetric models for arbitrary mixing (both 95% CL). See Ref. [11] and Ref. [12].

60. Quark Masses

Revised August 2021 by R.M. Barnett (LBNL), L.P. Lellouch (CNRS & Aix-Marseille U.) and A.V. Manohar (UC San Diego).

60.1 Introduction

This note discusses some of the theoretical issues relevant for the determination of quark masses, which are fundamental parameters of the Standard Model of particle physics. Unlike the leptons, quarks are confined inside hadrons and are not observed as physical particles. Quark masses therefore cannot be measured directly, but must be determined indirectly through their influence on hadronic properties. Although one often speaks loosely of quark masses as one would of the mass of the electron or muon, any quantitative statement about the value of a quark mass must make careful reference to the particular theoretical framework that is used to define it. It is important to keep this *scheme dependence* in mind when using the quark mass values tabulated in the data listings.

Historically, the first determinations of quark masses were performed using quark models. These are usually called constituent quark masses and are of order 350 MeV for the u and d quarks. Constituent quark masses model the effects of dynamical chiral symmetry breaking discussed below, and are not directly related to the quark mass parameters m_q of the QCD Lagrangian of Eq. (60.1). The resulting masses only make sense in the limited context of a particular quark model, and cannot be related to the quark mass parameters, m_q, of the Standard Model. In order to discuss quark masses at a fundamental level, definitions based on quantum field theory must be used, and the purpose of this note is to discuss these definitions and the corresponding determinations of the values of the masses.

60.2 Mass parameters and the QCD Lagrangian

The QCD [1] Lagrangian is

$$\mathcal{L} = \sum_{q=u,d,s,\ldots,t} \overline{q}\,(i\not{D} - m_q)\,q - \tfrac{1}{2}\mathrm{tr}\,G_{\mu\nu}G^{\mu\nu}, \tag{60.1}$$

where the sum runs over the quark flavors u, d, s, c, b and t. $\not{D} = (\partial_\mu - igA_\mu)\,\gamma^\mu$ is the gauge covariant derivative, A_μ is the SU(3)-valued gluon field, $G_{\mu\nu} = \frac{i}{g}[D_\mu, D_\nu]$ is the gluon field strength, m_q is the mass parameter of quark flavor q, and q is the quark Dirac field. After renormalization, the QCD Lagrangian Eq. (60.1) gives finite values for physical quantities, such as scattering amplitudes. Renormalization is a procedure that invokes a subtraction scheme to render the amplitudes finite, and requires the introduction of a dimensionful scale parameter μ. The mass parameters in the QCD Lagrangian Eq. (60.1) depend on the renormalization scheme used to define the theory, and also on the scale parameter μ. The most commonly used renormalization scheme for QCD perturbation theory is the $\overline{\mathrm{MS}}$ scheme.

The QCD Lagrangian has a chiral symmetry in the limit that the quark masses vanish. This symmetry is spontaneously broken by dynamical chiral symmetry breaking, and explicitly broken by the quark masses. The nonperturbative scale of dynamical chiral symmetry breaking, Λ_χ, is around 1 GeV [2]. It is conventional to call quarks heavy if $m_q > \Lambda_\chi$, so that explicit chiral symmetry breaking dominates (c, b, and t quarks are heavy), and light if $m_q < \Lambda_\chi$, so that spontaneous chiral symmetry breaking dominates (the u and d are light and the s is considered to be light when using $\mathrm{SU}(3)_L \times \mathrm{SU}(3)_R$ chiral perturbation theory). The determination of light- and heavy-quark masses is considered separately in Sec. 60.4 and Sec. 60.5 below.

At high energies or short distances, nonperturbative effects, such as chiral symmetry breaking, become small and one can, in principle, determine quark masses by analyzing mass-dependent effects using QCD perturbation theory. Such computations are conventionally performed using the $\overline{\mathrm{MS}}$ scheme at a scale $\mu \gg \Lambda_\chi$, and give the $\overline{\mathrm{MS}}$ "running" mass $\overline{m}(\mu)$. We use the $\overline{\mathrm{MS}}$ scheme when reporting quark masses; one can readily convert these values into other schemes using perturbation theory.

The μ dependence of $\overline{m}(\mu)$ at short distances can be calculated using the renormalization group (RG) equation,

$$\mu^2 \frac{\mathrm{d}\overline{m}\,(\mu)}{\mathrm{d}\mu^2} = -\gamma(\overline{\alpha}_s\,(\mu))\;\overline{m}\,(\mu)\,, \tag{60.2}$$

where γ is the anomalous dimension which is now known to four-loop order in perturbation theory [3] [4]. $\overline{\alpha}_s$ is the coupling constant [1] in the $\overline{\mathrm{MS}}$ scheme. Defining the expansion coefficients γ_r by

$$\gamma\,(\overline{\alpha}_s) \equiv \sum_{r=1}^{\infty} \gamma_r \left(\frac{\overline{\alpha}_s}{4\pi}\right)^r, \tag{60.3}$$

the first four coefficients are given by

$$\begin{aligned}
\gamma_1 &= 4,\\
\gamma_2 &= \frac{202}{3} - \frac{20N_L}{9},\\
\gamma_3 &= 1249 + \left(-\frac{2216}{27} - \frac{160}{3}\zeta\,(3)\right) N_L - \frac{140}{81}N_L^2,\\
\gamma_4 &= \frac{4603055}{162} + \frac{135680}{27}\zeta\,(3) - 8800\zeta\,(5)\\
&\quad + \left(-\frac{91723}{27} - \frac{34192}{9}\zeta\,(3) + 880\zeta\,(4) + \frac{18400}{9}\zeta\,(5)\right) N_L\\
&\quad + \left(\frac{5242}{243} + \frac{800}{9}\zeta\,(3) - \frac{160}{3}\zeta\,(4)\right) N_L^2\\
&\quad + \left(-\frac{332}{243} + \frac{64}{27}\zeta\,(3)\right) N_L^3,
\end{aligned}$$

where N_L is the number of active light quark flavors at the scale μ, i.e. flavors with masses $\leq \mu$, and ζ is the Riemann zeta function ($\zeta(3) \simeq 1.2020569$, $\zeta(4) \simeq 1.0823232$, and $\zeta(5) \simeq 1.0369278$). Eq. (60.2) must be solved in conjunction with the RG equation for $\overline{\alpha}_s\,(\mu)$ given in [1]. In addition, as the renormalization scale crosses quark mass thresholds one needs to match the scale dependence of $\overline{m}$ below and above the threshold. There are finite threshold corrections; the necessary formulae can be found in Ref. [5].

60.3 Lattice QCD

The use of lattice QCD calculations for *ab initio* determinations of the fundamental parameters of QCD, including the coupling constant and quark masses (except for the top-quark mass) is a very active area of research (see the review on Lattice Quantum Chromodynamics in this *Review*). Here we only briefly recall those features which are required for the determination of quark masses. In order to determine the lattice spacing (a, i.e. the distance between neighboring points of the lattice) and quark masses, one computes a convenient and appropriate set of physical quantities (frequently chosen to be a set of hadronic masses) for a variety of input values of the quark masses in units of the lattice spacing. These input quark masses are then tuned to their true (physical) values by requiring that the calculation correctly reproduces the set of physical quantities being used for the calibration.

The resulting values of the quark masses are bare quark masses, corresponding to a particular discretization of QCD and with the lattice spacing as the ultraviolet cut-off. In order for these results to be useful in phenomenological applications, it is necessary to relate them to renormalized masses defined in some standard renormalization scheme such as $\overline{\mathrm{MS}}$. Provided that both the ultraviolet cut-off a^{-1} and the renormalization scale μ are much greater than Λ_{QCD}, the bare and renormalized masses can be related in perturbation theory. However, in order to avoid uncertainties due to the unknown higher-order coefficients in lattice perturbation theory, most results obtained recently use *nonperturbative renormalization* to relate the bare masses to those defined in renormalization schemes which can be realized directly in lattice QCD (e.g. those obtained from quark and gluon Green functions at specified momenta in the Landau gauge [6] or those defined using finite-volume techniques and the Schrödinger functional [7], but not $\overline{\mathrm{MS}}$ that is only defined for dimensional regularization). These methods require $\mu \gg \Lambda_{\mathrm{QCD}}$ so that unwanted (nonperturbative) corrections proportional to inverse powers of μ, which appear in some

approaches, remain small corrections that can be identified and removed. This condition is also necessary so that matching to other schemes can be performed reliably in perturbation theory. Moreover, these methods require $a^{-1} \gg \mu$ so that cutoff effects are small enough to be extrapolated away. Thus, the calculations are repeated for finer and finer lattice spacings and the continuum limit, $a \to 0$, of these nonperturbatively renormalized masses is taken to eliminate all cutoff effects. The conversion to the $\overline{\rm MS}$ scheme is then performed using continuum perturbation theory, which is more readily obtained to higher orders and is usually better behaved than its lattice counterpart.

It is important to note that the final renormalized values for the quark masses must be the same in the continuum limit for any sensible choice of the physical quantities used for calibration, as long as the calculation is performed with a sufficient number of sea-quark flavors and the relevant electromagnetic and strong-isospin breaking corrections for the claimed precision. It is also worth noting that issues surrounding the renormalization of quark masses disappear when considering pairwise ratios of these masses (up to electromagnetic effects for quarks of different charge, which are still smaller than the errors bars quoted on these ratios, e.g. in the $\overline{\rm MS}$ scheme at a scale of a few GeV). Indeed, if the same scheme and scale are implemented, QCD renormalization factors are identical for all quark flavors, and these factors therefore cancel exactly in quark-mass ratios. In particular, this means that these ratios are scheme and scale independent. Moreover, these ratios may suffer less from the uncertainties in the determination of the lattice scale, in particular in cases where the quantities used to fix the two quarks masses entering the ratio depend on these masses in a similar way, but also because these ratios are dimensionless. Thus, quark-mass ratios are often determined with significantly higher precision using lattice QCD than are the individual masses.

The determination of quark masses using lattice simulations is well established and the current emphasis is on the reduction and control of the systematic uncertainties. With improved algorithms and access to more powerful computing resources, the precision of the results has improved immensely in recent years. Vacuum polarization effects are included with $N_f = 2$, $2+1$ or $N_f = 2+1+1$ flavors of sea quarks. The number 2 here indicates that the up and down quarks are degenerate. The first $+1$ corresponds to the inclusion of strange sea-quark effects and the second $+1$ to those of the charm. Simulations with $2+1$ and $2+1+1$ flavors represent controlled approximations to physical QCD at the low energies considered for quark mass determinations, up to corrections of $O((\Lambda_{\rm QCD}/m_c)^2/N_c)$ and $O((\Lambda_{\rm QCD}/m_b)^2/N_c)$, respectively. This is not the case for simulations with $N_f = 2$ or in which vacuum polarization effects are completely neglected (this is the so-called *quenched* approximation) and results obtained in such frameworks will not enter the discussion here.

Particularly pleasing is the observation that different formulations of lattice QCD, with different systematic uncertainties, yield results which are largely consistent with each other. This gives us broad confidence in the estimates of the systematic errors. As the precision of the results approaches (or even exceeds in some cases) 1%, isospin breaking effects, including electromagnetic corrections need to be included and this is beginning to be done as will be discussed below. In particular, a reliable estimate of these effects is required for determining the individual u and d quark masses.

Members of the lattice QCD community have organized a Flavour Lattice Averaging Group (FLAG) which critically reviews quantities computed in lattice QCD relevant to flavor physics, including the determination of quark masses, against stated quality criteria and presents its view of the current status of the results. The latest edition reviews lattice results that have been appeared in print before April 30th 2021 [8]. Since that deadline, there have been no new lattice, quark-mass determinations.

60.4 Light quarks

In this section we review the determination of the masses of the light quarks u, d and s from lattice simulations and then discuss the consequences of the approximate chiral symmetry.

60.4.1 *Lattice QCD results*

The most reliable determinations of the strange quark mass, m_s, and of the average of the up and down quark masses, $m_{ud} = (m_u + m_d)/2$, are obtained from lattice simulations. As explained in Sec. 60.3 above, the simulations are generally performed with degenerate up and down quarks ($m_u = m_d$) and so it is the average which is obtained directly from the computations. Below we discuss the derivation of m_u and m_d separately, but we start by briefly presenting our estimate of the current status of the latest lattice results in the isospin symmetric limit. The FLAG review [8] bases its summary numbers for these quark masses on references that the review's authors consider to have the most reliable estimates of systematic uncertainties, i.e. [9–15] for $N_f = 2+1$ and [16–21] for $N_f = 2+1+1$ flavors of sea quarks. Note that the $N_f = 2+1+1$ results [22] did not make the FLAG deadline. Compared to the previous editions of the FLAG [23] and of the present reviews, this corresponds to including the new calculation [15] and to dropping [24], whose simulations do not allow for as good a control over the tuning of m_{ud} as do the other calculations. For $N_f = 2+1$ flavors, the FLAG review quotes $\overline{m}_{ud} = (3.381 \pm 0.040)\,\text{MeV}$, $\overline{m}_s = (92.2 \pm 1.0)\,\text{MeV}$ and $(\overline{m}_s/\overline{m}_{ud}) = 27.42 \pm 0.12$. These numbers are $\overline{m}_{ud} = (3.410 \pm 0.043)\,\text{MeV}$, $\overline{m}_s = (93.40 \pm 0.57)\,\text{MeV}$ and $(\overline{m}_s/\overline{m}_{ud}) = 27.23 \pm 0.10$ for $N_f = 2+1+1$ simulations. The masses are given in the $\overline{\rm MS}$ scheme at a renormalization scale of 2 GeV. These results are not simply the combinations of all the results in quadrature, but include possible correlations between calculations. Since the different collaborations use different formulations of lattice QCD, the (relatively small) variations of the results between the groups provides important information about the reliability of the estimates.

Compared to the previous editions of the FLAG [23] and of the present reviews, the central values of these averages have changed by only a fraction of their error bars, which is not surprising given that they were obtained mostly from the same results. The most notable change is the significant increase in the error of $N_f = 2+1$ $\overline{m}_s$. This is due mainly to the inclusion of [15], whose larger value leads to a $\chi^2/\text{dof} = 1.7$ in the average, which is accounted for by increasing the uncertainties by the usual $\sqrt{\chi^2/\text{dof}}$ scale factor.

Despite being reported in the $\overline{\rm MS}$ scheme at a renormalization scale of 2 GeV, the results for $\overline{m}_{ud}$ and $\overline{m}_s$ in the two frameworks differ in their renormalization schemes, since $N_f = 2+1$ results are renormalized with $N_L = 3$ and $N_f = 2+1+1$ ones with $N_L = 4$. Thus, for a comparison, one should convert the results to the same scheme. This is not the case for $(\overline{m}_s/\overline{m}_{ud})$, where renormalization factors cancel. The conversion of the $N_f = 2+1$ results to the $N_L = 4$ scheme can be performed, for instance, by running them down to the charm threshold in the $N_L = 3$ theory, matching the results to the $N_L = 4$ theory at that scale, and running them back up to 2 GeV with four active flavors. Such a conversion leads to an upward shift in the values of the quark masses of only around 0.3%, well within the quoted errors. There are also nonperturbative contributions to this procedure, of $O((\Lambda_{\rm QCD}/m_c)^2/N_c) \sim 2\%$. However, lattice QCD studies of these effects have shown that they are typically an order of magnitude smaller on hadronic quantities or on $\Lambda_{\rm QCD}$ [25,26]. Given that the total errors on the $N_f = 2+1$ results for $\overline{m}_{ud}$ and $\overline{m}_s$ are larger than 1%, we choose to neglect these matching effects and simply to average the results from the two frameworks, yielding as a final lattice QCD estimate in the $\overline{\rm MS}$ scheme at $\mu = 2\,\text{GeV}$ in the $N_L = 4$ theory:

$$\overline{m}_{ud} = (3.39 \pm 0.04)\,\text{MeV}, \tag{60.4}$$

$$\overline{m}_s = (93.1 \pm 0.6)\,\text{MeV}, \tag{60.5}$$

and

$$r_s \equiv \frac{\overline{m}_s}{\overline{m}_{ud}} = 27.31 \pm 0.10, \tag{60.6}$$

where the error bars encompass statistical and systematic errors combined in quadrature. In performing these averages, small tensions are found in the results for $\overline{m}_s/\overline{m}_{ud}$, whose weighted av-

erage comes with a $\chi^2/\mathrm{dof} \simeq 1.5$, used to increase error bars in the usual way. As a final error we always quote the largest of the average's error and of the smaller of the erros on the individual flavor averages, to account for possible common systematics.

To obtain the individual values of $\overline{m}_u$ and $\overline{m}_d$ requires the introduction of isospin breaking effects, including electromagnetism. This is now being done completely using lattice field theory, albeit neglecting electromagnetic effects in the sea in most cases (for an exception, see [27] which includes a calculation of the QED contribution to $\Delta M_K^2 = M_{K^0}^2 - M_{K^+}^2$ that is critical for determining $\overline{m}_d - \overline{m}_u$). The effect of this neglect on the u and d quark masses has been estimated in [28], to induce a contribution to the uncertainty that ranges from about 3% in $\overline{m}_u/\overline{m}_d$ to less than 1% in $\overline{m}_d$. FLAG has also reviewed results for these masses in [8]. Again, they separate results obtained from $N_f = 2+1$ and $N_f = 2+1+1$ simulations. For the former, their number is that of [28], as in the previous review [23], and for the latter, it is the average of the results from [17, 29, 30]. Thus, for $N_f = 2+1$ they quote $\overline{m}_u = 2.27(9)\,\mathrm{MeV}$, $\overline{m}_d = 4.67(9)\,\mathrm{MeV}$, $(\overline{m}_u/\overline{m}_d) = 0.485(19)$ and, for $N_f = 2+1+1$, $\overline{m}_u = 2.14(8)\,\mathrm{MeV}$, $\overline{m}_d = 4.70(5)\,\mathrm{MeV}$, $(\overline{m}_u/\overline{m}_d) = 0.465(24)$. Compared to the previous editions of the FLAG [23] and of the present reviews, the inclusion of the $N_f = 2+1+1$ results [17, 30] changes the central values of $\overline{m}_u$ and $\overline{m}_u/\overline{m}_d$ outside error bars, indicating some tension between the results of the newer and older calculations, which is around 2 standard deviations. Here, $\overline{m}_u$ is 0.36 MeV smaller than the value given in [23] and $\overline{m}_u/\overline{m}_d$ is 0.066 units smaller. These reductions make the $N_f = 2+1+1$ results more compatible with the $N_f = 2+1$ ones.

As for the light quark masses in the isospin limit, we average the results obtained with different numbers of sea-quark flavors. Here, only the $\overline{m}_u$ average has a $\chi^2/\mathrm{dof} = 1.2 > 1$, and its error is thus appropriately scaled. Again, we do not allow the errors to become smaller than those on the individual flavor averages because of possible common systematics. Thus, we give as a final lattice QCD estimate in the $\overline{\mathrm{MS}}$ scheme at $\mu = 2\,\mathrm{GeV}$ in the $N_L = 4$ theory:

$$\overline{m}_u = 2.20(8)\,\mathrm{MeV},\ \overline{m}_d = 4.69(5)\,\mathrm{MeV},\ r \equiv \frac{\overline{m}_u}{\overline{m}_d} = 0.477(19). \tag{60.7}$$

As a consequence of the newly included $N_f = 2+1+1$ results [17,30], the central value of $\overline{m}_u$ has been reduced by 0.12 MeV and that of $\overline{m}_u/\overline{m}_d$ by 0.016 units compared to the previous edition of this review, while the error bar on $\overline{m}_u$ is 20% smaller and that on $\overline{m}_d$ is almost 50% smaller.

It is worth noting that m_u differs from zero by more than 20 times the quoted error, making a scenario in which $m_u = 0$ very unlikely. This is important because there would be no strong CP problem if m_u were to vanish identically.

It should also be emphasized that the results for the light quark masses given in the listings are dominated by the lattice values, since most phenomenological extractions have larger uncertainties.

60.4.2 *Chiral Perturbation Theory*

For light quarks, one can use the techniques of chiral perturbation theory [31–33] to extract quark mass ratios. The mass term for light quarks in the QCD Lagrangian is

$$\overline{\Psi} M \Psi = \overline{\Psi}_L M \Psi_R + \overline{\Psi}_R M^\dagger \Psi_L, \tag{60.8}$$

where M is the light quark mass matrix,

$$M = \begin{pmatrix} m_u & 0 & 0 \\ 0 & m_d & 0 \\ 0 & 0 & m_s \end{pmatrix}, \tag{60.9}$$

$\Psi = (u, d, s)$, and L and R are the left- and right-chiral components of Ψ given by $\Psi_{L,R} = P_{L,R}\Psi$, $P_L = (1-\gamma_5)/2$, $P_R = (1+\gamma_5)/2$. The mass term is the only term in the QCD Lagrangian that mixes left- and right-handed quarks. In the limit $M \to 0$, there is an independent $\mathrm{SU}(3)\times\mathrm{U}(1)$ flavor symmetry for the left- and right-handed quarks. The vector U(1) symmetry is baryon number; the axial U(1) symmetry of the classical theory is broken in the quantum theory due to the anomaly. The remaining $G_\chi = \mathrm{SU}(3)_L \times \mathrm{SU}(3)_R$ chiral symmetry of the QCD Lagrangian is spontaneously broken to $\mathrm{SU}(3)_V$, which, in the limit $M \to 0$, leads to eight massless Goldstone bosons, the π's, K's, and η.

The symmetry G_χ is only an approximate symmetry, since it is explicitly broken by the quark mass matrix M. The Goldstone bosons acquire masses which can be computed in a systematic expansion in M, in terms of low-energy constants, which are unknown nonperturbative parameters of the effective theory, and are not fixed by the symmetries. One treats the quark mass matrix M as a uniform, external field that transforms under G_χ as $M \to LMR^\dagger$, where $\Psi_L \to L\Psi_L$ and $\Psi_R \to R\Psi_R$ are the $\mathrm{SU}(3)_L$ and $\mathrm{SU}(3)_R$ transformations, and writes down the most general Lagrangian invariant under G_χ. Then one sets M to its given constant value Eq. (60.9), which implements the symmetry breaking. To first order in M one finds that [34]

$$\begin{aligned} m_{\pi^0}^2 &= B\,(m_u + m_d)\,, \\ m_{\pi^\pm}^2 &= B\,(m_u + m_d) + \Delta_{\mathrm{em}}, \\ m_{K^0}^2 &= m_{\overline{K}^0}^2 = B\,(m_d + m_s)\,, \\ m_{K^\pm}^2 &= B\,(m_u + m_s) + \Delta_{\mathrm{em}}, \\ m_\eta^2 &= \frac{1}{3} B\,(m_u + m_d + 4m_s)\,, \end{aligned} \tag{60.10}$$

with two unknown constants B, related to the light quark condensate, and Δ_{em}, the electromagnetic mass difference. From Eq. (60.10), one can determine the quark mass ratios [34]

$$\begin{aligned} \frac{m_u}{m_d} &= \frac{2m_{\pi^0}^2 - m_{\pi^+}^2 + m_{K^+}^2 - m_{K^0}^2}{m_{K^0}^2 - m_{K^+}^2 + m_{\pi^+}^2} = 0.56, \\ \frac{m_s}{m_d} &= \frac{m_{K^0}^2 + m_{K^+}^2 - m_{\pi^+}^2}{m_{K^0}^2 + m_{\pi^+}^2 - m_{K^+}^2} = 20.2, \end{aligned} \tag{60.11}$$

to lowest order in chiral perturbation theory, with an error which will be estimated below. Since the mass ratios extracted using chiral perturbation theory use the symmetry transformation property of M under the chiral symmetry G_χ, it is important to use a renormalization scheme for QCD that does not change this transformation law. Any mass-independent subtraction scheme such as $\overline{\mathrm{MS}}$ is suitable. The ratios of quark masses are scale independent in such a scheme (up to electromagnetic corrections), and Eq. (60.11) can be taken to be the ratio of $\overline{\mathrm{MS}}$ masses. Chiral perturbation theory cannot determine the overall scale of the quark masses, since it uses only the symmetry properties of M, and any multiple of M has the same G_χ transformation law as M.

Chiral perturbation theory is a systematic expansion in powers of the light quark masses. The typical expansion parameter is $m_K^2/\Lambda_\chi^2 \sim 0.25$ if one uses SU(3) chiral symmetry, and $m_\pi^2/\Lambda_\chi^2 \sim 0.02$ if instead one uses SU(2) chiral symmetry. Electromagnetic effects at the few percent level also break SU(2) and SU(3) symmetry. The mass formulæ Eq. (60.10) were derived using SU(3) chiral symmetry, and are expected to have approximately a 25% uncertainty due to second order corrections. This estimate of the uncertainty yields results consistent with the lattice results summarized in Eq. (60.5)–(60.6).

There is a subtlety which arises when one tries to determine quark mass ratios at second order in chiral perturbation theory. The second order quark mass term [35]

$$\left(M^\dagger\right)^{-1} \det M^\dagger \tag{60.12}$$

(which can be generated by instantons) transforms in the same way under G_χ as M. Chiral perturbation theory cannot distinguish between M and $(M^\dagger)^{-1}\det M^\dagger$; one can make the replacement $M \to M(\lambda) = M + \lambda M (M^\dagger M)^{-1} \det M^\dagger$ in the chiral Lagrangian,

$$\begin{aligned} M(\lambda) &= \mathrm{diag}\,(m_u(\lambda),\ m_d(\lambda),\ m_s(\lambda)) \\ &= \mathrm{diag}\,(m_u + \lambda m_d m_s,\ m_d + \lambda m_u m_s,\ m_s + \lambda m_u m_d)\,, \end{aligned} \tag{60.13}$$

and leave all observables unchanged.

The combination

$$\left(\frac{m_u}{m_d}\right)^2 + \frac{1}{Q^2}\left(\frac{m_s}{m_d}\right)^2 = 1 \tag{60.14}$$

where

$$Q^2 = \frac{m_s^2 - m_{ud}^2}{m_d^2 - m_u^2}, \qquad m_{ud} = \frac{1}{2}\left(m_u + m_d\right),$$

is insensitive to the transformation in Eq. (60.13). Eq. (60.14) gives an ellipse in the m_u/m_d-m_s/m_d plane. The ellipse is well-determined by chiral perturbation theory, but the location on the ellipse, and the absolute normalization of the quark masses, have larger uncertainties.

A leading-order result for Q in SU(3) chiral perturbation theory can be derived using Eq. (60.10) and the values for the relevant meson masses. This result actually holds to next-to-leading order, yielding $Q \overset{\text{NLO}}{=} 24.3$. Phenomenologically, the preferred way to determine Q is from $\eta \to 3\pi$ decay, giving the smaller value $Q = 22.1(7)$ [36]. Lattice QCD collaborations have also reported determinations of Q. Using $N_f = 2+1$ simulations, [28] obtains $Q = 23.4 \pm 0.6$ and [29] determines $Q = 23.8 \pm 1.1$ with $N_f = 2+1+1$ simulations, which are fully compatible. These results are also compatible with $Q = 22.9 \pm 0.4$, obtained from $Q^2 = (r_s^2 - 1)(1+r)/[4(1-r)]$ and from our lattice averages for r_s and r from Eqs. (60.6) and (60.7), respectively. On the whole, the lattice results are larger than the one from phenomenology [36]. This difference could be due to surprisingly large corrections to the NLO substitution of meson masses by Q in the phenomenological determination, as suggested by the authors of [36].

The absolute normalization of the quark masses cannot be determined using chiral perturbation theory. Other methods, such as lattice simulations discussed above, or spectral function sum rules [37,38] for hadronic correlation functions reviewed next, are necessary.

60.4.3 *Sum rules*

Sum rule methods have been used extensively to determine quark masses and for illustration we briefly discuss here their application to hadronic τ decays [39]. Other applications involve very similar techniques.

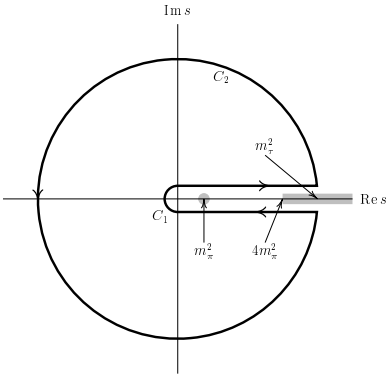

Figure 60.1: The analytic structure of $\Pi(s)$ in the complex s-plane. The contours C_1 and C_2 are the integration contours discussed in the text, and the integral over the closed contour C_1+C_2 vanishes. m_τ^2 has not been drawn to scale; $m_\tau^2 \sim 40(4m_\pi^2)$.

The experimentally measured quantity is R_τ,

$$\frac{\mathrm{d}R_\tau}{\mathrm{d}s} = \frac{\mathrm{d}\Gamma/\mathrm{d}s\left(\tau^- \to \text{hadrons} + \nu_\tau(\gamma)\right)}{\Gamma\left(\tau^- \to e^-\overline{\nu}_e\nu_\tau(\gamma)\right)} \tag{60.15}$$

the hadronic invariant mass spectrum in semihadronic τ decay, normalized to the leptonic τ decay rate. It is useful to define q as the total momentum of the hadronic final state, so $s = q^2$ is the hadronic invariant mass. The total hadronic τ decay rate R_τ is then given by integrating $\mathrm{d}R_\tau/\mathrm{d}s$ over the kinematically allowed range $0 \le s \le M_\tau^2$.

R_τ can be written as

$$R_\tau = 12\pi \int_0^{M_\tau^2} \frac{\mathrm{d}s}{M_\tau^2}\left(1 - \frac{s}{M_\tau^2}\right)^2 \times \left[\left(1 + 2\frac{s}{M_\tau^2}\right)\mathrm{Im}\,\Pi^T(s) + \mathrm{Im}\,\Pi^L(s)\right] \tag{60.16}$$

where the hadronic spectral functions $\Pi^{L,T}$ are defined from the time-ordered correlation function of two weak currents ($j^\mu(x)$ and $j^\nu(0)$) by

$$\Pi^{\mu\nu}(q) = i\int \mathrm{d}^4x\; e^{iq\cdot x}\,\langle 0|\,T\left(j^\mu(x)j^\nu(0)^\dagger\right)|0\rangle\,, \tag{60.17}$$

$$\Pi^{\mu\nu}(q) = (-g^{\mu\nu} + q^\mu q^\nu)\,\Pi^T(s) + q^\mu q^\nu \Pi^L(s), \tag{60.18}$$

and the decomposition Eq. (60.17) is the most general possible structure consistent with Lorentz invariance.

By the optical theorem, the imaginary part of $\Pi^{\mu\nu}$ is proportional to the total cross-section for the current to produce all possible states. A detailed analysis including the phase space factors leads to Eq. (60.16). The spectral functions $\Pi^{L,T}(s)$ are analytic in the complex s plane, with singularities along the real axis. There is an isolated pole at $s = m_\pi^2$, and single- and multi-particle singularities for $s \ge 4m_\pi^2$, the two-particle threshold. The discontinuity along the real axis is $\Pi^{L,T}(s + i0^+) - \Pi^{L,T}(s - i0^+) = 2i\mathrm{Im}\,\Pi^{L,T}(s)$. As a result, Eq. (60.16) can be rewritten with the replacement $\mathrm{Im}\,\Pi^{L,T}(s) \to -i\Pi^{L,T}(s)/2$, and the integration being over the contour C_1. Finally, the contour C_1 can be deformed to $-C_2$ without crossing any singularities, and so leaving the integral unchanged, i.e. the integral over the closed contour $C_1 + C_2$ vanishes. One can derive a series of sum rules analogous to Eq. (60.16) by weighting the differential τ hadronic decay rate by different powers of the hadronic invariant mass [40],

$$R_\tau^{kl} = \int_0^{M_\tau^2} \mathrm{d}s\,\left(1 - \frac{s}{M_\tau^2}\right)^k \left(\frac{s}{M_\tau^2}\right)^l \frac{\mathrm{d}R_\tau}{\mathrm{d}s}\,. \tag{60.19}$$

This leads to the final form of the sum rule(s),

$$R_\tau^{kl} = -6\pi i \int_{C_2} \frac{\mathrm{d}s}{M_\tau^2}\left(1 - \frac{s}{M_\tau^2}\right)^{2+k}\left(\frac{s}{M_\tau^2}\right)^l \times \left[\left(1 + 2\frac{s}{M_\tau^2}\right)\Pi^T(s) + \Pi^L(s)\right]. \tag{60.20}$$

The manipulations so far are completely rigorous and exact, relying only on the general analytic structure of quantum field theory. The left-hand side of the sum rule Eq. (60.20) is obtained from experiment. The right hand-side can be computed for s far away from any physical cuts using the operator product expansion (OPE) for the time-ordered product of currents in Eq. (60.16), and QCD perturbation theory. The OPE is an expansion in a series of local operators, and is an expansion about the $q \to \infty$ limit. It gives $\Pi^{L,T}(s)$ as an expansion in powers of $\alpha_s(s)$ and Λ_{QCD}^2/s, and is valid when s is far (in units of Λ_{QCD}^2) from any singularities in the complex s-plane.

The OPE gives $\Pi^{L,T}(s)$ as a series in α_s, quark masses, and various nonperturbative vacuum matrix elements. By computing $\Pi^{L,T}(s)$ theoretically, and comparing with the experimental values of R_τ^{kl}, one determines various parameters such as α_s and the quark masses. The theoretical uncertainties in using Eq. (60.20) arise from neglected higher order corrections (both perturbative and nonperturbative), and because the OPE is no longer valid near the real axis, where $\Pi^{L,T}$ have singularities. The contribution of neglected higher order corrections can be estimated as for any other perturbative computation. The error due to the failure of the OPE is more difficult to estimate. In Eq. (60.20), the OPE fails on the endpoints of C_2 that touch the real axis at $s = M_\tau^2$. The weight factor $(1 - s/M_\tau^2)$ in Eq. (60.20) vanishes at

this point, so the importance of the endpoint can be reduced by choosing larger values of k.

Light quark masses are often determined using QCD sum rules [38], which are similar to the τ sum rules. One takes the correlator of two light-quark-bilinear operators (e.g. an axial vector current), as in Eq. (60.16), and computes their Laplace transforms or moments

$$\mathcal{L}_n(\tau) = \int_0^\infty \mathrm{d}s\, s^n\, e^{-\tau s}\, \mathrm{Im}\, \Pi(s),$$
$$\mathcal{M}_n(Q^2) = \int_0^\infty \frac{\mathrm{d}s}{(s+Q^2)^n}\, \mathrm{Im}\, \Pi(s)$$

to get Laplace or moment sum rules, respectively. The quark masses are extracted by comparing the theoretical and experimental values of $\mathcal{L}_n(\tau)$ and $\mathcal{M}_n(Q^2)$. Considerable theoretical effort has gone into optimizing n and Q^2 to improve the precision of the resulting light quark masses.

60.5 Heavy quarks

60.5.1 *Continuum approaches and results*

For heavy quark physics one can exploit the fact that $m_Q \gg \Lambda_{\rm QCD}$ to construct effective theories (m_Q is the mass of the heavy quark Q). The masses and decay rates of hadrons containing a single heavy quark, such as the B and D mesons can be determined using the heavy quark effective theory (HQET) [41]. The theoretical calculations involve radiative corrections computed in perturbation theory with an expansion in $\alpha_s(m_Q)$ and nonperturbative corrections with an expansion in powers of $\Lambda_{\rm QCD}/m_Q$. Due to the asymptotic nature of the QCD perturbation series, the two kinds of corrections are intimately related; an example of this are renormalon effects in the perturbative expansion which are associated with nonperturbative corrections.

Systems containing two heavy quarks such as the Υ or J/Ψ are treated using non-relativistic QCD (NRQCD) [42]. The typical momentum and energy transfers in these systems are $\alpha_s m_Q$, and $\alpha_s^2 m_Q$, respectively, so these bound states are sensitive to scales much smaller than m_Q. However, smeared observables, such as the cross-section for $e^+e^- \to \bar{b}b$ averaged over some range of s that includes several bound state energy levels, are better behaved and only sensitive to scales near m_Q. For this reason, most determinations of the c, b quark masses using perturbative calculations compare smeared observables with experiment [43–45]. The method is similar to that outlined for τ decays. The current correlator in Eq. (60.16) is the electromagnetic current, and the experimental data is the value of $R(s)$ in the threshold region for $e^+e^- \to Q\overline{Q}$. The theoretical values for the moments are computed using renormalization group improved calculations in non-relativistic QCD.

There are many continuum extractions of the c and b quark masses, some with quoted errors of 10 MeV or smaller. There are systematic effects of comparable size, which are typically not included in these error estimates. Reference [46], for example, shows that even though the error estimate of m_c using the rapid convergence of the α_s perturbation series is only a few MeV, the central value of m_c can differ by a much larger amount depending on which algorithm (all of which are formally equally good) is used to determine m_c from the data. This leads to a systematic error from perturbation theory of around 20 MeV for the c quark and 25 MeV for the b quark. Electromagnetic effects, which also are important at this precision, are often not included. For this reason, we inflate the errors on the continuum extractions of m_c and m_b. The average values of m_c and m_b from continuum determinations are (see Sec. 60.6 for the 1S scheme)

$$\overline{m}_c(\overline{m}_c) = (1.280 \pm 0.025)\mathrm{GeV},$$

$$\overline{m}_b(\overline{m}_b) = (4.18 \pm 0.03)\,\mathrm{GeV}, \quad m_b^{1\mathrm{S}} = (4.65 \pm 0.03)\,\mathrm{GeV}.$$

60.5.2 *Lattice approaches and results*

Lattice QCD simulations of a heavy quark Q, described in a relativistic fermion formulation, lead to potentially large discretization errors which are powers of am_Q (modulated by logarithms); the leading power depends on the formulation of lattice QCD being used and in most cases is quadratic. Clearly those errors can be reduced by performing simulations at smaller lattice spacings a, but also by using *improved* discretizations of the theory, in which the leading discretization errors are systematically eliminated. Recently, with more powerful computing resources, better algorithms and techniques, it has become possible to perform simulations in the charm quark region and beyond, also decreasing the extrapolation which has to be performed to reach the b-quark. It is worth noting that computations using a relativistic fermion formulation for the valence charm with $N_f = 2+1$ sea-quark flavors, or with even $N_f = 2+1+1$ flavors and a relativistic b, suffer from partial-quenching effects. This is because the heavy valence quarks, in those calculations, are absent from the sea. While these effects are not expected to be large, they should be investigated when quoting results below the percent level, especially in the case of $N_f = 2+1$ sea-quark flavors. For that reason, we will omit relativistic heavy quark results obtained with $N_f = 2+1$ sea-quark flavors from our averages and, more generally focus on $N_f = 2+1+1$ results. Note that these partial-quenching effects can be and are accounted for systematically in lattice calculations in which the heavy valence quarks are described by HQET or NRQCD.

Traditionally the charm quark mass is obtained by tuning its bare, simulation input value to reproduce the physical mass of charmonium mesons or of the D, D_s mesons (requiring a more precise tuning of the light quark masses). This mass can then be renormalized and matched to the $\overline{\rm MS}$ scheme using the methods discussed for the light quarks.

An alternative approach for obtaining the $\overline{\rm MS}$ mass from the tuned bare quark mass was proposed in [47]. Euclidean-time moments of pseudoscalar, two-point functions of $c\bar{c}$ quark-bilinear operators can readily be computed on the lattice and extrapolated to the continuum limit where they can be compared to perturbative calculations of the same quantities at 4-loop order. In this way, both the strong coupling constant and the charm quark mass can be determined with remarkably small errors. As this approach uses the same perturbative expressions for two-point correlators as the continuum determinations discussed above, it suffers from similar perturbation-theory, systematic errors. FLAG [8] has reviewed lattice determinations of the charm quark mass obtained using both approaches. For their $N_f = 2+1$ average they retain the results [10, 48–50], with [51] being published after their deadline. As stated above, we focus here on $N_f = 2+1+1$ results. For these, the quoted average is

$$\overline{m}_c(\overline{m}_c) = 1.278(13)\,\mathrm{GeV},$$

based on the results of [16, 17, 19, 22, 52, 53], in good agreement with the continuum result given above, but with a smaller error. Compared to the previous editions of the FLAG [23] and of the present reviews, [53] updates [18] and [22] has appeared, but did not make the FLAG deadline.

It is worth noting that three [17, 18, 53] of the five results entering this average agree, while the two others [19, 52] are over 2 standard deviations larger, a deviation confirmed by [22]. This is taken into account by stretching errors in the usual way, but the total uncertainty on the lattice average of $\overline{m}_c$ will not significantly be reduced until this discrepancy is resolved. It should also be noted that [53] includes QED directly in the lattice calculation, albeit only for valence quarks, while some of the other computations account for these effects using phenomenology. For the moment these effects are still significantly smaller than the quoted error bars, at least when $\overline{m}_c$ is determined using the mass of the J/ψ.

Historically, the main approach to controlling the discretization errors in lattice studies of b quark physics was to perform simulations of effective theories such as HQET and NRQCD. This remains an important technique, both in its own right and in providing additional information for extrapolations from lower masses to the bottom region. Using effective theories, m_b is obtained from what is essentially a computation of the difference of $M_{H_b} - m_b$, where M_{H_b} is the mass of a hadron H_b containing a b-quark. The relative error on m_b is therefore much smaller

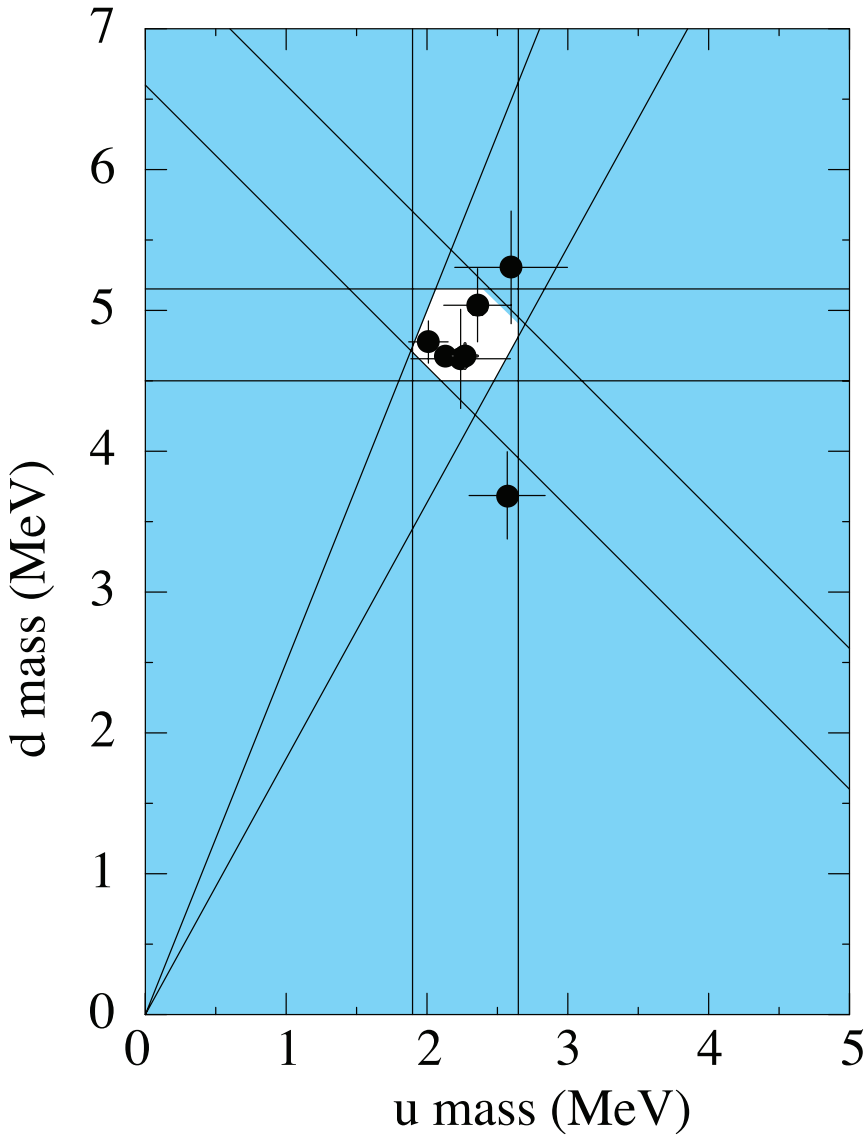

Figure 60.2: The allowed region (shown in white) for up quark and down quark masses renormalized in the $\overline{\rm MS}$ scheme at 2 GeV. This region was determined in part from papers reporting values for m_u and m_d (data points shown) and in part from an analysis of the allowed ranges of other mass parameters (see Fig. 60.3). The parameter $(m_u + m_d)/2$ yields the two downward-sloping lines, while m_u/m_d yields the two rising lines originating at (0,0). There are two overlapping data points, so one of them is shown as a white diamond (it has very small error bars).

than that for $M_{H_b} - m_b$. The principal systematic errors are the matching of the effective theories to QCD and the presence of power divergences in a^{-1} in the $1/m_b$ corrections which have to be subtracted numerically. A procedure for performing these subtractions fully nonperturbatively was proposed and implemented for the first time in [54].

The most recent lattice QCD determinations of the b quark mass rely on a variety of approaches, including Euclidean-time moments of correlation functions with [55] or without NRQCD [56] and HQET based interpolations [57,58] or extrapolations [17] from above the charm to the b region. Compared to the previous editions of the FLAG [23] and of the present reviews, [56] updates [16] with a significantly reduced error bar. The overall agreement of the results obtained using these very different approaches, which have different systematic errors, is a confirmation that the various groups control these uncertainties. As the range of heavy-quark masses which can be used in numerical simulations increases, results obtained by extrapolating the results to the physical b mass are becoming ever more reliable (see e.g. [17]). FLAG's compilation [8] of the above $N_f = 2+1+1$ results yields

$$\overline{m}_b(\overline{m}_b) = 4.203(11)\,\text{GeV}\ ,$$

barely changed from the previous edition. Again, this result is compatible with the average value of continuum results, but with a significantly smaller uncertainty. Note that FLAG [8] also provides an average of $N_f = 2+1$ results, taken from [10, 50]. It is about 1.4 combined, standard deviations lower that the result quoted above.

As explained in Sec. 60.3, ratios of quark masses can have significantly smaller errors than the individual masses if they are determined within the same lattice QCD framework (up to small electromagnetic corrections for quarks of different charge). This led HPQCD to leverage their precise determination of m_c [47] to determine m_s and m_{ud} [59], through a precise computation of m_c/m_s [59] and of m_s/m_{ud} [60]. The $N_f = 2+1$ calculation [59] was updated using $N_f = 2+1+1$ simulations in [16]. The ratio m_s/m_c was also computed in [24,48] with $N_f = 2+1$ simulations and in [17,19] with $N_f = 2+1+1$ ones. The results of [19] should be replaced by those of [22] once the latter are published. Based

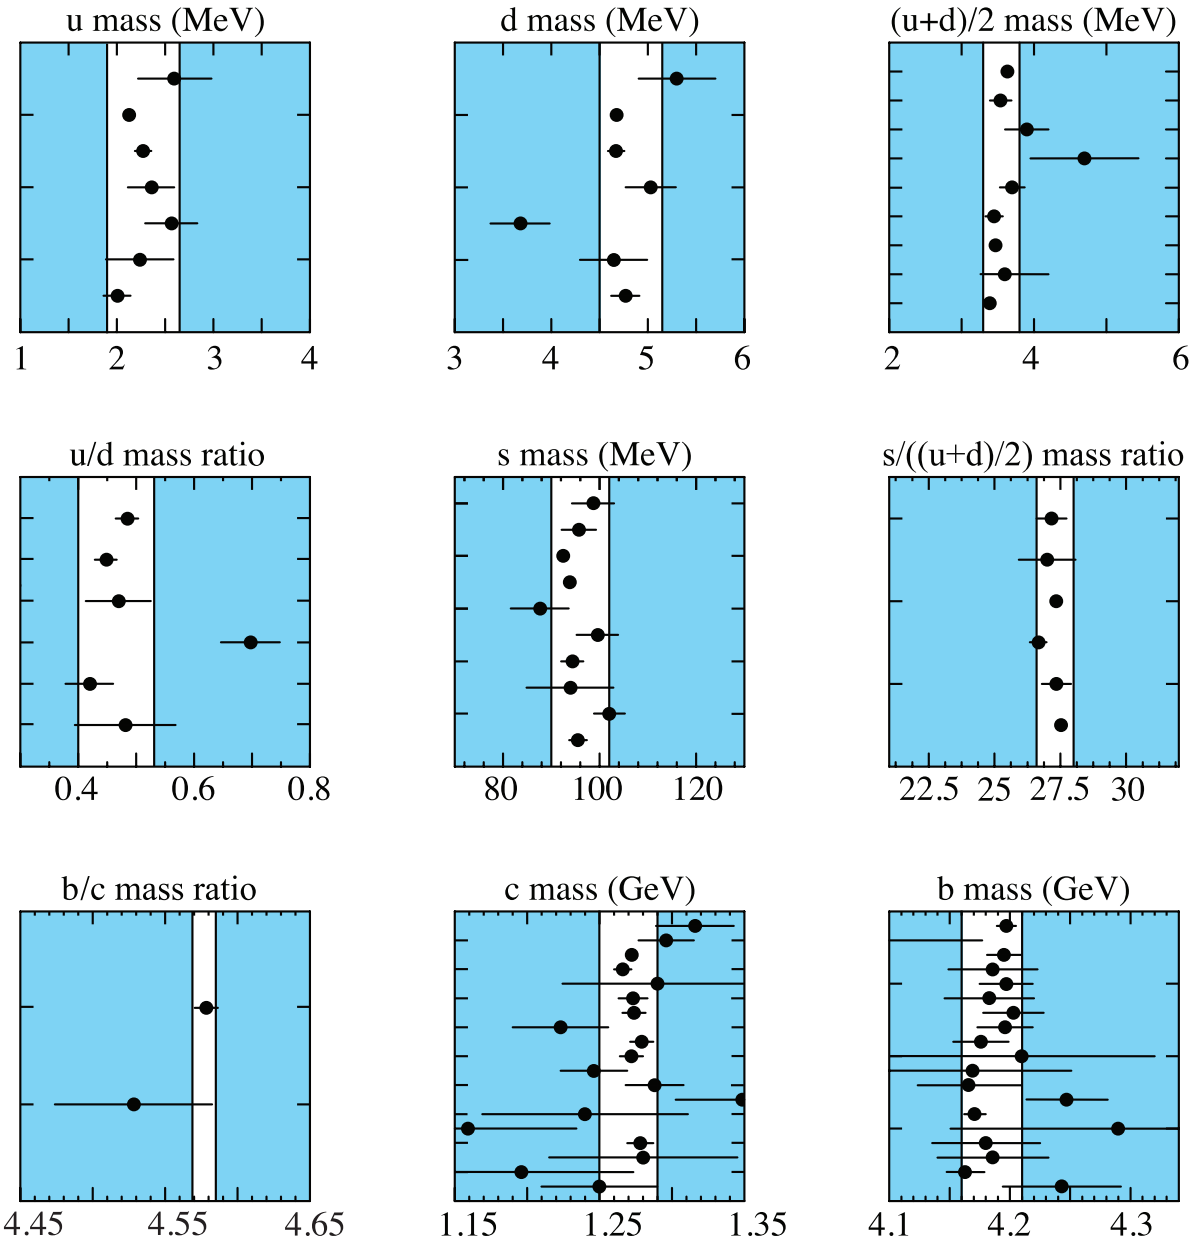

Figure 60.3: The values of each quark mass parameter taken from the Data Listings. The points are in chronological order with the more recent measurements at the top. The shaded regions indicate values excluded by our evaluations; some regions were determined in part through examination of Fig. 60.2.

on [48,59], FLAG [8] quotes $m_c/m_s = 11.82(16)$ for $N_f = 2+1$, and $m_c/m_s = 11.769(35)$ for $N_f = 2+1+1$, based on [16,17,19], where a ∼50% stretch of the error bars was applied due to tensions among the results. The latter average is completely dominated by the result of [17] that has a substantially smaller error than the other results. As a final lattice number we give the $N_f = 2+1+1$ average

$$m_c/m_s = 11.769(35),$$

which is renormalization scheme and scale independent (in the absence of electromagnetic corrections) and is identical to the one given in the last edition of the present review.

The ratio m_b/m_c has also been computed on the lattice. The two $N_f = 2+1$ results which satisfy FLAG's criteria are [10,50]. Here, as explained above, we focus on $N_f = 2+1+1$ calculations [17,56,57]. Amongst these, [56] updates [16], used in the previous edition of the present review, with a substantially reduced error. Averaging these results yields

$$m_b/m_c = 4.579(9),$$

where a scale factor of $\sqrt{\chi^2/\mathrm{dof}} = 1.38$ has been applied to the error bar. Indeed, [57] contributes 3.5 to the total χ^2. Note that [56] is the only calculation which accounts for QED directly in the lattice simulations, albeit only for valence quarks, and thus must specify the renormalization scheme and scale of its result, which it chooses to be $\overline{\mathrm{MS}}$ at 3 GeV.

60.5.3 *Warnings concerning the use of the pole mass*

For an observable particle such as the electron, the position of the pole in the propagator is the definition of its mass. In QCD this definition of the quark mass is known as the pole mass. It is known that the on-shell quark propagator has no infrared divergences in perturbation theory [61,62], so this provides a perturbative definition of the quark mass. However, the pole mass cannot be used to arbitrarily high accuracy because of nonperturbative infrared effects in QCD. In fact the full quark propagator has no pole because the quarks are confined, so that the pole mass cannot be defined outside of perturbation theory. The relation between the pole mass m_Q and the $\overline{\mathrm{MS}}$ mass $\overline{m}_Q$, used throughout this

review, is known to three loops [63–66]

$$m_Q = \overline{m}_Q(\overline{m}_Q)\Bigg\{1 + \frac{4\overline{\alpha}_s(\overline{m}_Q)}{3\pi} + \left[-1.0414\sum_q\left(1 - \frac{4}{3}\frac{\overline{m}_q}{\overline{m}_Q}\right) + 13.4434\right]\left[\frac{\overline{\alpha}_s(\overline{m}_Q)}{\pi}\right]^2 + \left[0.6527N_L^2 - 26.655N_L + 190.595\right]\left[\frac{\overline{\alpha}_s(\overline{m}_Q)}{\pi}\right]^3\Bigg\}, \tag{60.21}$$

where $\overline{\alpha}_s(\mu)$ is the strong interaction coupling constants in the $\overline{\rm MS}$ scheme, and the sum over q extends over the N_L flavors lighter than Q. The complete mass dependence of the α_s^2 term can be found in [63]; the mass dependence of the α_s^3 term is not known. For the b-quark, Eq. (60.21) reads

$$m_b = \overline{m}_b\,(\overline{m}_b)\,[1 + 0.10 + 0.05 + 0.03]\,, \tag{60.22}$$

where the contributions from the different orders in α_s are shown explicitly. The two and three loop corrections are comparable in size and have the same sign as the one loop term. This is a signal of the asymptotic nature of the perturbation series (there is a renormalon in the pole mass [67]). Such a badly behaved perturbation expansion can be avoided by directly extracting, from data, the mass defined in the $\overline{\rm MS}$ (used in this review) or other short-distance schemes (see below), without invoking the pole mass as an intermediate step.

60.6 Numerical values and caveats

The quark masses in the particle data listings have been obtained by using a wide variety of methods. Each method involves its own set of approximations and uncertainties. In most cases, the errors are an estimate of the size of neglected higher-order corrections or other uncertainties. The expansion parameters for some of the approximations are not very small (for example, they are $m_K^2/\Lambda_\chi^2 \sim 0.25$ for the SU(3) chiral expansion and $\Lambda_{\rm QCD}/m_b \sim 0.1$ for the heavy-quark expansion), so an unexpectedly large coefficient in a neglected higher-order term could significantly alter the results. Thus, before using a particular result, it is important to understand the possible limitations of the approach used to obtain it. It is also important to note that the quark mass values can be significantly different in the different schemes.

We have specified all masses in the $\overline{\rm MS}$ scheme. For light quarks, the renormalization scale has been chosen to be $\mu = 2$ GeV. Quoting these masses at smaller values of μ, where perturbative corrections become significantly larger, would introduce unnecessary uncertainties in the results. In fact, as lattice calculations, performed on finer and finer lattices, allow to determine quark masses, fully nonperturbatively, at larger and larger values of μ, it may become advantageous to quote quark mass results at renormalization scales above 2 GeV, where perturbative uncertainties are smaller.

The heavy quark masses obtained using HQET, QCD sum rules, or lattice gauge theory are consistent with each other if they are all converted into the same scheme and scale. For these quarks it is conventional to choose the renormalization scale equal to the quark mass, so we have quoted $\overline{m}_Q(\mu)$ at $\mu = \overline{m}_Q$ for the c and b quarks. Given the small size of the charm quark mass, in the future it may become advantageous to quote its value at larger values of μ so as not to introduce unnecessary perturbative uncertainties (see discussion above). Analyses of inclusive B meson decays have shown that other mass definitions lead to a better behaved perturbation series than for the $\overline{\rm MS}$ mass, and hence to more accurate mass values [68–71]. Thus, we have chosen to also give values for one of these, the b quark mass in the 1S scheme [68, 69]. Other schemes that have been proposed are the PS-scheme [70], the kinetic scheme [72] and, most recently, the minimal renormalon-subtracted mass (MRS) [71] used in the lattice calculation [17].

If necessary, we have converted values in the original papers to our chosen scheme using two-loop formulæ. It is important to realize that our conversions introduce significant additional errors. In converting to the $\overline{\rm MS}$ b-quark mass, for example, the three-loop conversions from the 1S and pole masses give values about 35 MeV and 135 MeV lower than the two-loop conversions. The uncertainty in $\alpha_s(M_Z) = 0.1179 \pm 0.0010$ [1] gives an uncertainty of ± 9 MeV and ± 21 MeV respectively in the same conversions. We have not added these additional errors when we do our conversions. The α_s value in the conversion is correlated with the α_s value used in determining the quark mass, so the conversion error is not a simple additional error on the quark mass.

61. Top Quark

Revised September 2021 by T.M. Liss (City Coll. of New York), F. Maltoni (CP3 U. catholique de Louvain; Bologna U.) and A. Quadt (Göttingen U.).

61.1 Introduction

In the Standard Model (SM), the left-handed top quark is the $Q = 2/3$, $T_3 = +1/2$ member of the weak-isospin doublet containing the bottom quark, while the right-handed top is an $SU(2)_L$ singlet (see, e.g., the review "Electroweak Model and Constraints on New Physics" here). Its phenomenology is driven by its large mass. Being heavier than a W boson, it is the only quark that decays semi-weakly, i.e., into a real W boson and a b quark. This results in a lifetime that is shorter than the hadronization time. In addition, it is the only quark whose Yukawa coupling to the Higgs boson is of order unity. For these reasons, the top quark plays a special role in the Standard Model and in many extensions thereof. Top quark physics provides a unique laboratory where our understanding of the strong, both in the perturbative and non-perturbative regimes, and electroweak interactions can be tested. An accurate knowledge of its properties (mass, couplings, production cross sections, decay branching ratios, *etc.*) can bring key information on fundamental interactions at the electroweak symmetry-breaking scale and beyond. This review provides a concise discussion of the experimental and theoretical issues involved in the determination of the top-quark properties.

61.2 Top-quark production at the Tevatron and LHC

In hadron collisions, top quarks are produced dominantly in pairs through the processes $q\bar{q} \to t\bar{t}$ and $gg \to t\bar{t}$, at leading order in QCD. At the Tevatron ($p\bar{p}$ at 1.96 TeV) approximately 85% of the production cross section is from $q\bar{q}$ annihilation, with the remainder from gluon-gluon fusion. Conversely, at the LHC about 90% (80%) of $t\bar{t}$ production is from gluon-gluon fusion at $\sqrt{s} = 13$ TeV ($\sqrt{s} = 7$ TeV).

Predictions for the top-quark production total cross sections are available at next-to-next-to leading order (NNLO) [1, 2], also including next-to-next-to-leading-log (NNLL) soft gluon resummation. Assuming a top-quark mass of 173.3 GeV/c^2, close to the Tevatron + LHC combination [3], the resulting theoretical prediction of the top-quark pair cross-section at NNLO+NNLL accuracy at the Tevatron at $\sqrt{s} = 1.96$ TeV is $\sigma_{t\bar{t}} = 7.16^{+0.11+0.17}_{-0.20-0.12}$ pb where the first uncertainty is from scale dependence and the second from parton distribution functions. At the LHC, assuming a top-quark mass of 172.5 GeV/c^2 the cross sections are: $\sigma_{t\bar{t}} = 177.3^{+4.6+9.0}_{-6.0-9.0}$ pb at $\sqrt{s} = 7$ TeV, $\sigma_{t\bar{t}} = 252.9^{+6.4+11.7}_{-8.6-11.7}$ pb at $\sqrt{s} = 8$ TeV, $\sigma_{t\bar{t}} = 831.8^{+19.8+35.1}_{-29.2-35.1}$ pb at $\sqrt{s} = 13$ TeV, and $\sigma_{t\bar{t}} = 984.5^{+23.2+41.3}_{-34.7-41.3}$ pb at $\sqrt{s} = 14$ TeV [1].

Electroweak single top-quark production mechanisms, namely from $q\bar{q}' \to t\bar{b}$ [4], $qb \to q't$ [5], mediated by virtual s-channel and t-channel W-bosons, and Wt-associated production, through $bg \to W^-t$, lead to somewhat smaller cross sections. For example, t-channel production, while suppressed by the weak coupling with respect to the strong pair production, is kinematically enhanced, resulting in a sizeable cross section both at Tevatron and LHC energies. At the Tevatron, the t- and s-channel cross sections for top quarks are identical to those for antitop quarks , while at the LHC they are not, due to the charge-asymmetric initial state. NNLO cross sections for t-channel single top-quark production ($t + \bar{t}$) are calculated for $m_t = 173.2$ GeV/c^2 to be $2.08^{+0.04+0.08}_{-0.03-0.10}$ pb in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV, where the first uncertainty is from scale dependence and the second from parton distribution functions. [6]. A calculation at NNLO accuracy for the t-channel cross section at the LHC has first appeared in [7], superseded by more recent calculations [6,8] which predict ($m_t = 172.5$ GeV/c^2): $\sigma_{t+\bar{t}} = 64.0^{+0.77}_{-0.38}$ pb at $\sqrt{s} = 7$ TeV, $\sigma_{t+\bar{t}} = 84.6^{+1.0}_{-0.5}$ pb at $\sqrt{s} = 8$ TeV, $\sigma_{t+\bar{t}} = 215^{+2.1}_{-1.3}$ pb at $\sqrt{s} = 13$ TeV, and $\sigma_{t+\bar{t}} = 245^{+2.7}_{-1.3}$ pb at $\sqrt{s} = 14$ TeV, where the quoted uncertainties are from scale variation only. For the s-channel, NNLO approximated calculations yield $1.03^{+0.05}_{-0.05}$ pb for the Tevatron [9]. An NLO calculation gives $4.3^{+0.13+0.14}_{-0.10-0.14}$ pb, $5.2^{+0.15+0.16}_{-0.12-0.16}$ pb, and $10.3^{+0.29+0.27}_{-0.24-0.27}$ pb for $\sqrt{s} = 7, 8, 13$ TeV at the LHC, respectively, with 64%, 64%, 62%, of top quarks. While negligible at the Tevatron, at LHC energies the Wt-associated production becomes relevant. At $\sqrt{s} = 7, 8, 13$ TeV, an approximate NNLO calculation gives $(t + \bar{t})$, $15.7^{+0.4+1.10}_{-0.4-1.14}$ pb , $22.4^{+0.6+1.40}_{-0.6-1.40}$ pb , $71.7^{+1.8+3.40}_{-1.8-3.40}$ pb , respectively, with an equal proportion of top and anti-top quarks [10].

Assuming $|V_{tb}| \gg |V_{td}|, |V_{ts}|$ (see the review "The CKM Quark-Mixing Matrix" for more information), the cross sections for single top production are proportional to $|V_{tb}|^2$, and no extra hypothesis is needed on the number of quark families or on the unitarity of the CKM matrix in extracting $|V_{tb}|$. Separate measurements of the s- and t-channel processes provide sensitivity to physics beyond the Standard Model [11].

With a mass above the Wb threshold, and $|V_{tb}| \gg |V_{td}|$, $|V_{ts}|$, the decay width of the top quark is expected to be dominated by the two-body channel $t \to Wb$. Neglecting terms of order m_b^2/m_t^2, α_s^2, and $(\alpha_s/\pi)M_W^2/m_t^2$, the width predicted in the SM at NLO is [12]:

$$\Gamma_t = \frac{G_F m_t^3}{8\pi\sqrt{2}} \left(1 - \frac{M_W^2}{m_t^2}\right)^2 \left(1 + 2\frac{M_W^2}{m_t^2}\right) \left[1 - \frac{2\alpha_s}{3\pi}\left(\frac{2\pi^2}{3} - \frac{5}{2}\right)\right], \tag{61.1}$$

where m_t refers to the top-quark pole mass. The width for a value of $m_t = 173.3$ GeV/c^2 is 1.35 GeV/c^2 (we use $\alpha_s(M_Z) = 0.118$) and increases with mass. With its correspondingly short lifetime of about 0.5×10^{-24} s, the top quark is expected to decay before top-flavored hadrons or $t\bar{t}$-quarkonium-bound states can form [13]. In fact, since the decay time is close to the would-be-resonance binding time, a peak will be visible in e^+e^- scattering at the $t\bar{t}$ threshold [14] and it is in principle present (yet very difficult to measure) in hadron collisions too [15, 16]. The order α_s^2 QCD corrections to Γ_t are also available [17], thereby improving the overall theoretical accuracy to better than 1%.

The final states for the leading pair-production process can be divided into three classes:

A. $t\bar{t} \to W^+ b\, W^- \bar{b} \to q\bar{q}'\, bq''\, \bar{q}'''\, \bar{b}$, (45.7%)
B. $t\bar{t} \to W^+ b\, W^- \bar{b} \to q\bar{q}'\, b\ell^-\bar{\nu}_\ell\, \bar{b} + \ell^+\nu_\ell\, b\, q''\bar{q}'''\, \bar{b}$, (43.8%)
C. $t\bar{t} \to W^+ b\, W^- \bar{b} \to \ell^+\, \nu_\ell\, b\, \ell'^-\bar{\nu}_{\ell'}\, \bar{b}$. (10.5%)

The quarks in the final state evolve into jets of hadrons. A, B, and C are referred to as the all-hadronic, lepton+jets (ℓ+jets), and dilepton ($\ell\ell$) channels, respectively. Their relative contributions, including hadronic corrections, are given in parentheses assuming lepton universality. While ℓ in the above processes refers to e, μ, or τ, most of the analyses distinguish the e and μ from the τ channel, which is more difficult to reconstruct. Therefore, in what follows, we will use ℓ to refer to e or μ, unless otherwise noted. Here, typically leptonic decays of τ are included. In addition to the quarks resulting from the top-quark decays, extra QCD radiation (quarks and gluons) from the colored particles in the event can lead to extra jets.

The number of jets reconstructed in the detectors depends on the decay kinematics, as well as on the algorithm for reconstructing jets used by the analysis. Information on the transverse momenta, p_T of the neutrinos is obtained from the imbalance in transverse momentum measured in each event (missing p_T, which is here also called missing transverse energy, E_T).

The identification of top quarks in the electroweak single top channel is much more difficult than in the QCD $t\bar{t}$ channel, due to a less distinctive signature and significantly larger backgrounds, mostly due to $t\bar{t}$ and W+jets production.

Fully exclusive predictions via Monte Carlo generators for the $t\bar{t}$ and single top production processes at NLO accuracy in QCD, including top-quark decays and possibly off-shell effects are available [18,19] through the MC@NLO [20] and POWHEG [21] methods. Very recently, the first Monte Carlo implementation of the NNLO computation has become available [22].

Besides fully inclusive QCD or EW top-quark production, more exclusive final states can be accessed at hadron colliders, whose

cross sections are typically much smaller, yet can provide key information on the properties of the top quark. For all relevant final states (*e.g.*, $t\bar{t}V$, $t\bar{t}VV$ with $V = \gamma, W, Z$, $t\bar{t}H, t\bar{t}$+jets, $t\bar{t}b\bar{b}, t\bar{t}t\bar{t}$) automatic or semi-automatic predictions at NLO accuracy both in QCD and EW expansions, also in the form of event generators are available (see the review "Monte Carlo event generators" for more information).

61.3 Top-quark measurements

Since the discovery of the top quark, direct measurements of $t\bar{t}$ production have been made at six center-of-mass energies in pp or $p\bar{p}$ and in pPb collisions, providing stringent tests of QCD. The first measurements were made in Run I at the Tevatron at $\sqrt{s} = 1.8$ TeV. In Run II at the Tevatron relatively precise measurements were made at $\sqrt{s} = 1.96$ TeV. Finally, beginning in 2010, measurements have been made at the LHC at $\sqrt{s} = 7$ TeV, $\sqrt{s} = 8$ TeV, and $\sqrt{s} = 13$ TeV, and recently also in dedicated low energy runs at $\sqrt{s} = 5.02$ in pp and at 8.16 TeV in pPb collisions.

Production of single top quarks through electroweak interactions has now been measured with good precision at the Tevatron at $\sqrt{s} = 1.96$ TeV, and at the LHC at $\sqrt{s} = 7$ TeV, $\sqrt{s} = 8$ TeV, and also at $\sqrt{s} = 13$ TeV. Measurements at the Tevatron have managed to separate the s- and t-channel production cross sections, and at the LHC, the tW mechanism as well, though the t-channel is measured with best precision to date. The measurements allow an extraction of the CKM matrix element V_{tb}. Also more exclusive production modes and top-quark properties have been measured in single-top production.

With approximately 10 fb^{-1} of Tevatron data, and almost 5 fb^{-1} at 7 TeV, 20 fb^{-1} at 8 TeV and 139 fb^{-1} at 13 TeV at the LHC, many properties of the top quark have been measured with high precision. These include properties related to the production mechanism, such as $t\bar{t}$ spin correlations, forward-backward or charge asymmetries, and differential production cross sections, as well as properties related to the tWb decay vertex, such as the helicity of the W-bosons from the top-quark decay. Also studies of the $t\bar{t}b\bar{b}$, $t\bar{t}t\bar{t}$, $t\bar{t}\gamma$, $t\bar{t}Z$, $t\bar{t}h$, th, tZq or $t\gamma q$ processes and the corresponding vertices as well as contact interactions have been made, some yielding first observations, others strong evidence. Those processes probe genuinely new aspects of the top-quark such as electroweak couplings to neutral gauge bosons or possibly four-top-quark interactions. In addition, many searches for physics beyond the Standard Model are being performed with increasing reach in both production and decay channels.

In the following sections we review the current status of measurements of the characteristics of the top quark.

61.3.1 *Top-quark production*

61.3.1.1 $t\bar{t}$ *production*

Fig. 61.1 summarizes the $t\bar{t}$ production cross-section measurements from both, the Tevatron and LHC. Please note that some cross section measurements at the LHC have luminosity-related uncertainties which have improved in the meantime [23]. The latest measurement from DØ [24] ($p\bar{p}$ at $\sqrt{s} = 1.96$ TeV), combining the measurements from the dilepton and lepton plus jets final states in 9.7 fb^{-1}, is 7.26 ± 0.13 (stat.)$^{+0.57}_{-0.50}$ (syst.) pb (7.5%). From CDF the most precise measurement made [25] is in 8.8 fb^{-1} in the dilepton channel requiring at least one b-tag, yielding 7.09 ± 0.84 pb. Both of these measurements assume a top-quark mass of 172.5 GeV/c^2. The dependence of the cross-section measurements on the value chosen for the mass is less than that of the theory calculations because it only affects the determination of the acceptance. In some analyses also the shape of topological variables might be modified.

Combining the recent cross section measurements with older ones in other channels yields $\sigma_{t\bar{t}} = 7.63 \pm 0.50$ pb (6.6%) for CDF, $\sigma_{t\bar{t}} = 7.56 \pm 0.59$ pb (7.8%) for DØ and $\sigma_{t\bar{t}} = 7.60 \pm 0.41$ pb (5.4%) for the Tevatron combination [26]. The contributions to the uncertainty are 0.20 pb from statistical sources, 0.29 pb from systematic sources, and 0.21 pb from the uncertainty on the integrated luminosity. The combined result is in good agreement with the SM expectation of $7.35^{+0.28}_{-0.33}$ pb at NNLO+NNLL in perturbative QCD [1] for a top mass of 172.5 GeV/c^2.

CDF has measured the $t\bar{t}$ production cross section in the dilepton channel with one hadronically decaying tau in 9.0 fb^{-1}, yielding $\sigma_{t\bar{t}} = 8.1 \pm 2.1$ pb. By separately identifying the single-tau and the ditau components, they measure the branching fraction of the top quark into the tau lepton, tau neutrino, and bottom quark to be (9.6 ± 2.8)% [27]. CDF has also performed measurements of the $t\bar{t}$ production cross section normalized to the Z production cross section in order to reduce the impact of the luminosity uncertainty [28].

DØ has performed a measurement of differential $t\bar{t}$ cross sections in 9.7 fb^{-1} of lepton+jets data as a function of the transverse momentum, and absolute value of the rapidity of the top quarks as well as of the invariant mass of the $t\bar{t}$ pair [29]. Observed differential cross sections are consistent with SM predictions.

The LHC experiments ATLAS and CMS use similar techniques to measure the $t\bar{t}$ cross section in pp collisions. The most precise measurements come from the dilepton channel, and in particular the $e\mu$ channel. In order to test consistency of the cross-section measurements with some systematic uncertainties cancelling out while testing pQCD and PDFs, cross-section ratios between measurements at 7 TeV and at 8 TeV are performed and quoted in several cases. In other cases, the cross-section ratio between $t\bar{t}$- and Z-production is determined as that is independent of luminosity uncertainties, but keeps its sensitivity to the ratio of gluon versus quark PDFs. These experimental results should be compared to the theoretical calculations at NNLO+NNLL that yield $7.16^{+0.20}_{-0.23}$ pb for top-quark mass of 173.3 GeV/c^2 [1] at $\sqrt{s} = 1.96$ TeV, $68.2 \pm 4.8^{+1.9}_{-2.3}$ pb [30] for top-quark mass of 172.5 GeV/c^2 at $\sqrt{s} = 5$ TeV, and for top-quark mass of 173.3 GeV/c^2 $\sigma_{t\bar{t}} = 173.6^{+4.5+8.9}_{-5.9-8.9}$ pb at $\sqrt{s} = 7$ TeV, $\sigma_{t\bar{t}} = 247.7^{+6.3+11.5}_{-8.5-11.5}$ pb at $\sqrt{s} = 8$ TeV, and $\sigma_{t\bar{t}} = 816.0^{+19.4+34.4}_{-28.6-34.4}$ pb at $\sqrt{s} = 13$ TeV, at the LHC [1]. In a special run, ATLAS recorded 257 pb^{-1} at $\sqrt{s} = 5.02$ TeV. Using opposite charged dilepton events and counting the number of b-jets, they perform a fit including m_{ll} information to constrain Z+jets background, yielding a result of $\sigma_{t\bar{t}} = 66.0 \pm 4.9$ pb, giving a total uncertainty of 7.5% [31]. CMS has measured the $t\bar{t}$ production cross section at $\sqrt{s} = 5.02$ TeV, accumulating 27.4 pb^{-1}. The measurement is performed by analyzing events with at least one charged lepton. The measured cross section is $\sigma_{t\bar{t}} = 69.5 \pm 8.4$ pb [32], in agreement with the expectation from the Standard Model. Recently, they performed a measurement in opposite-sign $e\mu$-dilepton events with at least two jets using 304 pb^{-1}. They obtain a Drell-Yan scale factor under the Z-boson mass to estimate the background and extract a cross section using a counting technique of $\sigma_{t\bar{t}} = 60.3 \pm 5.8$ pb. The combination of the two results yields $\sigma_{t\bar{t}} = 62.6 \pm 4.1(stat.) \pm 3.0(syst. + lumi.)$ pb with 7.9% total relative uncertainty [33]. At $\sqrt{s} = 7$ TeV, ATLAS uses 4.6 fb^{-1} of $e\mu$ events in which they select an extremely clean sample and determine the $t\bar{t}$ cross section simultaneously with the efficiency to reconstruct and tag b-jets, yielding $\sigma_{t\bar{t}} = 182.9 \pm 7.1$ pb, corresponding to 3.9% precision [34]. Other measurements by ATLAS at $\sqrt{s} = 7$ TeV, include a measurement in 0.7 fb^{-1} in the lepton+jets channel [35], in the dilepton channel [36], and in 1.02 fb^{-1} in the all-hadronic channel [37], which together yield a combined value of $\sigma_{t\bar{t}} = 177 \pm 3(stat.)^{+8}_{-7}(syst.) \pm 7(lumi.)$ pb (6.2%) assuming $m_t = 172.5$ GeV/c^2 [38]. Further analyses in the hadronic τ plus jets channel in 1.67 fb^{-1} [39] and the hadronic τ + lepton channel in 2.05 fb^{-1} [40], and the all-hadronic channel in 4.7 fb^{-1} [41] yield consistent albeit less precise results. Another simultaneous measurement of the $t\bar{t}, W^+W^-$, and $Z/\gamma^* \to \tau\tau$ cross section using the full 7 TeV dataset with 4.6 fb^{-1} yields $\sigma_{t\bar{t}} = 181 \pm 11$ pb, corresponding to a 6% precision [42]. The most precise measurement from CMS at $\sqrt{s} = 7$ TeV is also obtained in the dilepton channel, where they measure $\sigma_{t\bar{t}} = 161.9 \pm 2.5(stat.)^{+5.1}_{-5.0}(syst.) \pm 3.6(lumi.)$ pb, corresponding to a 4.2% precision [43]. Other measurements at $\sqrt{s} = 7$ TeV from CMS include measurements with 2.3 fb^{-1} in the e/μ+jets channel [44], with 3.5 fb^{-1} in the all-hadronic channel [45], with 2.2 fb^{-1} in the lepton+τ channel [46], and with 3.9 fb^{-1} in the τ+jets channel [47]. ATLAS and CMS also provide a combined cross section at $\sqrt{s} = 7$ TeV of $173.3 \pm 2.3(stat.) \pm$

$7.6(syst.) \pm 6.3(lumi.)$ pb using slightly older results based on $0.7-1.1$ fb^{-1} [48]. At $\sqrt{s} = 8$ TeV, ATLAS measures the $t\bar{t}$ cross section with 20.3 fb^{-1} using $e\mu$ dilepton events, with a simultaneous measurement of the $b-$tagging efficiency, yielding $\sigma_{t\bar{t}} = 242.9 \pm 1.7(stat.) \pm 5.5(syst.) \pm 5.1(lumi.) \pm 4.2(beam\,energy)$ pb [49] assuming $m_t = 172.5$ GeV/c^2, which corresponds to a 3.6% precision. In the $\ell + jets$ channel, they measure $\sigma_{t\bar{t}} = 260 \pm 1(stat.)^{+20}_{-23}(syst.) \pm 8(lumi.) \pm 4(beam\,energy)$ pb [50] in 20.3 fb^{-1} using a likelihood discriminant fit and b-jet identification. Subsequently, ATLAS performed a new analysis in 20.2 fb^{-1} $\ell+jets$ events. They model the $W+$jets background using $Z+$jets data and employ neural networks in three jet-multiplicity and b-jet multiplicity regions for the signal and background separation, yielding $\sigma_{t\bar{t}} = 248.3 \pm 0.7(stat.) \pm 13.4(syst.) \pm 4.7(lumi.)$ pb [51]. ATLAS also performed a cross section measurement in the hadronic $\tau+$jets channel yielding consistent, albeit less precise results [52]. CMS performs a template fit to the M_{lb} mass distribution using 19.6 fb^{-1} in the lepton+jets channel yielding $\sigma_{t\bar{t}} = 228.5 \pm 3.8(stat.) \pm 13.7(syst.) \pm 6.0(lumi.)$ pb [53, 54], which corresponds to a 6.7% precision. These 8 TeV measurements are in agreement with QCD predictions up to NLO accuracy. In the $e\mu$ channel, initially using 5.3 fb^{-1} [54] and then using 19.7 fb^{-1}, the cross sections are extracted using a binned likelihood fit to multi-differential final state distributions related to identified b quark and other jets in the event, yielding $\sigma_{t\bar{t}} = 244.9 \pm 1.4(stat.)^{+6.3}_{-5.5}(sys.) \pm 6.4(lumi.)$ pb [55]. The cross section and its ratio between 7 TeV and 8 TeV measurements are found to be consistent with pQCD calculations. The cross section is also measured in the hadronic $\tau+$jets channel, yielding $\sigma_{t\bar{t}} = 257 \pm 3(stat.) \pm 24(syst.) \pm 7(lumi.)$ pb [56] and in the all-hadronic final state giving $\sigma_{t\bar{t}} = 275.6 \pm 6.1(stat.) \pm 37.8(syst.) \pm 7.2(lumi.)$ pb [57]. In combination of the most precise $e\mu$ measurements in $5.3-20.3$ fb^{-1}, ATLAS and CMS together yield at 8 TeV $\sigma_{t\bar{t}} = 241.5 \pm 1.4(stat.) \pm 5.7(syst.) \pm 6.2(lumi.)$ pb [58], which corresponds to a 3.5% precision, challenging the precision of the corresponding theoretical predictions. The LHCb collaboration presented the first observation of top-quark production in the forward region in pp-collisions. The $W+b$ final state with $W \to \mu\nu$ is reconstructed using muons with a transverse momentum, p_T, larger than 25 GeV in the pseudorapidity range $2.0 < \eta < 4.5$. The b-jets are required to have 50 GeV $< p_T <$ 100 GeV and $2.2 < \eta < 4.2$, while the transverse component of the sum of the muon and b-jet momenta must satisfy $p_T > 20$ GeV. The results are based on data corresponding to integrated luminosities of 1.0 and 2.0 fb^{-1} collected at center-of-mass energies of 7 and 8 TeV by LHCb. The inclusive top quark production cross sections in the fiducial region are $\sigma_{t\bar{t}} = 239 \pm 53(stat.) \pm 38(syst.)$ pb at 7 TeV, and $\sigma_{t\bar{t}} = 289 \pm 43(stat.) \pm 46(syst.)$ pb at 8 TeV [59]. ATLAS and CMS have also measured the $t\bar{t}$ production cross section with Run-II data at $\sqrt{s} = 13$ TeV. In the $e\mu$ events with at least one b-tag, ATLAS uses 78 pb^{-1} and obtains $\sigma_{t\bar{t}} = 825 \pm 114$ pb [60]. This measurement is updated with lepton identification and trigger efficiencies to give $\sigma_{t\bar{t}} = 829 \pm 50(stat.) \pm 56(syst.) \pm 83(lumi)$ pb [61]. In this note, ATLAS also presents a $t\bar{t}$ cross section measurement in the ee and $\mu\mu$ dilepton channel with one and two b-tags using a counting approach, yielding $\sigma_{t\bar{t}} = 749 \pm 57(stat.) \pm 79(syst.) \pm 74(lumi.)$ pb. The cross section measurement in the $e\mu$ channel counting events with one or with two b-tags is also repeated using 3.2 pb^{-1} and yields $\sigma_{t\bar{t}} = 818 \pm 8(stat.) \pm 27(syst.) \pm 19(lumi.) \pm 12(beam)$ pb [62], consistent with theoretical QCD calculations at NNLO. In 36.1 fb^{-1} of $e\mu$ data with one or two b-tags, ATLAS measures the $t\bar{t}$ cross section to $\sigma_{t\bar{t}} = 826.4 \pm 3.6(stat.) \pm 11.5(syst.) \pm 15.7(lumi.) \pm 1.9(beam)$ pb, giving a total of 2.4%. This measurement is also used to determine the top quark pole mass and to derive ratios and double ratios of $t\bar{t}$ and Z cross-sections at different energies as well as absolute and normalised differential cross-sections as functions of single lepton and dilepton kinematic variables [63]. In the $\ell + jets$, using 85 pb^{-1}, the cross-section is extracted by counting the number of events with exactly one electron or muon and at least four jets, at least one of which is identified as originating from a b-quark, yielding $\sigma_{t\bar{t}} = 817 \pm 13(stat.) \pm 103(syst.) \pm 88(lumi.)$ pb, both assuming $m_t = 172.5$ GeV/c^2 [61]. Very recently, ATLAS measures the inclusive $t\bar{t}$ cross section in 139 fb^{-1} in the $\ell + jes$ through a profile-likelihood fit to be $\sigma_{t\bar{t}} = 830.4 \pm 0.4(stat.) \pm 36(syst.) \pm 14(lumi)$ pb, with a relative uncertainty of 4.6% [64]. The result is consistent with the theoretical calculations at NNLO order in QCD perturbation theory. CMS uses 43 pb^{-1} in the $e\mu$ channel to measure $\sigma_{t\bar{t}} = 746 \pm 58(stat.) \pm 53(syst.) \pm 36(lumi)$ pb, in agreement with the expectation from the standard model [65]. Using 2.2 fb^{-1} in the $e\mu$ channel with at least one b-jet, CMS measures $\sigma_{t\bar{t}} = 815 \pm 9(stat.) \pm 38(syst.) \pm 19(lumi.)$ pb (5.3%), in agreement with the expectation from the Standard Model [66]. Using 35.9 fb^{-1} of dilepton data, CMS measures the $t\bar{t}$ cross section using a likelihood fit $\sigma_{t\bar{t}} = 803 \pm 2(stat.) \pm 25(syst.) \pm 20(lumi.)$ pb (4.0%), in agreement with the expectation from the SM calculation at NNLO order. This result is also used to extract the top quark mass and the strong coupling constant [67]. Using the same dataset in the dilepton channel with a hadronically decaying τ, they measure $\sigma_{t\bar{t}} = 781 \pm 7(stat.) \pm 62(syst.) \pm 20(lumi.)$ pb (8.3%) [68]. A first measurement of the total inclusive and the normalized differential cross section in the $\ell + jets$ channel is made in 42 pb^{-1} yielding $\sigma_{t\bar{t}} = 836 \pm 27(stat.) \pm 88(syst.) \pm 100(lumi.)$ pb [69]. In 2.2 fb^{-1}, $\ell + jets$ events are categorized according to the accompanying jet multiplicity. From a likelihood fit to the invariant mass distribution of the isolated lepton and a b-jet, the cross section is measured to be $\sigma_{t\bar{t}} = 888 \pm 2(stat.)^{+26}_{-28}(syst.) \pm 20(lumi)$ pb, in agreement with the SM prediction [70]. This result is also used to extract the top-quark mass. Recently, CMS has used 137 pb^{-1} in four regions determined by top p_T and b-tag score to measure the cross section in the $\ell+jets$ channel. They employ a combined χ^2 fit considering the migration matrices. Most of the measured differential cross sections are well described by standard model predictions with the exception of some double-differential distributions. They obtain $\sigma_{t\bar{t}} = 791 \pm 1(stat.) \pm 21(syst.) \pm 14(lumi)$ pb (3.2%) [71]. In the all-hadronic channel, CMS uses 2.53 fb^{-1} of data, yielding a cross section of $\sigma_{t\bar{t}} = 834 \pm 25(stat.)^{+118}_{-104}(syst.) \pm 23(lumi.)$ pb [72]. Also differential cross sections as a function of the leading top quark transverse momentum are measured. As general feature across channels, it is found that the measured top quark p_T spectrum is significantly softer than the NLO+PS theory predictions considered in the corresponding publications. CMS also performed a measurement of top-quark pair production in pPb heavy ion collisions at $\sqrt{s} = 8.16$ TeV in 174 nb^{-1} of lepton+jets events. They measure a cross section of $\sigma_{t\bar{t}} = 45 \pm 8$ nb, which is consistent with pQCD calculations and with the scaled pp data [73].

In Fig. 61.1, one sees the importance of $p\overline{p}$ at Tevatron energies where the valence antiquarks in the antiprotons contribute to the dominant $q\bar{q}$ production mechanism. At LHC energies, the dominant production mode is gluon-gluon fusion and the pp-$p\overline{p}$ difference nearly disappears. The excellent agreement of these measurements with the theory calculations is a strong validation of QCD and the soft-gluon resummation techniques employed in the calculations. The measurements reach high precision and provide stringent tests of pQCD calculations at NNLO+NNLL level including their respective PDF uncertainties.

Most of these measurements assume a $t \to Wb$ branching ratio of 100%. CDF and DØ have made direct measurements of the $t \to Wb$ branching ratio [74]. Comparing the number of events with 0, 1 and 2 tagged b jets in the lepton+jets channel, and also in the dilepton channel, using the known b-tagging efficiency, the ratio $R = B(t \to Wb)/\sum_{q=d,s,b} B(t \to Wq)$ can be extracted. In 5.4 fb^{-1} of data, DØ measures $R = 0.90 \pm 0.04$, 2.5 standard deviations from unity. The currently most precise measurement was made by CMS in 19.7 fb^{-1} at $\sqrt{s} = 8$ TeV. They find $R = 1.014 \pm 0.003(stat.) \pm 0.032(syst.)$ and $R > 0.955$ at 95% C.L. [75]. A significant deviation of R from unity would imply either non-SM top-quark decay (for example a flavor-changing neutral-current decay), or a fourth generation of quarks. The latter is by other measurements.

Thanks to the large available event samples, the Tevatron and the LHC experiments also performed single-, double- or even triple-differential cross-section measurements in $t\bar{t}$ production. Such measurements are crucial, as they allow even more stringent tests of perturbative QCD as description of the production mech-

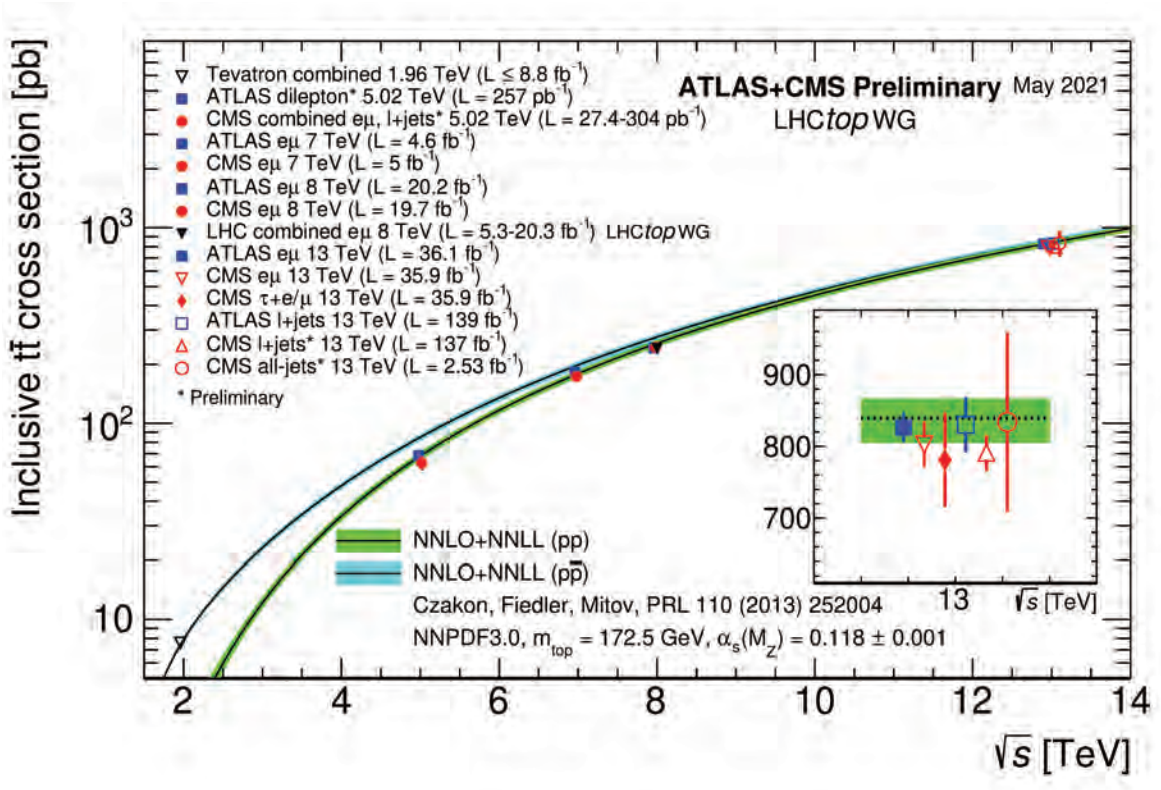

Figure 61.1: Measured and predicted $t\bar{t}$ production cross sections from Tevatron energies in $p\bar{p}$ collisions to LHC energies in pp collisions. The plot is kindly provided by the LHCtopWG working group, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

anism, allow along with other data the extraction of PDFs in PDF fits, and enhance the sensitivity to possible new physics contributions, especially now that NNLO predictions for the main differential observables in $t\bar{t}$ prediction have become available [76] and later confirmed [2]. Furthermore, such measurements reduce the uncertainty in the description of $t\bar{t}$ production as background in Higgs physics and searches for rare processes or beyond Standard Model physics. Differential cross sections are typically measured by a selection of candidate events, their kinematic reconstruction and subsequent unfolding of the obtained event counts in bins of kinematic distributions in order to correct for detector resolution effects, acceptance and migration effects. In some cases a bin-by-bin unfolding is used, while other analyses use more sophisticated techniques. Experiments at Tevatron and LHC measure the differential cross section with respect to the $t\bar{t}$ invariant mass, $d\sigma/dM_{t\bar{t}}$. The spectra are fully corrected for detector efficiency and resolution effects and are compared to several Monte Carlo simulations as well as selected theoretical calculations. Using 9.45 fb^{-1}, CDF measured $d\sigma/dM_{t\bar{t}}$, in the lepton+jets channel providing sensitivity to a variety of exotic particles decaying into $t\bar{t}$ pairs [77]. In 9.7 fb^{-1} of lepton+jets data, DØ measured the differential $t\bar{t}$ production cross section with respect to the transverse momentum and absolute rapidity of the top quarks as well as of the invariant mass of the $t\bar{t}$ pair [29], which are all found to be in good agreement with the SM predictions. ATLAS measured the differential $t\bar{t}$ production cross section with respect to the top-quark transverse momentum, and of the mass, transverse momentum and rapidity of the top quark, the antitop quark as well as the $t\bar{t}$ system in up to 4.6 fb^{-1} at $\sqrt{s} = 7$ TeV in the lepton+jets channel [78–80]. It is found that data is softer than all predictions for higher values of the mass of the $t\bar{t}$ system as well as in the tail of the top-quark p_T spectrum beginning at 200 GeV, particularly in the case of the `Alpgen+Herwig` generator. The $M_{t\bar{t}}$ spectrum is not well described by NLO+NNLL calculations and there are also disagreements between the measured rapidity of the $t\bar{t}$ system spectrum and the `MC@NLO+Herwig` and `POWHEG+Herwig` generators, both evaluated with the CT10 PDF set. All distributions show a preference for HERAPDF1.5 when used for the NLO QCD predictions. In 5.0 fb^{-1} of $\sqrt{s} = 7$ TeV data in the lepton+jets and the dilepton channels, CMS measured normalised differential $t\bar{t}$ cross sections with respect to kinematic properties of the final-state charged leptons and jets associated to b-quarks, as well as those of the top quarks and the $t\bar{t}$ system. The data are compared with several predictions from perturbative QCD calculations and found to be consistent [81]. ATLAS uses 4.6 fb^{-1} of data at 7 TeV and 20.2 fb^{-1} at 8 TeV to measure the differential $t\bar{t}$ cross section in the dilepton final state as a function of the mass, the transverse momentum and the rapidity of the $t\bar{t}$ system [82]. The results are compared with different Monte Carlo generators and theoretical calculations of $t\bar{t}$ production and found to be consistent with the majority of predictions in a wide kinematic range. Using 20.3 fb^{-1} of $t\bar{t}$ events in the lepton+jets channel, ATLAS measures the normalized differential cross sections of $t\bar{t}$ production as a function of the top-quark, $t\bar{t}$ system and event-level kinematic observables [83]. The observables have been chosen to emphasize the $t\bar{t}$ production process and to be sensitive to effects of initial- and final-state radiation, to the different parton distribution functions, and to non-resonant processes and higher-order corrections. The results are in fair agreement with the predictions over a wide kinematic range. Nevertheless, most generators predict a harder top-quark transverse momentum distribution at high values than what is observed in the data. Predictions beyond NLO accuracy improve the agreement with data at high top-quark transverse momenta. Using the current settings in the Monte Carlo programs and parton distribution functions, the rapidity distributions are not well modelled by any generator under consideration. However, the level of agreement is improved when more recent sets of parton distribution functions are used. Using 20.3 fb^{-1} of 8 TeV data, ATLAS performed a dedicated differential $t\bar{t}$ cross-section measurement of highly boosted top quarks in the lepton+jets channel, where the hadronically decaying top quark has a transverse momentum above 300 GeV [84].

Jet substructure techniques are employed to identify top quarks, which are reconstructed with an anti-k_t jet with a radius parameters $R = 1.0$. The predictions of NLO and LO matrix element plus parton shower Monte Carlo generators are found to generally overestimate the measured cross sections. Using 5.0 fb^{-1} of data at 7 TeV and 19.7 fb^{-1} at 8 TeV in the lepton+jets channel, CMS reports measurements of normalized differential cross sections for $t\bar{t}$ production with respect to four kinematic event variables: the missing transverse energy; the scalar sum of the jet transverse momentum (p_T); the scalar sum of the p_T of all objects in the event; and the p_T of leptonically decaying W bosons from top quark decays [85]. No significant deviations from the predictions of several SM event generators are observed. Using the full 19.7 fb^{-1} data in the $e\mu$ channel, CMS measures normalized double-differential cross sections for $t\bar{t}$ production as a function of various pairs of observables characterizing the kinematics of the top quark and $t\bar{t}$ system [86]. The data are compared to calculations using perturbative QCD at NLO and approximate NNLO orders. They are also compared to predictions of Monte Carlo event generators that complement fixed-order computations with parton showers, hadronization, and multiple-parton interactions. Overall agreement is observed with the predictions, which is improved when the latest global sets (as determined here by CMS) of proton parton distribution functions are used. The inclusion of the measured $t\bar{t}$ cross sections in a fit of parametrized parton distribution functions is shown to have significant impact on the gluon distribution [86]. Another analysis at high transverse momentum regime for the top quarks, is performed by the CMS collaboration in 19.7 fb^{-1} at $\sqrt{s} = 8$ TeV [87]. The measurement is performed for events in $e/\mu + jets$ final states where the hadronically decaying top quark is reconstructed as a single large-radius jet and identified as a top candidate using jet substructure techniques. The integrated cross section is measured at particle-level within a fiducial region resembling the detector-level selection as well as at parton-level. At particle-level, the fiducial cross section is measured to be $\sigma_{t\bar{t}} = 0.499 \pm 0.035(stat. + syst.) \pm 0.095(theo) \pm 0.013(lumi)$ pb for $p_T > 400$ GeV. At parton-level, it translates to $\sigma_{t\bar{t}} = 1.44 \pm 0.10(stat. + syst.) \pm 0.29(theo.) \pm 0.04(lumi.)$ pb. At parton-level, interactions between incoming partons (quarks or gluons) are considered via a gauge interaction yielding final state partons. While such interactions can be well described theoretically, partons are not visible in the detector. At the particle-level, visible and measurable hadrons, i.e. bound states of quarks and antiquarks, are considered to form jets. The hadronisation process takes us from one level to the other. In 19.7 fb^{-1} at $\sqrt{s} = 8$ TeV, CMS repeated those measurements in the lepton+jets and in the dilepton channels [88]. While the overall precision is improved, no significant deviations from the Standard Model are found, yet a softer spectrum for the top quark at high p_T with respect to theoretical available predictions has been observed. This behaviour has been also observed in the all-hadronic final state [89], where a total cross section measurement is performed, yielding $\sigma_{t\bar{t}} = 275.6 \pm 6.1(stat.) \pm 37.8(syst.) \pm 7.2(lumi)$ pb. At $\sqrt{s} = 13$ TeV, in 3.2 fb^{-1}, ATLAS measured the differential $t\bar{t}$ cross section as a function of the transverse momentum and absolute rapidity of the top quark, and of the transverse momentum, absolute rapidity and invariant mass of the $t\bar{t}$ system [90]. The measured differential cross sections are compared to predictions of NLO generators matched to parton showers and the measurements are found to be consistent with all models within the experimental uncertainties with the exception of the `Powheg-Box+Herwig++` predictions, which differ significantly from the data in both the transverse momentum of the top quark and the mass of the $t\bar{t}$ system. Using 3.2 fb^{-1} of data in the lepton+jets channel, ATLAS measured the differential cross sections of $t\bar{t}$ production in fiducial phase-spaces as a function of top-quark and $t\bar{t}$ system kinematic observables [91]. Two separate selections are applied that each focus on different top-quark momentum regions, referred to as resolved and boosted topologies of the $t\bar{t}$ final state. The measured spectra are corrected for detector effects and are compared to several Monte Carlo simulations by means of calculated χ^2 and p-values.

ATLAS presents a measurement of the boosted top quark differential cross section in the all-hadronic decay mode [92]. They require two top-quark candidates, one with $p_T > 500$ GeV and a second with $p_T > 350$ GeV, with each candidate reconstructed as an anti-k_T jet with radius parameter $R = 1.0$. The top-quark candidates are separated from the multijet background using the jet substructure and the presence of a b-quark tag in each jet. The observed kinematic distributions are unfolded to recover the differential cross sections in a limited phase-space region and compared with SM predictions, showing agreement. In 36 fb^{-1}, ATLAS measures the single- and double-differential $t\bar{t}$ cross-section in the lepton + jets channel at particle and parton level. Two topologies, resolved and boosted, are considered and the results are presented as a function of several kinematic variables characterising the top and $t\bar{t}$ system and jet multiplicities. Overall, there is good agreement between the theoretical predictions and the data [93]. In 36.1 fb^{-1} of dilepton events, ATLAS measures the differential $t\bar{t}$ cross section as a function of several lepton kinematic variables [63]. The NLO+PS predictions give a good description of several observables. However, `POWHEG` predicts a harder spectrum for lepton p_T variables than observed. In 139 fb^{-1} of data in the $\ell + jets$ channel in a boosted topology with at least one large-R "top-jet" from a hadronic decay with high-p_T, ATLAS employs a parameter sensitive to the top mass to reduce the jet uncertainties and measures the differential $t\bar{t}$ cross section as a function of kinematic variables characterising the $t\bar{t}$ system and also as a function of variables that characterise the additional radiation in the events [94]. The measured distribution of the top-quark transverse momentum, which is measured to be softer than expected, is used to set limits on the Wilson coefficients describing physics beyond the standard model. The modelling of the additional radiation events show some mild disagreements to the data. In the all-hadronic channel with six separately resolved jet, using 36.1 fb^{-1}, ATLAS measures single- and double-differential cross sections at particle and parton level as a function of various kinematic variables [95]. The rapidities of t and $t\bar{t}$ are found to be well modelled while discrepancies between theoretical predictions and data are found in the p_T distributions of the three leading jets, the top and the $t\bar{t}$ system. In 42 pb^{-1}, CMS measures the differential cross section at $\sqrt{s} = 13$ TeV as a function of kinematic properties of the top quarks and the $t\bar{t}$ system, as well as of the jet multiplicity in the event. Several predictions from perturbative QCD calculations are confronted with the data and are found to describe them well [96]. In 2.1 fb^{-1} at $\sqrt{s} = 13$ TeV, CMS measures the normalized differential cross sections for $t\bar{t}$ production in the dilepton channels as a function of the kinematic properties of the leptons, jets from bottom quark hadronization, top quarks, and top quark pairs at the particle and parton levels [97]. The results are compared to several Monte Carlo generators that implement calculations up to NLO in perturbative QCD interfaced with parton showering, and also to fixed-order theoretical calculations of top quark pair production up to NNLO, showing agreement. In 2.3 fb^{-1} of events in the lepton+jets channel, CMS measures the differential and double-differential cross sections for the $t\bar{t}$ production as a function of jet multiplicity and of kinematic variables of the top quarks and the $t\bar{t}$ system [98]. The differential cross sections are presented at particle level, within a phase space close to the experimental acceptance, and at parton level in the full phase space. The results are compared to several SM predictions. Using 35.9 fb^{-1}, CMS measures the differential $t\bar{t}$ cross section in the single-lepton decay channel, as a function of a number of kinematic event variables. The data are compared to a variety of state-of-the-art LO and NLO simulations [99]. In 35.8 fb^{-1}, CMS measures the differential and double-differential $t\bar{t}$ cross sections in the $\ell + jets$ channel as a function of kinematic variables of the top quarks and the top quark-antiquark ($t\bar{t}$) system. In addition, kinematic variables and multiplicities of jets associated with the $t\bar{t}$ production are measured. The kinematic variables of the top quarks and the $t\bar{t}$ system are reasonably described in general, though none predict all the measured distributions. In particular, the transverse momentum distribution of the top quarks is more steeply falling than predicted. The kinematic distributions and multiplicities of jets are adequately modeled by certain combinations of NLO calculations and parton

shower models [100]. In the dilepton channel, CMS measures differential $t\bar{t}$ cross sections in 35.9 fb^{-1} as functions of kinematic observables of the top quarks and their decay products, the $t\bar{t}$ system, and the total number of jets in the event. All results are compared with SM predictions from Monte Carlo simulations with NLO accuracy in QCD at matrix-element level interfaced to parton-shower simulations. Where possible, parton-level results are compared to calculations with beyond-NLO precision in QCD. Significant disagreement is observed between data and all predictions for several observables. The measurements are used to constrain the top quark chromomagnetic dipole moment in an effective field theory framework at NLO in QCD and to extract $t\bar{t}$ and leptonic charge asymmetries [101]. In 35.9 fb^{-1} of dilepton events, CMS measures normalised multi-differential $t\bar{t}$ cross sections as a function of the kinematic properties of the top quark and of the $t\bar{t}$ system at parton level in the full phase space. A triple-differential measurement is performed as a function of the invariant mass and rapidity of the $t\bar{t}$ system and the multiplicity of additional jets at particle level. The data are compared to predictions of Monte Carlo event generators that complement NLO QCD calculations with parton showers. The measurement is used to extract the strong coupling constant and the top-quark pole mass and parton distribution functions [102]. In 137 fb^{-1} of $\ell + jets$ data, arranged in four regions according to the top p_T, boosted vs. resolved, and the b-tagging score, CMS measures the single- and double-differential $t\bar{t}$ cross sections [71]. Here also the longitudinal momentum is measured well into the TeV range in one measurement starting in the resolved regime. Most of the measured differential cross sections are well described by standard model predictions with the exception of some double-differential distributions. The top p_T and $m_{t\bar{t}}$ is found to be softer than predicted. In 35.9 fb^{-1} of all-hadronic and $\ell + jets$ events in a boosted topology with at least two large-R jets with a b-tag inside and $p_T > 400$ GeV or one large-R jet, respectively, CMS measures the differential cross section as a function of kinematic variables of individual top quarks or of the $t\bar{t}$ system [103]. The observed absolute cross sections are significantly lower than the predictions from theory, while the normalized differential measurements are well described.

61.3.1.2 *Other $t\bar{t}$ production processes*

Further cross-section measurements are performed by ATLAS for $t\bar{t}$+heavy flavour [104] and $t\bar{t}$+jets production as well as the differential measurement of the jet multiplicity in $t\bar{t}$ events by ATLAS [105] and by CMS [106]. Here, `MC@NLO+Herwig` MC is found to predict too few events at higher jet multiplicities. In addition, CMS measured the cross-section ratio $\sigma_{t\bar{t}b\bar{b}}/\sigma_{t\bar{t}jj}$ using 19.6 fb^{-1} of 8 TeV data [107]. This is of high relevance for top quark production as background to searches, for example for measurements of $t\bar{t}h$ production and ongoing searches for 4-top quark production. Later, ATLAS also measured the $t\bar{t}$ production cross section along with the branching ratios into channels with leptons and quarks using 4.6 fb^{-1} of 7 TeV data [108]. They find agreement with the standard model at the level of a few percent.

Using 139 fb^{-1} of $t\bar{t} \to$ dilepton events, ATLAS distinguishes in a dedicated analysis muons originating from $W \to \mu\nu$ decays and those from $W \to \tau\nu \to \mu\nu\nu\nu$ decays via their transverse momentum spectrum and the impact parameter of the muon track, that reflects the tau lifetime, yielding high sensitivity. The measured ratio of $R(\tau/\mu) = 0.992 \pm 0.013$ is in agreement with the hypothesis of universal lepton couplings [109].

Using 36 fb^{-1} of dilepton events at 13 TeV, ATLAS also measures differential cross sections with respect to high-resolution variables, constructed to characterize the longitudinal and transverse momentum distributions of the b-hadron within the b-jets [110]. They are used to test the heavy-quark-fragmentation modelling.

Using 137 fb^{-1} of dilepton events at 13 TeV, CMS measures differential cross sections with respect to the mass of the $t\bar{t}$ system and the rapidity difference of the top-quark and antiquark [111]. Exploiting their sensitivity to the top-quark Yukawa coupling yields a best fit value of $Y_t = 1.16^{+0.24}_{-0.35}$, bounding $Y_t < 1.54$ at a 95% confidence level.

In 36.1 fb^{-1}, ATLAS measures the $t\bar{t}b\bar{b}$ cross section in the dilepton and the $\ell + jets$ channels. Results are presented at particle level in the form of inclusive cross-sections of $t\bar{t}$ final states with three and four b-jets as well as differential cross-sections as a function of global event properties and properties of b-jet pairs. The measured inclusive fiducial cross-sections generally exceed the $t\bar{t}b\bar{b}$ predictions from various NLO matrix element calculations matched to a parton shower, but are compatible within the total uncertainties [112]. In 2.3 fb^{-1}, CMS measures the $t\bar{t}b\bar{b}$ cross section in the dilepton channel [113]. They also determine the cross section ratio $\sigma_{t\bar{t}b\bar{b}}/\sigma_{t\bar{t}jj}$. In 35.9 fb^{-1}, CMS recently measured the cross section $t\bar{t}b\bar{b}$ as well as the cross section ratio $\sigma_{t\bar{t}b\bar{b}}/\sigma_{t\bar{t}jj}$ in the dilepton and the lepton+jets channel [114]. They fit the distribution of the b-tagging discriminant variable of the two jets that do not belong to the $t\bar{t}$ decay. In the same dataset, CMS measures the $t\bar{t}b\bar{b}$ cross section in the all-jet channel by selecting events containing at least eight jets, of which at least two are identified as b-jets. A combination of multivariate analysis techniques is used to reduce the large background from multijet events not containing a top quark pair, and to help discriminate between jets originating from top quark decays and other additional jets. The measured cross sections are found to be larger than theoretical predictions by a factor of 1.5-2.4, corresponding to 1-2 standard deviations [115]. Recently, CMS measured the $t\bar{t} + b\bar{b}$ cross section in 35.9 fb^{-1} of dilepton and $\ell + jets$ events [114]. The cross section is extracted from the cross section ratio $R(t\bar{t} + b\bar{b})$ in order to reduce systematic uncertainties. The assignment of jets to the top or to the additional jets is based on b-tagging scores in the dilepon channel and on a kinematic fit in the $\ell + jets$ channel. Using the same data set in the all-hadronic channel, CMS measured the $t\bar{t} + b\bar{b}$ cross section to $\approx 25\%$ precision employing a multivariate analysis technique and a 2-dimensional likelihood fit [116]. Very recently, CMS also measured the $t\bar{t} + c\bar{c}$ cross section using 41.5 fb^{-1} of events with dileptonic final states [117]. A multi-class neural network is employed to separate $t\bar{t} + b\bar{b}$, $t\bar{t} + c\bar{c}$ and $t\bar{t} + ll$. The results are compatible with the prediction within $1 - 2\ \sigma$.

The production of four top-quarks is an interesting test of QCD and at the same time sensitive to the top quark Yukawa coupling and to production mechanisms with new mediators with strong couplings to top quarks. The latest cross section calculation yields $\sigma_{t\bar{t}t\bar{t}} = 12.0$ fb $\pm 20\%$ [118]. Using the full Run-II data set of 139 fb^{-1}, ATLAS measures the four-tops cross section in the two-lepton same sign or three-lepton channel with 13% branching ratio and dominant $t\bar{t}V$ background as $\sigma_{t\bar{t}t\bar{t}} = 24^{+7}_{-6}$ fb [119]. Using the same data set in the one-lepton or two-lepton opposite-sign channel with 57% branching ratio and dominant $t\bar{t}$ + heavy flavor background, they measure $\sigma_{t\bar{t}t\bar{t}} = 26^{+17}_{-15}$ fb [120]. The combination yields $\sigma_{t\bar{t}t\bar{t}} = 24^{+7}_{-6}$ fb [120], corresponding to an observed (expected) significance of 4.7 (2.6) σ significance. CMS measures the four-top cross section in the two-lepton same sign or thee-lepton channel in 137 fb^{-1} to $\sigma_{t\bar{t}t\bar{t}} = 12.6^{+5.8}_{-5.2}$ fb [121], corresponding to an observed (expected) significance of 2.6 (2.7) σ significance. Using 35.8 fb^{-1}, they also study the one-lepton or two-lepton opposite-sign channel and obtain an upper limit of $\sigma_{t\bar{t}t\bar{t}} < 48$ fb at 95% CL [122]. The results are also interpreted in terms of the top-Yukawa coupling and various scenarios of physics beyond the standard model via effective field theory fits.

61.3.1.3 *Single-top production*

Single-top quark production was first observed in 2009 by DØ [123] and CDF [124, 125] at the Tevatron. The production cross section at the Tevatron is roughly half that of the $t\bar{t}$ cross section, but the final state with a single W-boson and typically two jets is less distinct than that for $t\bar{t}$ and much more difficult to distinguish from the background of W+jets and other sources. A comprehensive review of the first observation and the techniques used to extract the signal from the backgrounds can be found in [126].

The dominant production at the Tevatron is through s-channel and t-channel W-boson exchange. Associated production with a W-boson (tW production) has a cross section that is too small to observe at the Tevatron. The t-channel process is $qb \to q't$, while the s-channel process is $q\overline{q'} \to t\bar{b}$. The s- and t-channel

productions can be separated kinematically. This is of particular interest because potential physics beyond the Standard Model, such as fourth-generation quarks, heavy W and Z bosons, flavor-changing-neutral-currents [11], or a charged Higgs boson, would affect the s- and t-channels differently. However, the separation is difficult and initial observations and measurements at the Tevatron by both experiments were of combined $s+t$-channel production. The two experiments combined their measurements for maximum precision with a resulting $s+t$-channel production cross section of $2.76^{+0.58}_{-0.47}$ pb [127]. The measured value assumes a top-quark mass of 170 GeV/c^2. The mass dependence of the result comes both from the acceptance dependence and from the $t\bar{t}$ background evaluation. Also the shape of discriminating topological variables is sensitive to m_t. The dependence on m_t is therefore not necessarily a simple linear dependence but amounts to only a few tenths of picobarns over the range $170-175$ GeV/c^2. The measured value agrees well with the theoretical calculation at $m_t = 173$ GeV/c^2 of $\sigma_{s+t} = 3.12^{+0.00}_{-0.04}(scale) \pm 0.18(pdf)$ pb (including both top and anti-top production) [9, 128].

Using the full Run-II data set of up to 9.7 fb^{-1}, CDF and DØ have measured the t-channel single-top quark production to be $\sigma_{t+\bar{t}} = 2.25^{+0.29}_{-0.31}$ pb [129, 130]. In the same publication, they also present the simultaneously measured $s-$ and $t-$channel cross sections and the $s+t$ combined cross section measurement resulting in $\sigma_{s+t} = 3.30^{+0.52}_{-0.40}$ pb, without assuming the SM ratio of σ_s/σ_t. The modulus of the CKM matrix element obtained from the $s+t$-channel measurement is $|V_{tb}| = 1.02^{+0.06}_{-0.05}$ and its value is used to set a lower limit of $|V_{tb}| > 0.92$ at 95% C.L. Those results are in good agreement with the theoretical value at the mass 172.5 GeV/c^2 of $\sigma_t = 2.08 \pm 0.13$ pb [128]. It should be noted that the theory citations here list cross sections for t or $\bar{t}$ alone, whereas the experiments measure the sum. At the Tevatron, these cross sections are equal. The theory values quoted here already include this factor of two.

Using datasets of 9.7 fb^{-1} each, CDF and DØ combine their analyses and report the first observation of single-top-quark production in the s-channel, yielding $\sigma_s = 1.29^{+0.26}_{-0.24}$ pb [131]. The probability of observing a statistical fluctuation of the background of the given size is 1.8×10^{-10}, corresponding to a significance of 6.3 standard deviations.

At the LHC, the t-channel cross section is expected to be more than three times as large as s-channel and tW production, combined. Both ATLAS and CMS have measured single top production cross sections at $\sqrt{s} = 7$ TeV in pp collisions (assuming $m_t = 172.5$ GeV/c^2 unless noted otherwise). Using 4.59 fb^{-1} of data at $\sqrt{s} = 7$ TeV, ATLAS measures the t-channel single-top quark cross section in the lepton plus 2 or 3 jets channel with one b-tag by fitting the distribution of a multivariate discriminant constructed with a neural network, yielding $\sigma_t = 46 \pm 6$ pb, $\sigma_{\bar{t}} = 23 \pm 4$ pb with a ratio $R_t = \sigma_t/\sigma_{\bar{t}} = 2.04 \pm 0.18$ and $\sigma_{t+\bar{t}} = 68 \pm 8$ pb, consistent with SM expectations [132, 133]. CMS follows two approaches in 1.6 fb^{-1} of lepton plus jets events. The first approach exploits the distributions of the pseudorapidity of the recoil jet and reconstructed top-quark mass using background estimates determined from control samples in data. The second approach is based on multivariate analysis techniques that probe the compatibility of the candidate events with the signal. They find $\sigma^{t-channel}_{t+\bar{t}} = 67.2 \pm 6.1$ pb, and $|V_{tb}| = 1.020 \pm 0.046(exp.) \pm 0.017(th.)$ [134].

At $\sqrt{s} = 8$ TeV, both experiments repeat and refine their measurements. ATLAS uses 20.2 fb^{-1} of data. Total, fiducial and differential cross-sections are measured for both top-quark and top-antiquark production [135]. An artificial neural network is employed to separate signal from background. The fiducial cross-section is measured with a precision of 5.8% (top quark) and 7.8% (top antiquark), respectively. The total cross-sections are measured to be $\sigma^{t-channel}_t(tq) = 56.7^{+4.3}_{-3.8}$ pb for top-quark production and $\sigma^{t-channel}_{\bar{t}}(\bar{t}q) = 32.9^{+3.0}_{-2.7}$ pb for top-antiquark production, in agreement with the SM prediction. In addition, the ratio of top-quark to top-antiquark production cross-sections is determined to be $R_t = 1.72 \pm 0.09$. The total cross-section is used to extract the Wtb coupling: $f_{LV} \cdot |V_{tb}| = 1.029 \pm 0.048$, which corresponds to $|V_{tb}| > 0.92$ at the 95% confidence level, when assuming $f_{LV} = 1$ and restricting the range of $|V_{tb}|$ to the interval $[0, 1]$. The differential cross-sections as a function of the transverse momentum and rapidity of both the top quark and the top antiquark are measured at both the parton and particle levels. The transverse momentum and rapidity differential cross-sections of the accompanying jet from the t-channel scattering are measured at particle level. All measurements are compared to various Monte Carlo predictions as well as to fixed-order QCD calculations where available. The SM predictions provide good descriptions of the data. Using the same dataset, ATLAS probes the Wtb vertex structure from polarization observables in t-channel single-top quark events. The polarization observables are extracted from asymmetries in angular distributions measured with respect to spin quantisation axes appropriately chosen for the top quark and the W-boson. The asymmetry measurements are performed at parton level by correcting the observed angular distributions for detector effects and hadronisation after subtracting the background contributions. The measured top-quark and W-boson polarization values are in agreement with the Standard Model predictions [136]. CMS uses 19.7 fb^{-1} in the electron or muon plus jets channel, exploiting the pseudorapidity distribution of the recoil jet. They find $\sigma_t = 53.8 \pm 1.5(stat.) \pm 4.4(syst.)$ pb and $\sigma_{\bar{t}} = 27.6 \pm 1.3(stat.) \pm 3.7(syst.)$ pb, resulting in an inclusive t-channel cross section of $\sigma_{t+\bar{t}} = 83.6 \pm 2.3(stat.) \pm 7.4(syst.)$ [137]. They measure a cross section ratio of $R_t = \sigma_t/\sigma_{\bar{t}} = 1.95 \pm 0.10(stat.) \pm 0.19(syst.)$, in agreement with the SM. The CKM matrix element V_{tb} is extracted to be $|V_{tb}| = 0.998 \pm 0.038(exp.) \pm 0.016(th.)$. Later, CMS has also provided a fiducial cross section measurement for t-channel single top at $\sqrt{s} = 8$ TeV with 19.7 fb^{-1} of data in signal events with exactly one muon or electron and two jets, one of which is associated with a b-hadron [138]. The definition of the fiducial phase space follows closely the constraints imposed by event-selection criteria and detector acceptance. The total fiducial cross section is measured using different generators at next-to-leading order plus parton-shower accuracy. Using as reference the `aMC@NLO` MC predictions in the four-flavour scheme $\sigma_t^{\rm fid} = 3.38 \pm 0.25(exp.) \pm 0.20(th.)$ pb is obtained, in good agreement with the theory predictions. At 13 TeV, ATLAS uses 3.2 fb^{-1} to measure the t-channel cross section. Using a binned maximum-likelihood fit to the discriminant distribution of a neural network, the cross-sections are determined to be $\sigma_t(tq) = 156 \pm 5(stat.) \pm 27(syst.) \pm 3(lumi.)$ pb and $\sigma(\bar{t}q) = 91 \pm 4(stat.) \pm 18(syst.) \pm 2(lumi.)$ pb [139]. The cross-section ratio is measured to be $R_t = \sigma_t/\sigma_{\bar{t}} = 1.72 \pm 0.09(stat.) \pm 0.18(syst.)$. All results are in agreement with SM predictions. A measurement of the t-channel single top-quark cross section is also available at 13 TeV with the CMS detector, corresponding to an integrated luminosity of 2.2 fb^{-1}. Fits to the transverse W-mass and the output of an artificial neural network allow the determination of the background and the signal contribution. The measured cross-section is $\sigma_t = 238 \pm 13(stat.) \pm 29(syst.)$ pb [140]. The CKM matrix element is determined to $|V_{tb}| = 1.05 \pm 0.07(exp.) \pm 0.02(th.)$. Using 35.9 fb^{-1} of data, CMS performs measurements of the t-channel cross sections of single top quarks and antiquarks in the t channel, and their ratio. Events with one muon or electron are selected, and different categories of jet and b-jet multiplicity and multivariate discriminators are applied to separate the signal from the background, resulting in $\sigma_t(tq) = 130 \pm 1(stat) \pm 19(syst)$ pb and $\sigma_t(\bar{t}q) = 77 \pm 1(stat) \pm 12(syst)$ pb, respectively, and their ratio is $1.68 \pm 0.02(stat) \pm 0.05(syst)$. The results are in agreement with the predictions from the Standard Model [141]. Recently, CMS used the same dataset to measure the CKM matrix elements from their t-channel single-top quark production cross section. In the standard model hypothesis of CKM unitarity, a lower limit of $|V_{tb}| > 0.970$ is measured at the 95% confidence level. Several theories beyond the standard model are considered, and by releasing all constraints among the involved parameters, the values $|V_{tb}| = 0.988 \pm 0.024$, and $|V_{td}|^2 + |V_{ts}|^2 = 0.06 \pm 0.06$, where the uncertainties include both statistical and systematic components, are measured [142].

The predicted cross section for the tW process at the LHC

$\sqrt{s}$ = 7 TeV is 15.6 ± 1.2 pb [10]. This is of interest because it probes the Wtb vertex in a different kinematic region than s- and t-channel production, and because of its similarity to the associated production of a charged-Higgs boson and a top quark. The signal is difficult to extract because of its similarity to the $t\bar{t}$ signature. Furthermore, it is difficult to uniquely define because at NLO a subset of diagrams has the same final state as $t\bar{t}$ and the two interfere [143]. The cross section is calculated using the *diagram removal* technique [144] to define the signal process. In the diagram removal technique the interfering diagrams are removed, at the amplitude level, from the signal definition (an alternative technique, *diagram subtraction* removes these diagrams at the cross-section level and yields similar results [144]). These techniques work provided the selection cuts are defined such that the interference effects are small, which is usually the case.

Both, ATLAS and CMS, also provide evidence for the associate tW production at $\sqrt{s}$ = 7 TeV [145, 146]. ATLAS uses 2.05 fb^{-1} in the dilepton plus missing E_T plus jets channel, where a template fit to the final classifier distributions resulting from boosted decision trees as signal to background separation is performed. The result is incompatible with the background-only hypothesis at the 3.3σ (3.4σ expected) level, yielding $\sigma_{tW} = 16.8 \pm 2.9(stat.) \pm 4.9(syst.)$ pb and $|V_{tb}| = 1.03^{+0.16}_{-0.19}$ [145]. CMS uses 4.9 fb^{-1} in the dilepton plus jets channel with at least one b-tag. A multivariate analysis based on kinematic properties is utilized to separate the $t\bar{t}$ background from the signal. The observed signal has a significance of 4.0σ and corresponds to a cross section of $\sigma_{tW} = 16^{+5}_{-4}$ pb [146].

Both experiments repeated their tW-analyses at $\sqrt{s}$ = 8 TeV. ATLAS uses 20.3 fb^{-1} to select events with two leptons and one central b-jet. The tW signal is separated from the backgrounds using boosted decision trees, each of which combines a number of discriminating variables into one classifier. Production of tW events is observed with a significance of 7.7σ. The cross section is extracted in a profile likelihood fit to the classifier output distributions. The tW cross section, inclusive of decay modes, is measured to be $\sigma_{tW} = 23.0 \pm 1.3(stat.)^{+3.2}_{-3.5}(syst.) \pm 1.1(lumi.)$ pb, yielding a value for the CKM matrix element $|V_{tb}| = 1.01 \pm 0.10$ and a lower limit of 0.80 at the 95% C.L. [147]. A fiducial cross section is also measured. ATLAS and CMS also combine their early measurements and obtain $\sigma_{tW} = 16.3 \pm 4.1$ pb [148], in agreement with the NLO+NNLL expectation. Very recently, ATLAS used 20.2 fb^{-1} in the single-lepton channel with at least three jets to measure the Wt production cross section. A neural network is trained to separate the tW signal from the dominant $t\bar{t}$ background. The cross-section is extracted from a binned profile maximum-likelihood fit to a two-dimensional discriminant built from the neural-network output and the invariant mass of the hadronically decaying W boson. The measured cross section is $\sigma_{tW} = 26 \pm 7$ pb, in good agreement with the Standard Model expectation [149]. CMS uses 12.2 fb^{-1} in events with two leptons and a jet originating from a b-quark. A multivariate analysis based on kinematic properties is utilized to separate the signal and background. The tW associate production signal is observed at the level of 6.1σ, yielding $\sigma_{tW} = 23.4 \pm 5.4$ pb and $|V_{tb}| = 1.03 \pm 0.12(exp.) \pm 0.04(th.)$ [150]. ATLAS and CMS also combine their early measurements and obtain $\sigma_{tW} = 23.1 \pm 3.6$ pb [148], in agreement with the NLO+NNLL expectation. The product of a form factor with the CKM matrix element V_{tb} is determined to be $|V_{tb}| = 1.02 \pm 0.04(meas.) \pm 0.02(theo.) > 0.79$. At 13 TeV in the tW-channel, ATLAS uses 3.2 fb^{-1} of events with two opposite sign isolated leptons and at least one jet; they are separated into signal and control regions based on their jet multiplicity and the number of jets with b-tags. Signal is separated from background in two regions using boosted decision trees. The cross section is extracted by fitting templates to the data distributions, and is measured to be $\sigma_{tW} = 94 \pm 10(stat.)^{+28}_{-22}(syst.) \pm 2(lumi.)$ pb [151]. The measurement is in agreement with the SM prediction. CMS uses 36 fb^{-1} of events with two opposite sign isolated leptons, one tight and one loose jet and one b-tag. Signal and background is separated in categories depending on the number of jets and the subset of b-tagged jets using a boosted decision tree. A maximum likelihood fits yields $\sigma_{tW} = 63.1 \pm 1.8(stat.) \pm 6.4(syst.) \pm 2.1(lumi.)$ pb [152]. Very recently, CMS uses 36 fb^{-1} in the single-lepton channel, where a boosted decision tree is used to separate the tW signal from the dominant $t\bar{t}$ background, whilst the subleading W+jets and multijet backgrounds are constrained using data-based estimates. This result is the first observation of the tW process in final states containing a muon or electron and jets, with a significance exceeding 5 standard deviations. The cross section is determined to be $\sigma_{tW} = 89 \pm 4(stat) \pm 12(syst)$ pb, consistent with the Standard Model [153].

The s-channel production cross section is expected to be 4.6 ± 0.3 pb for m_t = 173 GeV/c^2 at $\sqrt{s}$ = 7 TeV [9]. At ATLAS, a search for s-channel single top quark production is performed in 0.7 fb^{-1} at 7 TeV using events containing one lepton, missing transverse energy and two b-jets. Using a cut-based analysis, an observed (expected) upper limit at 95% C.L. on the s-channel cross-section of $\sigma_s < 26.5$ (20.5) pb is obtained [154]. At 8 TeV, ATLAS uses 20.3 fb^{-1} of data with one lepton, large missing transverse momentum and exactly two b-tagged jets. They perform a maximum-likelihood fit of a discriminant based on a Matrix Element Method and optimized in order to separate single top-quark s-channel events from the main background contributions which are top-quark pair production and W boson production in association with heavy flavor jets. They find $\sigma_s = 4.8 \pm 0.8(stat.)^{+1.6}_{-1.3}(syst.)$ pb with a signal significance of 3.2 standard deviations [155], which provides first evidence for s-channel single-top production at 8 TeV. The signal is extracted through a maximum-likelihood fit to the distribution of a multivariate discriminant defined using boosted decision trees to separate the expected signal contribution from background processes. At 7 TeV and 8 TeV, CMS uses 5.1 fb^{-1} and 19.3 fb^{-1}, respectively, and analyses leptonic decay modes by performing a maximum likelihood fit to a multivariate discriminant defined using a Boosted Decision Tree, yielding cross sections of $\sigma_s = 7.1 \pm 8.1$ pb and $\sigma_s = 13.4 \pm 7.3$ pb, respectively, and a best fit value of 2.0 ± 0.9 for the combined ratio of the measured σ_s values and the ones expected in the Standard Model [156]. The signal significance is 2.5 standard deviations. ATLAS and CMS present the combinations of their single-top-quark production cross-section measurements, using Run-I data corresponding to integrated luminosities of 1.17 to 5.1 fb^{-1} at $\sqrt{s}$ = 7 TeV and 12.2 to 20.3 fb^{-1} at $\sqrt{s}$ = 8 TeV. These combinations are performed per centre-of-mass energy and for each production mode: t-channel, tW, and s-channel. The combined t-channel cross-sections are 67.5 ± 5.7 pb and 87.7 ± 5.8 pb at $\sqrt{s}$ = 7 and 8 TeV, respectively. The combined tW cross-sections are 16.3 ± 4.1 pb and 23.1 ± 3.6 pb at $\sqrt{s}$ = 7 and 8 TeV, respectively. For the s-channel cross-section, the combination yields 4.9 ± 1.4 pb at $\sqrt{s}$ = 8 TeV. The square of the magnitude of the CKM matrix element V_{tb} multiplied by a form factor f_{LV} is determined for each production mode and centre-of-mass energy, using the ratio of the measured cross-section to its theoretical prediction. All combined measurements are consistent with their corresponding SM predictions [157]. Both, ATLAS and CMS, also measured the electroweak production of single top-quarks in association with a Z-boson, see section 61.3.2.4 of this review.

Fig. 61.2 provides a summary of all single top cross-section measurements at the LHC as a function of the center-of-mass energy. All cross-section measurements are very well described by the theory calculation within their uncertainty.

Thanks to the large statistics now available at the LHC, both CMS and ATLAS experiments also performed differential cross-section measurements in single-top t-channel production [132], [158]. Such measurements are extremely useful as they test our understanding of both QCD and EW top-quark interactions. The CMS collaboration has measured differential single top quark t-channel production cross sections as functions of the transverse momentum and the absolute value of the rapidity of the top quark. The analysis is performed in the leptonic decay channels of the top quark, with either a muon or an electron in the final state, using data collected with the CMS experiment at the LHC at $\sqrt{s}$ = 8 TeV and corresponding to an integrated luminosity of 19.7 fb^{-1}. Neural networks are used to discriminate the signal process from the various background contributions. The results

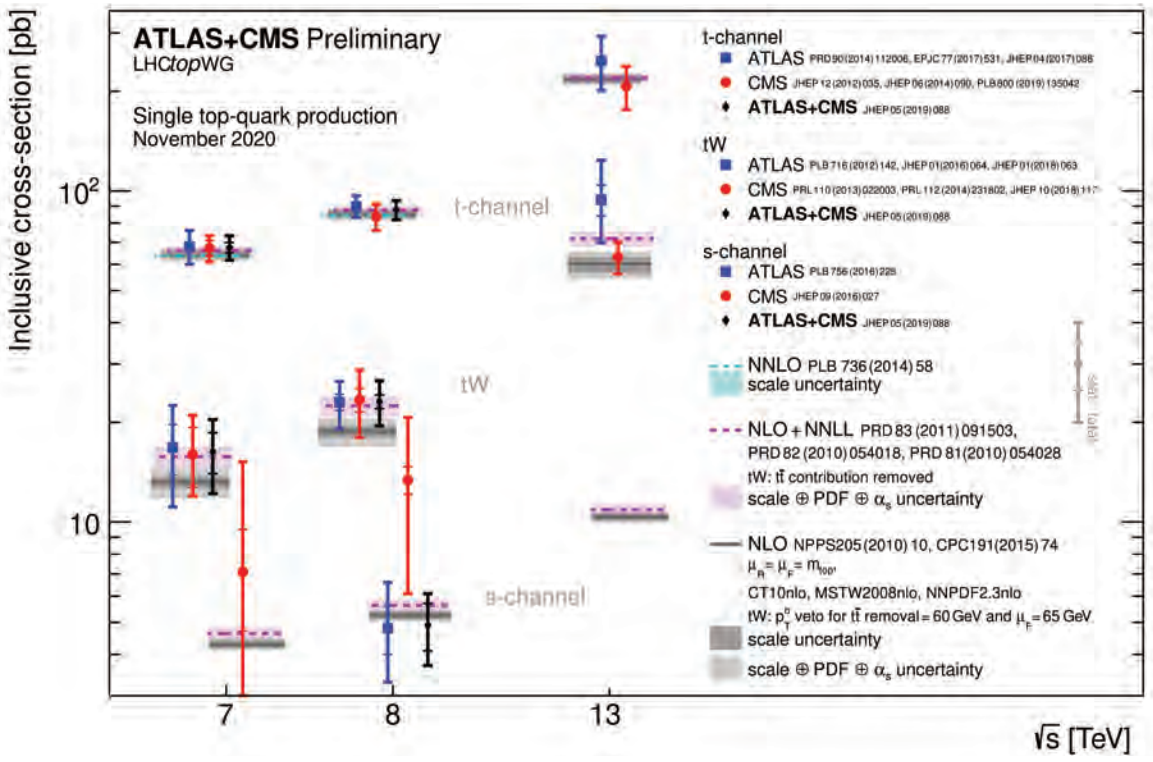

Figure 61.2: Measured and predicted single top production cross sections at LHC energies in pp collisions. The recent CMS measurement of the tW production cross section at 13 TeV in the l+jets channel is not yet shown here. The plot is kindly provided by the LHCtopWG working group, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

are found to agree with predictions from Monte Carlo generators [158]. Using the same data set and under the assumption that the spin analyzing power of a charged lepton is 100% as predicted in the SM, they are also able to measure the polarization of the top quark $P_t = 0.82 \pm 0.12(stat.) \pm 0.32(syst.)$ [159]. At 13 TeV, using 35.9 fb^{-1}, CMS measures the differential t-channel cross sections, for the first time in single-top production, and charge ratios for t-channel single top quark production [160]. The results are found to be in agreement with SM predictions using various NLO event generators and sets of parton distribution functions. Additionally, the spin asymmetry, sensitive to the top quark polarization, is determined from the differential distribution of the polarization angle at parton level to be 0.439 ± 0.062, in agreement with the SM prediction. This disfavours the results obtained at 8 TeV. ATLAS has measured the differential tW cross section in 36.1 fb^{-1} at 13 TeV with respect to the energy of the b-jet, the energy of the system of the two leptons and b-jet, and the transverse mass or mass of combinations of leptons, the b-jet and neutrinos [161]. Using 35.9 fb^{-1} of $e\mu$ events, CMS to measure the differential tW cross section. A fiducial region is defined according to the detector acceptance, and the requirement of exactly one b-tagged jet. The resulting distributions are unfolded to particle-level and compared with predictions calculated at next-to-leading order in perturbative QCD. Within current uncertainties, all the predictions agree with the data [162].

61.3.1.4 *Top-Quark Asymmetries*

A forward-backward asymmetry in $t\bar{t}$ production at a $p\bar{p}$ collider arises starting at order α_S^3 in QCD from the interference between the Born amplitude $q\bar{q} \to t\bar{t}$ with 1-loop box production diagrams and between diagrams with initial- and final-state gluon radiation. The asymmetry, A_{FB}, is defined by

$$A_{FB} = \frac{N(\Delta y > 0) - N(\Delta y < 0)}{N(\Delta y > 0) + N(\Delta y < 0)}, \qquad (61.2)$$

where $\Delta y = y_t - y_{\bar{t}}$ is the rapidity difference between the top- and the anti-top quark. Calculations at α_S^3 predict a measurable A_{FB} at the Tevatron. The most recent calculations up to order α_S^4, including electromagnetic and electroweak corrections, yield a predicted asymmetry of $\approx(9.5 \pm 0.7)\%$ [163]. This is about 10% higher than the previous calculation at NLO [164, 165], and improves the agreement with experiment.

Both CDF and DØ measured asymmetry values in excess of the SM prediction, fueling speculation about exotic production mechanisms (see, for example, [166] and references therein). The first measurement of this asymmetry by DØ in 0.9 fb^{-1} [167] found an asymmetry at the detector level of $(12 \pm 8)\%$. The first CDF measurement in 1.9 fb^{-1} [168] yielded $(24 \pm 14)\%$ at parton level. Both values were higher, though statistically consistent with the SM expectation. With the addition of more data, the uncertainties have been reduced, and the central values, if somewhat smaller, have remained consistent with the first measurements. At the same time, the improved calculations from theory have increased the predicted asymmetry values, improving the agreement between theory and experiment.

CDF and DØ have now combined results using the full Tevatron dataset at $\sqrt{s} = 1.96$ TeV [169]. Three combined asymmetries are reported: $A_{FB}^{t\bar{t}}$ as defined in Eq. 2 for fully-reconstructed $t\bar{t}$ events, a single-lepton asymmetry, A_{FB}^{ℓ} defined as in Eq. 2 but with Δy replaced by the product of the lepton charge and pseudo-rapidity, and a dilepton asymmetry, $A_{FB}^{\ell\ell}$, defined as in Eq. 2 but with Δy replaced by $\Delta\eta$ between the two leptons. The combined results are $A_{FB}^{t\bar{t}} = 0.128 \pm 0.021 \pm 0.014$, $A_{FB}^{\ell} = 0.073 \pm 0.016 \pm 0.012$, and $A_{FB}^{\ell\ell} = 0.108 \pm 0.043 \pm 0.016$, where the first uncertainty is statistical and the second systematic. These are to be compared to SM predictions at NNLO QCD and NLO electroweak of $A_{FB}^{t\bar{t}} = 0.095 \pm 0.007$ [163], $A_{FB}^{\ell} = 0.038 \pm 0.003$, and $A_{FB}^{\ell\ell} = 0.048 \pm 0.004$ [165], respectively. Both experiments have also measured differential asymmetries, in bins of $M_{t\bar{t}}$, Δy, $q_\ell \times \eta_\ell$, and $\Delta\eta_{\ell\ell}$, with consistent results, though the growth of $A_{FB}^{t\bar{t}}$ with increasing $M_{t\bar{t}}$ and Δy appears somewhat more rapid than the SM prediction [169].

At the LHC, where the dominant $t\bar{t}$ production mechanism is the charge-symmetric gluon-gluon fusion, the measurement is

more difficult. For the sub-dominant $q\bar{q}$ production mechanism, the symmetric pp collision does not define a forward and backward direction. Instead, the charge asymmetry, A_C, is defined in terms of a positive versus a negative $t-\bar{t}$ rapidity difference, Δy

$$A_C^{t\bar{t}} = \frac{N(\Delta|y|>0) - N(\Delta|y|<0)}{N(\Delta|y|>0) + N(\Delta|y|<0)}. \quad (61.3)$$

Both CMS and ATLAS have measured A_C in the LHC dataset. Using lepton+jets events in 4.7 fb^{-1} of data at $\sqrt{s}=7$ TeV, ATLAS measures $A_C^{t\bar{t}} = (0.6 \pm 1.0)\%$ [170]. ATLAS has reported on the same measurement performed at $\sqrt{s}=8$ TeV with 20.3 fb^{-1} of data, with a result of $A_C^{t\bar{t}} = (0.9 \pm 0.5)\%$ [171]. In the dilepton channel at $\sqrt{s}=8$ TeV, ATLAS measures [172] $A_C^{t\bar{t}} = (2.1 \pm 1.6)\%$, and $A_C^{\ell\ell} = (0.8 \pm 0.6)\%$ (defined in terms of the $\Delta\eta$ of the two leptons) in agreement with the SM predictions of $(1.11 \pm 0.04)\%$ and $(0.64 \pm 0.03)\%$, respectively [165]. Using lepton+jets events CMS has measured A_C at both $\sqrt{s}=7$ and 8 TeV. They measure $A_C^{t\bar{t}} = (0.4 \pm 1.5)\%$ and $A_C^{t\bar{t}} = (0.33 \pm 0.26(stat.) \pm 0.33(syst.))\%$ in 5.0 fb^{-1} at $\sqrt{s}=7$ TeV and In 19.7 fb^{-1} at $\sqrt{s}=8$ TeV, respectively [173, 174]. Both measurements are consistent with the SM expectations of $A_C^{t\bar{t}} = (1.23 \pm 0.05)\%$ at $\sqrt{s}=7$ TeV and $(1.11 \pm 0.04)\%$ at $\sqrt{s}=8$ TeV [165], although the uncertainties are still too large for a precision test. In 19.5 fb^{-1} of dilepton events at $\sqrt{s}=8$ TeV, CMS measures $A_C^{t\bar{t}} = (1.1 \pm 1.3)\%$ and $A_C^{\ell\ell} = (0.3 \pm 0.7)\%$ [175], consistent with SM expectations [176].

In their 7 and 8 TeV analyses ATLAS and CMS also provide differential measurements as a function of $M_{t\bar{t}}$ and the transverse momentum p_T and rapidity y of the $t\bar{t}$ system. To reduce model-dependence, the CMS collaboration has performed a measurement in a reduced fiducial phase space [177], with a result of $A_C = (-0.35 \pm 0.72(stat.) \pm 0.31(syst.))\%$, in agreement with SM expectations.

To specifically address the dependence of the asymmetry on $M_{t\bar{t}}$, ATLAS has performed a measurement in boosted $t\bar{t}$ events [178]. In 20.3 fb^{-1} of data at $\sqrt{s}=8$ TeV, in events with $M_{t\bar{t}} > 0.75$ TeV, and $|(\Delta|y|)| < 2$, ATLAS measures $A_C^{t\bar{t}} = (4.2 \pm 3.2)\%$ compared to a NLO SM prediction of $(1.60 \pm 0.04)\%$. The measurement is also presented in three bins of $M_{t\bar{t}}$, each in agreement, though with large uncertainties, with the SM expectations.

Both ATLAS and CMS have measured asymmetries in the distribution of leptons from $t\bar{t}$ decays. ATLAS, in 4.6 fb^{-1} of $\sqrt{s}=7$ TeV data, has measured $A^{\ell\ell} = (2.4 \pm 1.5(\text{stat.}) \pm 0.9(\text{sys.}))\%$ in dilepton events [179]. Using a neutrino weighting technique in the same dataset to reconstruct the top quarks, ATLAS measures $A_C = (2.1 \pm 2.5\ (\text{stat.}) \pm 1.7\ (\text{sys.}))\%$. CMS, in 5.0 fb^{-1} of $\sqrt{s}=7$ TeV data, uses dilepton events to measure $A_C = (1.0 \pm 1.5\ (\text{stat.}) \pm 0.6\ (\text{sys.}))\%$, where a matrix weighting technique is used to reconstruct the top quarks, and $A^{\ell\ell} = (0.9 \pm 1.0\ (\text{stat.}) \pm 0.6\ (\text{sys.}))\%$ [180]. An earlier result using lepton+jets events from the same CMS dataset found $A_C = (0.4 \pm 1.0 \pm 1.1)\%$ [173]. Combined results from ATLAS and CMS have now been released [181]. At $\sqrt{s}=7$ TeV the combined result is $A_C = (0.5 \pm 0.7\ (\text{stat.}) \pm 0.6\ (\text{sys.}))\%$, and at $\sqrt{s}=8$ TeV it is $A_C = (0.55 \pm 0.23 \pm 0.25)\%$. These results are all consistent, within their large uncertainties, with the SM expectations of $A^{\ell\ell} = (0.70 \pm 0.03)\%$ and $A_C = (1.23 \pm 0.05)\%$ [165].

ATLAS has released a charge asymmetry measurement at $\sqrt{s} = 13$ TeV using the full 139 fb^{-1} dataset. A Bayesian unfolding procedure is used in lepton plus jets events, combining both resolved and boosted topologies, to infer the asymmetry at parton level, correcting for detector resolution and acceptance effects. The inclusive charge asymmetry is measured as $A_C = (0.60 \pm 0.15)\%$ (stat+syst.) [182]. In addition to the inclusive measurement, the result includes differential measurements in five bins of $M_{t\bar{t}}$, and four bins of longitudinal boost. Both inclusive and differential results are found consistent with Standard Model predictions at NNLO in QCD and NLO in electroweak theory.

A model-independent comparison of the Tevatron and LHC results is made difficult by the differing $t\bar{t}$ production mechanisms at work at the two accelerators and by the symmetric nature of the pp collisions at the LHC. A recent result from the CMS Collaboration [183] in 35.9 fb^{-1} of lepton plus jets events at $\sqrt{s}=13$ TeV, uses a likelihood analysis to separate the $q\bar{q}$ process from production via gluon-gluon and gluon-quark interactions and extract $A_{FB} = (4.8^{+8.8}_{-8.4}\ (\text{stat.}) \pm 2.8\ (\text{sys.}))\%$. In addition, given a particular model of BSM physics, a comparison can be obtained through the resulting asymmetry predicted by the model at the two machines, see for example [178].

A new measurement from ATLAS explores a so-called 'energy asymmetry' in $t\bar{t}$ production in association with a high-p_T jet ($t\bar{t}j$ production). The energy asymmetry is defined as a difference between the top and anti-top quarks' energies, and is measured in ATLAS in three bins of the associated high-p_T jet angle, θ_j. Both the energies and jet angle are measured in the $t\bar{t}j$ rest frame. A Bayesian unfolding method corrects for resolution and acceptance effects. The measurement is in agreement with the Standard Model at NLO accuracy [184].

61.3.2 *Top-Quark Properties*

61.3.2.1 *Top-Quark Mass Measurements*

The most precisely studied property of the top quark is its mass. The top-quark mass has been measured in the lepton+jets, the dilepton, and the all-jets channel by all four Tevatron and LHC experiments, and now in single-top events at the LHC. The latest and/or most precise results are summarized in Table 61.1. The lepton+jets channel yields the most precise single measurements because of good signal to background ratio (in particular after b-tagging) and the presence of only a single neutrino in the final state. The momentum of a single neutrino can be reconstructed (up to a quadratic ambiguity) via the missing E_T measurement and the constraint that the lepton and neutrino momenta reconstruct to the known W boson mass. In the large data samples available at the LHC, measurements in the dilepton channel can be competitive and certainly complementary to those in the lepton+jets final state.

A large number of techniques have now been applied to measuring the top-quark mass. The original 'template method' [185], in which Monte Carlo templates of reconstructed mass distributions are fit to data, has evolved into a precision tool in the lepton+jets channel, where the systematic uncertainty due to the jet energy scale (JES) uncertainty is controlled by a simultaneous, *in situ* fit to the $W \to jj$ hypothesis [186]. All the latest measurements in the lepton+jets and the all-jets channels use this technique in one way or another. In 20.2 fb^{-1} of data at $\sqrt{s}=8$ TeV in the lepton+jets channel, ATLAS achieves a total uncertainty of 0.53% with a statistical component of 0.23% [187]. The measurement is based on a 3-dimensional template fit, determining the top-quark mass, the global jet energy scale and a b-to-light jet energy scale factor. The most precise CMS result in the lepton+jets channel uses an ideogram method and comes from a so-called 'hybrid' approach in which the prior knowledge about the jet energy scale is incorporated as a Gaussian constraint, with a width determined by the uncertainty on the jet energy corrections. In 19.7 fb^{-1} of $\sqrt{s}=8$ TeV data, CMS achieves a total uncertainty of 0.30% with a statistical component of 0.09% with the hybrid approach [188]. Using this same method, CMS has released a top-mass measurement from $\sqrt{s}=13$ TeV data. Using 35.9 fb^{-1} of lepton+jets events they measure the top mass with a precision of 0.36%, with a statistical component of 0.05% [189]. The measurements at $\sqrt{s}=13$ TeV include, for the first time, an uncertainty due to 'color reconnection' [190, 191]. In this same dataset, CMS has extracted a top mass from highly boosted top-quark decays by selecting events in which the hadronic-side top decay is reconstructed as a single jet with $P_T > 400$ GeV. The cross section as a function of jet mass is unfolded at the particle level to extract a top mass with a precision of 1.4% [192].

The template method is complemented by the 'matrix element' method. This method was first applied by the DØ Collaboration [193], and is similar to a technique originally suggested by Kondo *et al.* [194] and Dalitz and Goldstein [195] In the matrix element method a probability for each event is calculated as a function of the top-quark mass, using a LO matrix element for the production and decay of $t\bar{t}$ pairs. The *in situ* calibration of dijet pairs to the $W \to jj$ hypothesis is now also used with the matrix element

technique to constrain the jet energy scale uncertainty. In the lepton+jets channel, DØ uses the full Tevatron dataset of 9.7 fb^{-1} and yields an uncertainty of about 0.43% [196].

In the dilepton channel, the signal to background is typically very good, but reconstruction of the mass is non-trivial because there are two neutrinos in the final state, yielding a kinematically unconstrained system. A variety of techniques have been developed to handle this. An analytic solution to the problem has been proposed [197], but this has not yet been used in the mass measurement. One of the most precise measurements in the dilepton channel comes from using the invariant mass of the charged lepton and b-quark system ($M_{\ell b}$), which is sensitive to the top-quark mass and avoids the kinematic difficulties of the two-neutrino final state. In 4.6 fb^{-1} of $\sqrt{s} = 7$ TeV data, ATLAS has measured the top-quark mass in the dilepton channel to a precision of 0.53% using a template fit to the $M_{\ell b}$ distribution [198]. Using 19.7 fb^{-1} of data at $\sqrt{s} = 8$ TeV, CMS has released [199] a mass measurement in the dilepton channel based on a simultaneous fit to $M_{\ell b}$ and a transverse-mass-like variable M_{T2} [200]. The most precise result in this analysis, which comes from a linear combination of fits with the jet energy scale fixed at its nominal value and one that simultaneously determines the top mass and jet energy scale, has a total uncertainty of 0.54%. At the LHC, because of their precision, these techniques have largely displaced a number of earlier techniques in the dilepton channel, though these techniques are still included, and described, in the combined results from CMS, reported in Ref. [188].

In the neutrino weighting technique, used by CDF to analyze the full Run 2 dilepton dataset of 9.1 fb^{-1}, a weight is assigned by assuming a top-quark mass value and applying energy-momentum conservation to the top-quark decay, resulting in up to four possible pairs of solutions for the neutrino and anti-neutrino momenta. The missing E_T calculated in this way is then compared to the observed missing E_T to assign a weight [205]. The CDF result achieves a precision of 1.8% using a combination of neutrino weighting and an "alternative mass", which is insensitive to the jet energy scale [206]. The alternative mass depends on the angles between the leptons and the leading jets and the lepton four-momenta.

In the all-jets channel there is no ambiguity due to neutrino momenta, but the signal to background is significantly poorer due to the severe QCD multijets background. The emphasis therefore has been on background modeling, and reduction through event selection. The most recent measurement in the all-jets channel, by CMS in 35.9 fb^{-1} of $\sqrt{s} = 13$ TeV data [201], uses an ideogram method and a 2-dimensional simultaneous fit for m_t and the jet energy scale to extract the top-quark mass and achieves a precision of 0.36%. A measurement from ATLAS [202] uses a template fit to the ratio of three-jet (m_t) to two-jet (M_W) mass in the all-hadronic channel, the two-jet denominator provides an *in situ*, fit to the $W \to jj$ hypothesis. In 20.2 fb^{-1} of data at $\sqrt{s} = 8$ TeV, the result has a precision of 0.65%. A measurement from CDF in 9.3 fb^{-1} uses a two-dimensional template fit and achieves a precision of 1.1% [207].

The CMS Collaboration extracted a top-quark mass measurement from single-top events, something not previously done because of the poor signal to background ratio. The mass is extracted from the invariant mass of the muon, bottom quark, and missing transverse energy. The first measurement with 19.7 fb^{-1} of data at $\sqrt{s} = 8$ TeV, achieved a precision of 0.71% [208]. A more recent measurement in 35.9 fb^{-1} of data at $\sqrt{s} = 13$ TeV achieves 0.44% precision [203].

A dominant systematic uncertainty in these methods is the understanding of the jet energy scale, and so several techniques have been developed that have little sensitivity to the jet energy scale uncertainty. In addition to Reference [206] mentioned above, these include the measurement of the top-quark mass using the following techniques: Fitting of the lepton p_T spectrum of candidate events [209]; fitting of the transverse decay length of the b-jet (L_{xy}) [210]; fitting the invariant mass of a lepton from the W-decay and a muon from the semileptonic b decay [211, 212], kinematic properties of secondary vertices from b-quark fragmentation [213], the invariant mass of the $J/\psi + \ell$ system in events in which a b-quark fragments to a J/ψ particle [214], fitting the b-jet energy peak [215], and dilepton kinematics in $e\mu$ events [216].

Several measurements have now been made in which the top-quark mass is extracted from the measured $t\bar{t}$ cross section using the theoretical relationship between the mass and the production cross section. These determinations make use of predictions calculated at higher orders, where the top mass enters as an input parameter defined in a given scheme. At variance with the usual methods, which involve the kinematic properties of the final states and therefore the pole mass, this approach can also directly determine a short-distance mass, such as the $\overline{\text{MS}}$ mass [217]. With an alternative method ATLAS extracted the top-quark pole mass using $t\bar{t}$ events with at least one additional jet, basing the measurement on the relationship between the differential rate of gluon radiation and the mass of the quark [218]. A similar analysis by CMS used the differential cross section as a function of the invariant mass of the $t\bar{t}$ system and the leading jet not associated with the top decays [219].

Each of the experiments has produced a measurement combining its various results. The combined measurement from CMS with up to 19.7 fb^{-1} of data achieves statistical and systematic uncertainties of 0.08% and 0.27%, respectively [188]. The combined measurement from ATLAS, with up to 20.3 fb^{-1} yields statistical and systematic uncertainties of 0.14% and 0.24%, respectively [187]. CDF has combined measurements with up to 9.3 fb^{-1} [220] and achieves a statistical precision of 0.33% and a systematic uncertainty of 0.43%. DØ achieves a 0.33% statistical+JES and a 0.28% systematic uncertainty by combining results in 9.7 fb^{-1} [221].

Combined measurements from the Tevatron experiments and from the LHC experiments take into account the correlations between different measurements from a single experiment and between measurements from different experiments. The Tevatron average [204], using up to 9.7 fb^{-1} of data, now has a precision of 0.37%. The LHC combination, using up to 4.9 fb^{-1} of data, has a precision of 0.56% [222], where more work on systematic uncertainties is required. A Tevatron-LHC combination has been released, combining the results of all four experiments, using the full Tevatron dataset and the $\sqrt{s} = 7$ TeV LHC data, with a resulting precision of 0.44% [3]

The direct measurements of the top-quark mass, such as those shown in Table 61.1, correspond to the parameter used in the Monte Carlo generators, which is closely related to the pole mass [223]. The relation between the pole mass and short-distance masses, such as $\overline{\text{MS}}$, is affected by non-perturbative effects. Recent calculations evaluate the size of this ambiguity to be below 250 MeV and therefore still smaller than the current measurement uncertainty [224, 225]. ATLAS has recently performed a 'calibration' of the top mass parameter in Powheg + Pythia 8 with respect to the so-called 'MSR' mass scheme [226]. Using simulated lepton+jets events and the mass distribution of large-radius jets containing the three quarks from the hadronically decaying top quark, they find a mass difference between the Monte Carlo mass and the MSR mass of 80 MeV with large uncertainties [227].

As a result of renormalization at higher-orders in perturbation theory, the top quark mass depends on the scale at which it is evaluated. The CMS collaboration has made the first measurement of the so-called running of the top-quark mass in the $\overline{\text{MS}}$ scheme [228]. The running mass is extracted from a measurement of the differential cross section as a function of the $t\bar{t}$ invariant mass, unfolded back to the parton level, in $e\mu$ final states. The running mass varies by about 15% from $M_{t\bar{t}} = 400$ GeV to $M_{t\bar{t}} \approx 1$ TeV, in good agreement with the renormalization group calculation at one-loop level. Compared to the hypothesis of no running, the significance of the measured running is 2.6σ. However, caveats of such an interpretation have been raised as a result of the large theoretical uncertainties [229].

With the discovery of a Higgs boson at the LHC with a mass of about 125 GeV/c^2 [230, 231], the precision measurement of the top-quark mass takes a central role in the question of the stability of the electroweak vacuum because top-quark radiative corrections tend to drive the Higgs quartic coupling, λ, negative, potentially leading to an unstable vacuum. A calculation at NNLO [232]

Table 61.1: Measurements of top-quark mass from Tevatron and LHC. The results are a selection of both published and preliminary (not yet submitted for publication as of September 2021) measurements. For a complete set of published results see the Listings. Statistical uncertainties are listed first, followed by systematic uncertainties.

m_t (GeV/c^2)	Source	$\int \mathcal{L}$dt fb^{-1}	Ref.	Channel
$172.08 \pm 0.25 \pm 0.41$	ATLAS	20.2	[187]	ℓ+jets+$\ell\ell$+All jets

leads to the conclusion of vacuum stability for a Higgs mass satisfying $M_H \geq 129.4 \pm 5.6$ GeV/c^2 [233]. Given the uncertainty, a Higgs mass of 125 GeV/c^2 satisfies the limit, but the central values of the Higgs and top-quark masses put the electroweak vacuum squarely in the metastable region. The uncertainty is dominated by the precision of the top-quark mass measurement and its interpretation as the pole mass. For more details, see the Higgs boson review in this volume.

As a test of the CPT-symmetry, the mass difference of top- and antitop-quarks $\Delta m_t = m_t - m_{\bar{t}}$, which is expected to be zero, can be measured. CDF measures the mass difference in 8.7 fb^{-1} of 1.96 TeV data in the lepton+jets channel using a template methode to find $\Delta m_t = -1.95 \pm 1.11(stat.) \pm 0.59(syst.)$ GeV/c^2 [234] while DØ uses 3.6 fb^{-1} of lepton+jets events and the matrix element method with at least one b-tag. They find $\Delta m_t = 0.8 \pm 1.8(stat.) \pm 0.5(syst.)$ GeV/c^2 [235]. In 4.7 fb^{-1} of 7 TeV data, ATLAS measures the mass difference in lepton+jets events with a double b-tag requirement and hence very low background to find $\Delta m_t = 0.67 \pm 0.61(stat.) \pm 0.41(syst.)$ GeV/c^2 [236]. CMS measures the top-quark mass difference in 5 fb^{-1} of 7 TeV data in the lepton+jets channel and finds $\Delta m_t = -0.44 \pm 0.46(stat.) \pm 0.27(syst.)$ GeV/c^2 [237]. They repeat this measurement with 19.6 fb^{-1} of 8 TeV data to find $\Delta m_t = -0.15 \pm 0.19(stat.) \pm 0.09(syst.)$ GeV/c^2 [238]. Now that the top mass has been measured in single-top events, the mass difference can be measured by tagging the top- or anti-top quark with the lepton charge. In 35.9 fb^{-1} of 13 TeV single-top candidate events CMS measures the mass ratio and difference to be $0.995^{+0.005}_{-0.006}$ and $0.83^{+0.77}_{-1.01}$ GeV, respectively [203]. All measurements are consistent with the SM expectation.

61.3.2.2 *Top-Quark Spin Correlations, Polarization, and Width*

One of the unique features of the top quark is that it decays before its spin can be flipped by the strong interaction. Thus the top-quark polarization is directly observable via the angular distribution of its decay products and it is possible to define and measure observables sensitive to the top-quark spin and its production mechanism. Although the top- and antitop-quarks produced by strong interactions in hadron collisions are essentially unpolarized, the spins of t and $\bar{t}$ are correlated. For QCD production at threshold, the $t\bar{t}$ system is produced in a $^3S_1$ state with parallel spins for $q\bar{q}$ annihilation or in a $^1S_0$ state with antiparallel spins for gluon-gluon fusion. The situations at the Tevatron, where the production is primarily from $q\bar{q}$ annihilation, and at the LHC, where the production is primarily from gluon-gluon fusion, are therefore somewhat complementary. However, at the LHC production of $t\bar{t}$ pairs at large invariant mass occurs primarily via fusion of gluons with opposite helicities, and the $t\bar{t}$ pairs so produced have parallel spins as in production at the Tevatron via $q\bar{q}$ annihilation. The direction of the top-quark spin is 100% correlated to the angular distributions of the down-type fermion (charged leptons or d-type quarks) in the decay. The joint angular distribution [239–241]

$$\frac{1}{\sigma}\frac{d^2\sigma}{d(\cos\theta_+)d(\cos\theta_-)} = \frac{1}{4}(1 + B_+\cos\theta_+ + B_-\cos\theta_- + \kappa\cdot\cos\theta_+\cdot\cos\theta_-), \quad (61.4)$$

where θ_+ and θ_- are the angles of the daughters in the top-quark rest frame with respect to a particular spin quantization axis (assumed here to be the same for θ_+ and θ_-), is a very sensitive observable. The maximum value for κ, 0.782 at NLO at the Tevatron [242], is found in the off-diagonal basis [239], while at the LHC the value at NLO is 0.326 in the helicity basis [242]. The coefficients B_+ and B_- are near zero in the SM because the top quarks are unpolarized in $t\bar{t}$ production. In place of κ, $A\alpha_+\alpha_-$ is often used, where α_i is the spin analyzing power, and A is the spin correlation coefficient, defined as

$$A = \frac{N(\uparrow\uparrow) + N(\downarrow\downarrow) - N(\uparrow\downarrow) - N(\downarrow\uparrow)}{N(\uparrow\uparrow) + N(\downarrow\downarrow) + N(\uparrow\downarrow) + N(\downarrow\uparrow)}, \quad (61.5)$$

where the first arrow represents the direction of the top-quark spin along a chosen quantization axis, and the second arrow represents the same for the antitop-quark. The spin analyzing power α_i is +0.998 for positively charged leptons, -0.966 for down-type quarks from W decays, and -0.393 for bottom quarks [243]. The sign of α flips for the respective antiparticles. The spin correlation could be modified by a new $t\bar{t}$ production mechanism such as through a Z' boson, Kaluza-Klein gluons, a dark-matter mediator, or a Higgs boson.

The experiments typically use a Monte Carlo to provide templates for the measured distributions, or alternatively a matrix-element technique, and fit a parameter f, representing the fraction of events with the expected Standard Model correlation, with $(1-f)$ the fraction with no correlation. The correlation coefficient is extracted via $A_{\rm meas} = f \cdot A_{\rm SM}$. A 'fraction' $f > 1$ means that the measured correlation coefficient is larger than the Standard Model expectation.

CDF used 5.1 fb^{-1} in the dilepton channel to measure the correlation coefficient in the beam axis [244]. The measurement was made using the expected distributions of $(\cos\theta_+, \cos\theta_-)$ and $(\cos\theta_b, \cos\theta_{\bar{b}})$ of the charged leptons or the b-quarks in the $t\bar{t}$ signal and background templates to calculate a likelihood of observed reconstructed distributions as a function of assumed κ. They determined the 68% confidence interval for the correlation coefficient κ as $-0.52 < \kappa < 0.61$ or $\kappa = 0.04 \pm 0.56$ assuming $m_t = 172.5$ GeV/c^2.

CDF also analyzed lepton+jets events in 5.3 fb^{-1} [245] assuming $m_t = 172.5$ GeV/c^2. They form three separate templates - the same-spin template, the opposite-spin template, and the background template for the 2-dimensional distributions in $\cos(\theta_l)\cos(\theta_d)$ vs. $\cos(\theta_l)\cos(\theta_b)$. The fit to the data in the helicity basis returns an opposite helicity fraction of $F_{OH} = 0.74 \pm 0.24(stat.) \pm 0.11(syst.)$. Converting this to the spin correlation coefficient yields $\kappa_{helicity} = 0.48 \pm 0.48(stat.) \pm 0.22(syst.)$. In the beamline basis, they find an opposite spin fraction of

$F_{OS} = 0.86 \pm 0.32(stat.) \pm 0.13(syst.)$ which can be converted into a correlation coefficient of $\kappa_{beam} = 0.72 \pm 0.64(stat.) \pm 0.26(syst.)$.

DØ performed a measurement of the ratio f of events with correlated t and $\bar{t}$ spins to the total number of $t\bar{t}$ events. Combining dilepton and lepton plus jets events, and using a matrix-element technique in 9.7 fb^{-1} of Tevatron data, DØ measures $f = 1.16 \pm 0.21$, corresponding to $A_{exp.} = 0.89 \pm 0.22(stat.+syst.)$ in the off-diagonal basis [246].

In Ref. [247] DØ presents a measurement of top-quark polarization in $t\bar{t}$ production at the Tevatron. In 9.7 fb^{-1} of $p\bar{p}$ collisions, DØ uses lepton angular distributions in lepton+jets events to measure polarization in the beam, helicity, and transverse bases. The measurements are, respectively, 0.081 ± 0.048, -0.102 ± 0.061 and, 0.040 ± 0.035, where the beam-basis result is a combination with an earlier DØ result in dilepton events [248]. These results are all consistent near-zero polarization, as predicted in the SM.

Spin correlations have been conclusively measured at the LHC by both the ATLAS and CMS collaborations. In the dominant gluon fusion production mode for $t\bar{t}$ pairs at the LHC, the angular distribution between the two leptons in $t\bar{t}$ decays to dileptons is sensitive to the degree of spin correlation [249].

Measurements have been made at 7, 8, and now 13 TeV. While there is some interest in the $\sqrt{s}$ dependence of the correlations as a test of the production mechanism ($q\bar{q}$ vs gluon-gluon and possible sensitivity to new physics) the earlier measurements at 7 and 8 TeV [250–255] had relatively large uncertainties and have now been overtaken by the high-statistics 13 TeV measurements, which we review here.

The most recent result from ATLAS, in 36.1 fb^{-1} at $\sqrt{s} =$ 13 TeV, uses $\Delta\phi$, the azimuthal angle between the two charged leptons in $e\mu$ events in an analysis that also measures the differential cross sections in $\Delta\phi$ and $\Delta\eta$ between the two leptons [256]. The result, measured by comparison with NLO Monte Carlo generators, is $f = 1.249 \pm 0.024 \pm 0.061^{+0.067}_{-0.090}$, where the uncertainties are statistical, systematic, and theoretical, is again greater than 1.0. Whereas the previous results were statistically consistent with the Standard Model expectation of 1.0, this result is inconsistent at the level of 2.2σ. The NLO generators are NLO in QCD only (and only at the production level). Including electroweak couplings produces an expected Standard Model distribution consistent with the data, but results in a large scale uncertainty, giving $f = 1.03 \pm 0.13$.

In 35.9 fb^{-1} of data at $\sqrt{s} = 13$ TeV, CMS has measured spin correlations in dilepton events using $\Delta\phi$ and found $f = 1.05 \pm 0.03 \pm 0.08^{+0.09}_{-0.12}$ [257], where the uncertainties are statistical, systematic, and theoretical. The correlation is also measured using the coefficient κ in Eq. 61.4 (called $-C_{ij}$ in Reference [257]) using three orthogonal spin quantization axes defined in Ref. [258]. All results are consistent with $f = 1$. Measurements of the coefficients B_i in Eq. 61.4 in this analysis, which are expected to be nearly zero in the SM, yield $B_+ = 0.005 \pm 0.023$ and $B_- = 0.007 \pm 0.023$, consistent with the SM predictions at NLO of $0.0040^{+0.0017}_{-0.0012}$ [258]. These results are part of a complete study of the top-quark spin density matrix at $\sqrt{s} = 13$ TeV, through the measurement of the coefficients of Eq. 61.4.

In a similar ATLAS measurement at $\sqrt{s} = 8$ TeV [259], the spin-correlation coefficient κ is measured in the helicity basis to be $\kappa = 0.296 \pm 0.093$ in good agreement with the SM expectation of 0.318 (corresponding to a central value of f of 0.931). The polarization coefficients, B, in Eq. 61.4 are measured, also in the helicity basis, to be $B_+ = -0.044 \pm 0.038$ and $B_- = -0.064 \pm 0.040$, consistent with the SM predictions of 0.0030 ± 0.0010 and 0.0034 ± 0.00104, respectively.

Observation of top-quark spin correlations requires a top-quark lifetime less than the spin decorrelation timescale [260]. The top-quark width, inversely proportional to its lifetime, is expected to be of order 1 GeV/c^2 (Eq. 1). Early measurements made at CDF [261] and CMS [262] established confidence-level intervals for the width, but did not have the sensitivity to make a direct measurement.

The first direct measurement comes from an ATLAS analysis that directly fits reconstructed lepton+jets events in 20.2 fb^{-1} of data at $\sqrt{s} = 8$ TeV. They find $\Gamma_t = 1.76 \pm 0.33^{+0.79}_{-0.68}$ GeV/c^2 [263]. A more recent measurement from ATLAS with 139 fb^{-1} of data at $\sqrt{s} = 13$ TeV [264], uses a template fit to the lepton-b-quark invariant mass in dilepton final states. The result, $\Gamma_t = (1.9 \pm 0.5)$ GeV/c^2, is the most precise measurement to date.

The total width of the top-quark can also be determined from the partial decay width $\Gamma(t \to Wb)$ and the branching fraction $B(t \to Wb)$. DØ obtains $\Gamma(t \to Wb)$ from the measured t-channel cross section for single top-quark production in 5.4 fb^{-1}, and $B(t \to Wb)$ is extracted from a measurement of the ratio $R = B(t \to Wb)/B(t \to Wq)$ in $t\bar{t}$ events in lepton+jets channels with 0, 1 and 2 b-tags. Assuming $B(t \to Wq) = 1$, where q includes any kinematically accessible quark, the result is: $\Gamma_t = 2.00^{+0.47}_{-0.43}$ GeV/c^2 which translates to a top-quark lifetime of $\tau_t = (3.29^{+0.90}_{-0.63}) \times 10^{-25}$ s. Assuming a high mass fourth generation b' quark and unitarity of the four-generation quark-mixing matrix, they set the first upper limit on $|V_{tb'}| < 0.59$ at 95% C.L. [265]. A similar analysis has performed by CMS in 19.7 fb^{-1} of $\sqrt{s} = 8$ TeV data. It provides a better determination of the total width with respect to the measurement by DØ giving $\Gamma_t = 1.36 \pm 0.02(stat.)^{+0.14}_{-0.11}(syst.)$ GeV/c^2 [75].

61.3.2.3 *W-Boson Helicity in Top-Quark Decay*

The Standard Model dictates that the top quark has the same vector-minus-axial-vector ($V - A$) charged-current weak interactions $\left(-i\frac{g}{\sqrt{2}}V_{tb}\gamma^\mu\frac{1}{2}(1-\gamma_5)\right)$ as all the other fermions. In the SM, the fraction of top-quark decays to longitudinally polarized W bosons is proportional to its Yukawa coupling and hence enhanced with respect to the weak coupling. It is expected to be [266] $\mathcal{F}_0^{\rm SM} \approx x/(1+x)$, $x = m_t^2/2M_W^2$ ($\mathcal{F}_0^{\rm SM} \sim 70\%$ for $m_t = 173$ GeV/c^2). Fractions of left-handed, right-handed, or longitudinal W bosons are denoted as $\mathcal{F}_-$, $\mathcal{F}_+$, and $\mathcal{F}_0$ respectively. In the SM, $\mathcal{F}_-$ is expected to be $\approx 30\%$ and $\mathcal{F}_+ \approx 0\%$. Predictions for the W polarization fractions at NNLO in QCD are available [267].

The Tevatron and the LHC experiments use various techniques to measure the helicity of the W boson in top-quark decays, in both the lepton+jets and in dilepton channels in $t\bar{t}$ production.

The first method uses a kinematic fit, similar to that used in the lepton+jets mass analyses, but with the top-quark mass constrained to a fixed value, to improve the reconstruction of final-state observables, and render the under-constrained dilepton channel solvable. Alternatively, in the dilepton channel the final-state momenta can also be obtained through an algebraic solution of the kinematics. The distribution of the helicity angle ($\cos\theta^*$) between the lepton and the b quark in the W rest frame provides the most direct measure of the W helicity. In a simplified version of this approach, the $\cos\theta^*$ distribution is reduced to a forward-backward asymmetry.

The second method (p_T^ℓ) uses the different lepton p_T spectra from longitudinally or transversely polarized W-decays to determine the relative contributions.

A third method uses the invariant mass of the lepton and the b-quark in top-quark decays ($M_{\ell b}^2$) as an observable, which is directly related to $\cos\theta^*$.

At the LHC, top-quark pairs in the dilepton channels are reconstructed by solving a set of six independent kinematic equations in the missing transverse energy in x- and in y-direction, two W-masses, and the two top/antitop-quark masses. In addition, the two jets with the largest p_T in the event are interpreted as b-jets. The pairing of the jets to the charged leptons is based on the minimization of the sum of invariant masses M_{min}. Simulations show that this criterion gives the correct pairing in 68% of the events.

Finally, the Matrix Element Method (MEM) has also been used [194], in which a likelihood is formed from a product of event probabilities calculated from the MEM for a given set of measured kinematic variables and assumed W-helicity fractions.

The results of recent CDF, DØ, ATLAS, and CMS analyses are summarized in Table 61.2. The datasets are now large enough to allow for a simultaneous fit of $\mathcal{F}_0$, $\mathcal{F}_-$ and $\mathcal{F}_+$, which we denote by '3-param' or $\mathcal{F}_0$ and $\mathcal{F}_+$, which we denote by '2-param' in the table. Results with either $\mathcal{F}_0$ or $\mathcal{F}_+$ fixed at its SM value are denoted '1-param'. For the simultaneous fits, the correlation

coefficient between the two values is about −0.8. A complete set of published results can be found in the Listings. All results are in agreement with the SM expectation.

CDF and DØ combined their results based on $2.7 - 5.4$ fb^{-1} [268] for a top-quark mass of 172.5 GeV/c^2. ATLAS presents results from 1.04 fb^{-1} of $\sqrt{s} = 7$ TeV data using a template method for the $\cos\theta^*$ distribution and angular asymmetries from the unfolded $\cos\theta^*$ distribution in the lepton+jets and the dilepton channel [269]. CMS performs a similar measurement based on template fits to the $\cos\theta^*$ distribution with 5.0 fb^{-1} of 7 TeV data in the lepton+jets final state [270]. As the polarization of the W bosons in top-quark decays is sensitive to the Wtb vertex Lorentz structure and anomalous couplings, both experiments also derive limits on anomalous contributions to the Wtb couplings. CMS and ATLAS collaborations have also combined their results from 7 TeV data to obtain values on the helicity fractions as well as limits on anomalous couplings [271].

At 8 TeV, ATLAS came out with a measurement of the W-helicity fractions in 20.2 fb^{-1} in lepton+jets events with at least one b-tag [272]. Using 19.8 fb^{-1} of 8 TeV data, CMS measured the W-helicity in lepton + 4 jet events with two b-tags [273]. In $t\bar{t}$ events with two opposite-sign leptons (electron or muon) in the final state in this dataset, CMS applied six kinematic constraints on the kinematics of the produced particles [274]. Also, using the same dataset a first measurement of the W-boson helicity in top-quark decays was made in electroweak single top production [275], yielding similarly precise and consistent results. The 8 TeV results obtained in $t\bar{t}$ and single-top events by ATLAS and CMS have also been combined recently [276]. These results are in agreement with the standard model predictions at next-to-next-to-leading order in perturbative QCD and represent an improvement in precision of 25 (29)% for F_0 (F_L) with respect to the most precise single measurement. A limit on anomalous right-handed vector (V_R), and left- and right-handed tensor (g_L, g_R) tWb couplings and on corresponding Wilson coefficients is set.

61.3.2.4 *Top-Quark Electroweak Charges and Couplings*

The top quark is the only quark whose electric charge has not been measured through production at threshold in e^+e^- collisions. Furthermore, it is the only quark whose electromagnetic coupling has not been observed and studied until recently. Since the CDF and DØ analyses on top-quark production did not associate the b, $\bar{b}$, and $W^\pm$ uniquely to the top or antitop, decays such as $t \to W^+\bar{b}, \bar{t} \to W^-b$ were not excluded. A charge 4/3 quark of this kind is consistent with current electroweak precision data. The $Z \to \ell^+\ell^-$ and $Z \to b\bar{b}$ data, in particular the discrepancy between A_{LR} from SLC at SLAC and $A_{FB}^{0,b}$ of b-quarks and $A_{FB}^{0,\ell}$ of leptons from LEP at CERN, can be fitted with a top quark of mass $m_t = 270$ GeV/c^2, provided that the right-handed b quark mixes with the isospin +1/2 component of an exotic doublet of charge −1/3 and −4/3 quarks, $(Q_1, Q_4)_R$ [278,279]. Also the third component of the top quark's weak isospin has not been measured so far.

DØ studied the top-quark charge in double-tagged lepton+jets events, CDF did it in single tagged lepton+jets and dilepton events. Assuming the top- and antitop-quarks have equal but opposite electric charge, then reconstructing the charge of the b-quark through jet charge discrimination techniques, the $|Q_{top}| = 4/3$ and $|Q_{top}| = 2/3$ scenarios can be differentiated. For the exotic model of Chang *et al.* [279] with a top-quark charge $|Q_{top}| = 4/3$, CDF excluded the model at 99% C.L. [280] in 5.6 fb^{-1}, while DØ excluded the model at a significance greater than 5 standard deviations using 5.3 fb^{-1} and set an upper limit of 0.46 on the fraction of such quarks in the selected sample [281]. These results indicate that the observed particle is indeed consistent with being a SM $|Q| = 2/3$ quark.

In 2.05 fb^{-1} at $\sqrt{s} = 7$ TeV, ATLAS performed a similar analysis, reconstructing the b-quark charge either via a jet-charge technique or via the lepton charge in soft muon decays in combination with a kinematic likelihood fit. They measure the top-quark charge to be $0.64 \pm 0.02(stat.) \pm 0.08(syst.)$ from the charges of the top-quark decay products in single lepton $t\bar{t}$ events, and hence exclude the exotic scenario with charge −4/3 at more than 8σ [282].

In 4.6 fb^{-1} at $\sqrt{s} = 7$ TeV, CMS discriminates between the SM and the exotic top-quark charge scenario in the muon+jets final states in $t\bar{t}$ events. They exploit the charge correlation between high-p_t muons from W-boson decays and soft muons from B-hadron decays in b-jets. Using an asymmetry technique, where $A = -1$ represents the exotic $Q = -4/3$ scenario and $A = +1$ the SM $Q = +2/3$ scenario, they find $A_{meas} = 0.97 \pm 0.12(stat.) \pm 0.31(sys.)$, which agrees with the Standard Model expectation and excludes the exotic scenario at 99.9% C.L. [283].

The electromagnetic or the weak coupling of the top quark can be probed directly by investigating $t\bar{t}$ events with an additional gauge boson, such as $t\bar{t}\gamma$, $t\bar{t}W$, and $t\bar{t}Z$ events. The corresponding coupling can be extracted from the corresponding cross section or extracted from effective field theory (EFT) fits to various measured distributions and differential cross sections.

CDF performed a search for events containing a lepton, a photon, significant missing transverse momentum, and a jet identified as containing a b-quark and at least three jets and large total transverse energy in 6.0 fb^{-1}. They reported evidence for the observation of $t\bar{t}\gamma$ production with a cross section $\sigma_{t\bar{t}\gamma} = 0.18 \pm 0.08$ pb and a ratio of $\sigma_{t\bar{t}\gamma}/\sigma_{t\bar{t}} = 0.024 \pm 0.009$ [284].

ATLAS performed a first measurement of the $t\bar{t}\gamma$ cross section in pp collisions at $\sqrt{s} = 7$ TeV using 4.6 fb^{-1} of data. Events are selected that contain a large transverse momentum electron or muon and a large transverse momentum photon. The production of $t\bar{t}\gamma$ events was observed with a significance of 5.3 standard deviations. The resulting cross section times branching ratio into the single lepton channel for $t\bar{t}\gamma$ production with a photon with transverse momentum above 20 GeV is $\sigma^{fid.}(t\bar{t}\gamma) \times BR = 63 \pm 8(stat.)^{+17}_{-13}(syst.) \pm 1(lumi.)$ pb per lepton flavour [285], which is consistent with leading-order theoretical calculations.

At 8 TeV, ATLAS has used 20.2 fb^{-1} of data to measure the $t\bar{t}\gamma$ cross section with a photon above 15 GeV and $|\eta| < 2.37$. The fiducial cross section is measured to be 139 ± 18 fb [286], in good agreement with the NLO prediction [287]. Using 19.7 fb^{-1} of data at 8 TeV, CMS performed a similar measurement of the $t\bar{t}\gamma$ production cross section in the lepton+jets decay mode with a photon transverse momentum above 25 GeV and $|\eta|$ <1.44. They obtain a normalized cross section $\mathcal{R} = \sigma_{t\bar{t}+\gamma}/\sigma_{t\bar{t}} = (5.7 \pm 1.8) \times 10^{-4}$ in e+jets and $(4.7 \pm 1.3) \times 10^{-4}$ in μ+jets. The fiducial $t\bar{t}\gamma$ cross section is obtained by multiplying by the measured $t\bar{t}$ fiducial cross section of $244.9 \pm 1.4(stat.)^{+6.3}_{-5.5}(sys.) \pm 6.4(lumi.)$ pb. Extrapolating to the full phase space, the result is $\sigma_{t\bar{t}\gamma} \times$BR$=(515 \pm 108)$ fb, per lepton+jets final state [288], in good agreement with the theoretical prediction.

At $\sqrt{s} = 13$ TeV, using 36.1 fb^{-1} of single-lepton and dilepton events with exactly one photon, ATLAS measures the $t\bar{t}\gamma$ cross section. They employ neural network algorithms to separate the signal from the backgrounds. The fiducial cross-sections are measured to be $521 \pm 9(stat.) \pm 41(sys.)$ fb and $69 \pm 3(stat.) \pm 4(sys.)$ fb for the single-lepton and dilepton channels, respectively. The differential cross-sections are measured as a function of photon transverse momentum, photon absolute pseudorapidity, and angular distance between the photon and its closest lepton in both channels, as well as azimuthal opening angle and absolute pseudorapidity difference between the two leptons in the dilepton channel. All measurements are in agreement with the theoretical predictions [289]. Very recently, ATLAS uses 139 fb^{-1} of $\sqrt{s} = 13$ TeV $e\mu + \gamma$ events with at least two jets, out of which at least one is b-tagged, to measure the inclusive and differential cross-sections for the production of a top-quark pair in association with a photon. This analysis is sensitive to both processes, $t\bar{t}\gamma + tW\gamma$. The fiducial cross-section is measured to be $39.6^{+2.7}_{-2.3}$ fb in good agreement with the dedicated theoretical calculation provided by the authors of refs. [290, 291], which predicts a value of $\sigma_{fid} = 38.50^{+0.56}_{-2.18}$ (scale)$^{+1.04}_{-1.18}$ (PDF) fb for the chosen fiducial phase space. Differential cross-sections as functions of several observables are compared to state-of-the-art Monte Carlo simulations and next-to-leading order theoretical calculations. These include cross-sections as functions of the photon transverse momentum and absolute pseudorapidity and angular variables related to the photon and the leptons and between the two leptons in the event. All measurements are in agreement with the predic-

Table 61.2: Measurement and 95% C.L. upper limits of the W helicity in top-quark decays. The table includes both preliminary, as of September 2021, and published results. A full set of published results is given in the Listings.

W Helicity	Source	$\int \mathcal{L}dt$ (fb^{-1})	Ref.	Method

tions [292]. In 35.9 fb^{-1} of lepton-plus-photon-plus-jets events, CMS manages to establish the first evidence for the associated production of a single-top quark and a photon at $\sqrt{s} = 13$ TeV. They employ a multivariate discriminant based on topological and kinematic event properties to separate signal from background processes. An excess above the background-only hypothesis is observed, with a significance of 4.4 standard deviations. A fiducial cross section is measured for isolated photons with transverse momentum greater than 25 GeV in the central region of the detector. The measured product of the cross section and branching fraction is $\sigma(pp \to t\gamma j)B(t \to \mu\gamma b) = 115 \pm 17(stat) \pm 30(syst)$ fb, which is consistent with the SM prediction [293]. Very recently, CMS used 137 fb^{-1} of data to measure the $t\bar{t}\gamma$ cross section. In the lepton-plus-jets channel, they perform measurements in a fiducial volume defined at the particle level. Events with an isolated, highly energetic lepton, at least three jets from the hadronization of quarks, among which at least one is b-tagged, and one isolated photon are selected. The inclusive fiducial $t\bar{t}\gamma$ cross section, for a photon with transverse momentum greater than 20 GeV and pseudorapidity $|\eta| < 1.4442$, is measured to be $\sigma_{t\bar{t}\gamma} = 800 \pm 7(stat) \pm 46(syst)$ fb, in good agreement with the prediction from the standard model at NLO in QCD [294]. The differential cross sections are also measured as a function of several kinematic observables and interpreted in the framework of the standard model effective field theory (EFT), leading to the most stringent direct limits to date on anomalous electromagnetic dipole moment interactions of the top quark and the photon. Using the same dataset, in the dilepton channel, an inclusive cross section of $174.4 \pm 2.5(stat) \pm 6.1(syst)$ fb is measured in a signal region with at least one b-tagged jet and exactly one photon with transverse momentum above 20 GeV [295]. In the same analysis, differential cross sections are measured as a function of several kinematic observables of the photon, leptons, and jet, and compared to standard model predictions. The measurements are also interpreted in the standard model effective field theory framework, and limits on the relevant Wilson coefficients are combined with a previous CMS measurement of the same production process using single-lepton events. Using 35.9 fb^{-1} of data with a single muon and a photon, CMS reports first evidence of events consistent with the production of a single top quark in association with a photon. A multivariate discriminant based on topological and kinematic event properties is employed to separate signal from background processes. An excess above the background-only hypothesis is observed, with a significance of 4.4 standard deviations [296]. A precision test of the vector and axial vector couplings in $t\bar{t}\gamma$ events or searches for possible tensor couplings of top-quarks to photons will only be feasible with an integrated luminosity of several hundred fb^{-1} in the future [297].

ATLAS and CMS have also studied the associate production of top-antitop quark pairs along with an electroweak gauge boson, where in the Standard Model the W-boson is expected to be produced via initial state radiation, while the Z-boson can also be radiated from a final-state top-quark and hence provides sensitivity to the top-quark neutral current weak gauge coupling, which implies a sensitivity to the third component of the top-quark's weak isospin, which has not been measured so far.

CMS performed measurements of the $t\bar{t}W$ and $t\bar{t}Z$ cross section at $\sqrt{s} = 7$ TeV with 5 fb^{-1}, yielding $\sigma_{t\bar{t}V} = 0.43^{+0.17}_{-0.15}(stat.)^{+0.09}_{-0.07}(syst.)$ pb ($V = Z, W$) and $\sigma_{t\bar{t}Z} = 0.28^{+0.14}_{-0.11}(stat.)^{+0.06}_{-0.03}(syst.)$ fb, at about 3 standard deviations significance [298] and compatible with the SM expectations of $0.306^{+0.031}_{-0.053}$ pb and $0.137^{+0.012}_{-0.016}$ pb, respectively [299, 300]. ATLAS performed a similar analysis with 4.7 fb^{-1} in the three-lepton channel and set an upper limit of 0.71 pb at 95% C.L. [301].

Using 20.3 fb^{-1} of 8 TeV data, ATLAS performs a simultaneous measurement of the $t\bar{t}W$ and $t\bar{t}Z$ cross section. They observe the $t\bar{t}W$ and $t\bar{t}Z$ production at the 5.0σ and 4.2σ level, respectively, yielding $\sigma_{t\bar{t}W} = 369^{+100}_{-91}$ fb and $\sigma_{t\bar{t}Z} = 176^{+58}_{-52}$ fb [302]. CMS performs an analysis where signal events are identified by matching reconstructed objects in the detector to specific final state particles from $t\bar{t}W$ and $t\bar{t}Z$ decays using 19.5 fb^{-1} of 8 TeV data. They obtain $\sigma_{t\bar{t}W} = 382^{+117}_{-102}$ fb and $\sigma_{t\bar{t}Z} = 242^{+65}_{-55}$ fb, yielding a significance of 4.8 and 6.4 standard deviation, respectively [303]. These measurements are used to set bounds on five anomalous dimension-six operators that would affect the $t\bar{t}W$ and $t\bar{t}Z$ cross sections.

The most recent measurements in these channels are made at 13 TeV from ATLAS and CMS in multilepton final states. ATLAS made a measurement using 36.1 fb^{-1} of events with two, three or four leptons. In multiple regions, the $t\bar{t}Z$ and $t\bar{t}W$ cross sections are simultaneously measured using a combined fit to all regions, yielding $\sigma_{t\bar{t}Z} = 0.95 \pm 0.08(stat) \pm 0.10(syst)$ pb and $\sigma_{t\bar{t}W} = 0.87 \pm 0.13(stat) \pm 0.14(syst)$ pb [304] to be compared with the NLO+NLL (QCD) and NLO (EW) SM predictions, $\sigma_{t\bar{t}W} = 579^{+14\%}_{-9\%}$ fb and $\sigma_{t\bar{t}Z} = 811^{+11\%}_{-10\%}$ fb [305]. Very recently, ATLAS uses 139 fb^{-1} in three and four lepton events to measure the inclusive and differential $t\bar{t}Z$ cross section. The inclusive cross

section is measured to be $\sigma_{t\bar{t}Z} = 0.99 \pm 0.05(stat.) \pm 0.08(syst.)$ pb [306], in agreement with the most precise theoretical predictions. The differential measurements are presented as a function of a number of kinematic variables which probe the kinematics of the $t\bar{t}Z$ system. Overall, good agreement is observed between the unfolded data and the predictions. CMS uses 35.9 fb^{-1} of data to measure $\sigma_{t\bar{t}W} = 0.77^{+0.12}_{-0.11}(stat.)^{+0.13}_{-0.12}(syst.)$ pb and $\sigma_{t\bar{t}Z} = 0.99^{+0.09}_{-0.08}(stat.)^{+0.12}_{-0.10}(syst.)$ pb production cross sections, and significances over the background-only hypotheses of 5.5σ and 9.5σ, respectively [307], firmly establishing the observation of these processes. Very recently, CMS measured the inclusive $t\bar{t}Z$ cross section in 77.5 fb^{-1} of events with three or four charged leptons, and the Z boson is detected through its decay to an oppositely charged lepton pair. The production cross section is measured to be $\sigma(t\bar{t}Z) = 0.95 \pm 0.05(stat) \pm 0.06(syst)$ pb. This measurement includes differential cross sections as functions of the transverse momentum of the Z boson and the angular distribution of the negatively charged lepton from the Z boson decay as well as stringent direct limits on the anomalous tZ couplings [308].

The electroweak couplings can also be probed in single-top production in association with a Z boson. The $pp \to tZq$ process at the LHC probes both the WWZ coupling in the case where the Z emerges from the t-channel W in single-top production and, in the case where the Z is radiated from the top quark, the tZ coupling. A CMS search at 8 TeV using 19.7 fb^{-1} produced a hint of a tZq signal in tri-lepton events, with a significance compared to the background-only hypothesis of 2.4σ [309]. Very recently, CMS and ATLAS collaborations used 139 fb^{-1} in three-lepton events to measure $tZ(\to \ell^+\ell^-)q$. CMS obtains $\sigma_{tZq} = 87.9^{+7.5}_{-7.3}(stat)^{+7.3}_{-6.0}(syst)$ fb for $m(\ell\ell) > 30$ GeV [310]. The ratio between the cross sections for the top quark and the top antiquark production in association with a Z boson is measured as $2.37^{+0.56}_{-0.42}(stat)^{+0.27}_{-0.13}(syst)$. Differential measurements at parton and particle levels are performed for the first time. Additionally, the spin asymmetry, which is sensitive to the top quark polarization, is determined from the differential distribution of the polarization angle at parton level to be $0.58^{+0.15}_{-0.16}$ (stat) ± 0.06 (syst), in agreement with SM predictions at next-to-leading order. Using neural networks, ATLAS improves the background rejection and extracts the signal. The measured cross-section for $m(\ell\ell) > 30$ GeV is $97 \pm 13(stat.) \pm 7(syst.)$ fb, consistent with the Standard Model prediction [311].

Searches for and now also measurements of the associate production of a top-antitop quark pair along with a Higgs boson, $t\bar{t}h$, with various subsequent decays provide sensitivity to the top-Higgs Yukawa coupling. For further details, see the review on "Higgs".

61.3.3 *Searches for Physics Beyond the Standard Model*

The top quark plays a special role in the SM. Being the only quark with a coupling to the Higgs boson of order one, it provides the most important contributions to the quadratic radiative corrections to the Higgs mass exposing the issue of the naturalness of the SM. It is therefore very common for models where the naturalness problem is addressed to have new physics associated with the top quark. In SUSY, for instance, naturalness predicts the scalar top partners to be the lightest among the squarks and to be accessible at the LHC energies (see the review "Supersymmetry: Theory"). In models where the Higgs is a pseudo-Goldstone boson, such as Little Higgs models, naturalness predicts the existence of partners of the top quarks with the same spin and color, but with different electroweak couplings, the so-called vectorial t'. Stops and t''s are expected to have sizeable branching ratios to top quarks. Another intriguing prediction of SUSY models with universal couplings at the unification scale is that for a top-quark mass close to the measured value, the running of the Yukawa coupling down to 1 TeV naturally leads to the radiative breaking of the electroweak symmetry [312]. In fact, the top quark plays a role in the dynamics of electroweak symmetry breaking in many models [313]. One example is topcolor [314], where a large top-quark mass can be generated through the formation of a dynamic $t\bar{t}$ condensate, X, which is formed by a new strong gauge force coupling preferentially to the third generation. Another example is topcolor-assisted technicolor [315], predicting the existence of a heavy Z' boson that couples preferentially to the third generation of quarks. If light enough such a state might be directly accessible at the present hadron collider energies, or if too heavy, lead to four-top interactions possibly visible in the $t\bar{t}t\bar{t}$ final state. This final state has been recently observed by CMS [316] and by ATLAS [119].

Current strategies to search for new physics in top quark events at hadron colliders are either tailored to the discovery of specific models or model independent. They can be broadly divided in two classes. In the first class new resonant states are looked for through decay processes involving the top quarks. Current searches for bosonic resonances in $t\bar{t}$ final states, or for direct stop and t' production, or for a charged Higgs in $H^+ \to t\bar{b}$ fall in the category. On the other hand, if new states are too heavy to be directly produced, they might still give rise to deviations from the SM predictions for the strength and Lorentz form of the top-quark couplings to other SM particles. Accurate SM predictions and measurements are therefore needed and the results be interpreted in the framework of an effective field theory [317–319] as done for example in recent analyses sensitive to the strength and structure of the top quark couplings by the ATLAS [94, 184, 276, 304, 320–323] and CMS [111, 121, 324–330] collaborations. Global effective field theory interpretations based on publicly available measurements in the top quark sector have also appeared [331–337].

61.3.3.1 *New Physics in Top Quark Production*

Theoretical [338, 339] and experimental efforts have been devoted to the searches of $t\bar{t}$ resonances, both at the Tevatron and at the LHC. Most the analyses have been performed in the hypothesis that resonances are narrow, yet generalizations have been considered for specific scenarios. At the Tevatron, both the CDF and DØ collaborations have searchedfor resonant production of $t\bar{t}$ pairs in the lepton+jets channel [340, 341]. In both analyses, the data indicate no evidence of resonant production of $t\bar{t}$ pairs. They place upper limits on the production cross section times branching fraction to $t\bar{t}$ in comparison to the prediction for a narrow ($\Gamma_{Z'} = 0.012 M_{Z'}$) leptophobic topcolor Z' boson. Within this model, they exclude Z' bosons with masses below 915 (CDF-full data set) and 835 (DØ, 5 fb^{-1}) GeV/c^2 at the 95% C.L. These limits turn out to be independent of couplings of the $t\bar{t}$ resonance (pure vector, pure axial-vector, or SM-like Z'). A similar analysis has been performed by CDF in the all-hadronic channel using 2.8 fb^{-1} of data [342]. At the LHC, both the CMS and ATLAS collaborations have searched for resonant production of $t\bar{t}$ pairs, employing different techniques and final-state signatures (all-hadronic, lepton+jets, dilepton) at $\sqrt{s} = 7$, 8 and 13 TeV. In the low mass range, from the $t\bar{t}$ threshold to about one TeV/c^2, standard techniques based on the reconstruction of each of the decay objects (lepton, jets and b-jets, missing E_T) are used to identify the top quarks, while at higher invariant mass, the top quarks are boosted and the decay products more collimated and can appear as large-radius jets with substructure. Dedicated reconstruction techniques have been developed in recent years for boosted top quarks [343] that are currently employed at the LHC. Most of the analyses are model-independent (i.e., no assumption on the quantum numbers of the resonance is made) yet they assume a small width and no signal-background interference. Using lepton+jets and fully hadronic channels in a data set corresponding to an integrated luminosity of 35.9 fb^{-1} at 13 TeV, the CMS collaboration finds no significant deviations from the SM background [344]. In particular, the existence of a leptophobic topcolor particle Z' is excluded at the 95% confidence level for resonances in the mass range $0.6 < M_{Z'} < 3.8$ TeV/c^2, $0.5 < M_{Z'} < 5.25$ TeV/c^2, and $0.5 < M_{Z'} < 6.65$ TeV/c^2 for $\Gamma_{Z'} = 1\%, 10\%, 30\% M_{Z'}$, respectively [345]. Kaluza-Klein excitations of a gluon with $M_{G_{KK}} < 4.55$ TeV/c^2 (at 95% confidence level) in the Randall-Sundrum model are also excluded. A dedicated analysis [346] searching for a scalar resonance, set bounds between 400 and 750 GeV in various scenarios. The ATLAS collaboration has performed a search for resonant $t\bar{t}$ production in the lepton+jets channel using 36.1 fb^{-1} of proton-proton (pp) collision data collected at a center-of-mass energy

$\sqrt{s}$ = 13 TeV [347]. A search for local excesses in the number of data events compared to the Standard Model expectation in the $t\bar{t}$ invariant mass spectrum is performed. No evidence for a $t\bar{t}$ resonance is found and 95% confidence-level limits on the production rate are determined for massive states predicted in several benchmark models. For instance, a narrow leptophobic topcolor Z' boson with a mass below 3.0 TeV/c^2 is excluded. A Kaluza-Klein excitation of the graviton is excluded for masses in the range 0.45 TeV/c^2 < m_G < 0.65 TeV/c^2. A Kaluza-Klein excitation of the gluon in a Randall-Sundrum model is excluded for masses below 3.8 TeV/c^2. ATLAS has also conducted a search for resonances in the all-jet final state at 13 TeV corresponding to an integrated luminosity of 139 fb^{-1} [348]. The $t\bar{t}$ events are reconstructed by selecting two top quarks in their fully hadronic decay modes. A Z' in the topcolor-assisted-technicolor model is excluded at 95% confidence level for masses below 3.9 and 4.7 TeV for the decay widths of 1% and 3%, respectively.

Heavy charged bosons, such as W' or H^+, can also be searched for in $t\bar{b}, tj$ final states (for more information see the review "W'-boson searches" and "Higgs Bosons: theory and searches"), while heavy fermion resonances, such as vectorial or excited quarks, in final states such as tZ, tH, tW, bW. CMS has performed several searches in this context, the most stringent limits coming from those at $\sqrt{s}$ = 13 TeV [349–356]. For instance, a $W' \to t\bar{b}$ has been searched for in all-hadronic final state in 137 fb^{-1}. No evidence has been found for left- and right-handed W' boson and masses below 3.4 TeV/c^2 are excluded at 95% confidence level [356]. Single production of a vector-like quark decaying to a W boson and a top quark, in fully hadronic final state also been searched in the same data set. No significant deviation from the SM background expectation is observed. The hypotheses of b* quarks with left-handed, right-handed, and vector-like chiralities are excluded at 95% confidence level for masses below 2.6, 2.8, and 3.1 TeV/c^2, respectively. These represent the most stringent exclusion limits for the single production of vector-like quarks in this channel. [357] In the same data set, searches for pair production of vector-like T or B quarks in fully hadronic final states have been performed. Lower limits are set on the mass at 95% confidence level equal to 1570 TeV/c^2 in the case where decays exclusively to a b quark and a Higgs boson, 1390 TeV/c^2 for when it decays exclusively to a b quark and a Z boson, and 1450 TeV/c^2 for when it decays equally in these two modes. [358]. ATLAS has performed searches for heavy bosons and fermions decaying to one top quark at $\sqrt{s}$ = 7, 8 and 13 TeV. A $W' \to t\bar{b}$ has been searched for at 13 TeV in lepton+jets in 36.1 fb^{-1}. No evidence has been found for a right-handed W' boson with a mass below 3.25 TeV/c^2 are excluded at 95% [359]. A $H^+ \to t\bar{b}$ has been searched for at 13 TeV in lepton+jets in 139 fb^{-1}. No significant excess above the background-only hypothesis is observed and exclusion limits are derived for the production cross-section times branching ratio as a function of its mass, ranging from 3.6 pb at 200 GeV/c^2 to 0.036 pb at 2000 GeV/c^2 at 95% confidence level. [360]. ATLAS has conducted a search for the single and pair production of a new charge +2/3 quark (T) decaying via $T \to Zt$ (and also -1/3 quark (B) decaying via $B \to Zb$) in a dataset corresponding to 139 fb^{-1} luminosity at $\sqrt{s}$ = 13 TeV [361]. No significant excess of events above the SM expectation is observed, and upper limits are derived for vector-like quarks of various masses in a two-dimensional plane of branching ratios. Under branching ratio assumptions corresponding to a weak-isospin singlet scenario, a T quark with mass lower than 1.27 TeV/c^2 (1.2 TeV/c^2 for a B quark) is excluded at the 95% confidence level. Under branching ratio assumptions corresponding to a particular weak-isospin doublet scenario, a T quark with mass lower than 1.46; TeV/c^2 (1.32 TeV/c^2 for a B quark) is excluded at the 95% confidence level. In the same dataset, ATLAS combines the searches for pair-produced vector-like partners of the top and bottom quarks in various decay channels ($T \to Zt/Wb/Ht, B \to Zb/Wt/Hb$). The observed data are found to be in good agreement with the SM background prediction in all individual searches. Therefore, combined 95% confidence-level upper limits are set on the production cross-section for a range of vector-like quark scenarios, significantly improving upon the reach of the individual searches. Model-independent limits are set assuming the vector-like quarks decay to SM particles. A singlet T is excluded for masses below 1.31 TeV/c^2 and a singlet B is excluded for masses below 1.22 TeV/c^2. Assuming a weak isospin (T, B) doublet and $|V_{Tb}| << |V_{tB}|$, T and B masses below 1.37 TeV/c^2 are excluded [362].

Vector-like partners of the top and bottom quarks have been searched also in single (electroweak) production, in several decay modes: $T \to tH$ [363], $T \to Wb$ [364], $T \to t(Z \to \nu\nu)$ [365] and $B \to bH$ with $H \to b\bar{b}$ [366] and $H \to \gamma\gamma$ [367].

In many models top-quark partners preferably decay to top quarks and weakly interacting neutral stable particles, i.e., possibly dark matter candidates, that are not detected. In addition, top quarks could be coupled to states that would mostly decay to dark matter or be invisible. In both cases, an observable especially sensitive to new physics effects in $t\bar{t}$ production is therefore the missing transverse momentum. CMS has presented a differential cross section measurement of top-quark pair and single production with missing transverse energy and corresponding interpretations in the context of dark matter (effective and simplified) models at 8 and 13 TeV [368–371]. The results obtained so far are consistent with the SM expectations. In particular the search performed at 13 TeV [371] is based on 35.9 fb^{-1} of integrated luminosity. Upper limits are derived on the production cross section and interpreted in terms of a simplified model with a scalar/pseudoscalar mediator. Scalar and pseudoscalar mediator particles with masses below 290 and 300 GeV/c^2, respectively, are excluded at 95% confidence level, assuming a dark matter particle mass of 1 GeV/c^2 and mediator couplings to fermions and dark matter particles equal to unity. A generic search for new phenomena with top quark pairs in final states with one isolated electron or muon, multiple jets, and large missing transverse momentum has been performed by ATLAS in a dataset corresponding to 139 fb^{-1} luminosity at $\sqrt{s}$ = 13 TeV. No significant excess above the SM background is observed, and limits at 95% confidence level are set in various models. The results exclude top squark masses up to about 1 TeV/c^2, and masses of the lightest neutralino up to about 500 GeV/c^2. Limits on dark-matter production are set for scalar (pseudoscalar) mediator masses up to about 250 (300) GeV/c^2. [372].

ATLAS has also conducted searches for missing transverse momenta in association with single top quarks [373, 374].

Flavor-changing-neutral-currents (FCNC) are hugely suppressed in the SM as non zero contributions only arise at one-loop and are proportional to the splitting between the quark masses. In the case of the top quark $B(t \to Bq)$ with $B = g, \gamma, Z, H$ and $q = u, c$ are predicted to be order of 10^{-12} ($t \to cg$) or much smaller [375]. Several observables are accessible at colliders to test and constrain such couplings. CMS has performed several studies on the search for FCNC in top-quark production. They have considered single-top quark production in the t-channel in 5 fb^{-1} integrated luminosity at 7 TeV and 19.7 fb^{-1} integrated luminosity at 8 TeV [376]. Events with the top quark decaying into a muon, neutrino and two or three jets are selected. The upper limits on effective coupling strength can be translated to the 95% upper limits on the corresponding branching ratios $B(t \to gu) \leq 2.0 \cdot 10^{-5}$, $B(t \to gc) \leq 4.1 \cdot 10^{-4}$. They have performed a search for a single top quark produced in association with a photon in 19.1 fb^{-1} integrated luminosity at 8 TeV [377]. The event selection requires the presence of one isolated muon and jets in the final state. The upper limits on effective coupling strength can be translated to the 95% upper limits on the corresponding branching ratios $B(t \to \gamma u) \leq 0.0161\%$, $B(t \to \gamma c) \leq 0.182\%$. A search for flavor-changing neutral currents in associated production of a top quark with a Higgs boson decaying into $b\bar{b}$ has also been presented by CMS, corresponding to an integrated luminosity of 35.9 fb^{-1} at 13 TeV. Two complementary channels are considered: top quark pair production, with FCNC decay of the top quark or antiquark, and single top associated production. A final state with one isolated lepton and at least three reconstructed jets, among which at least two are identified as b quark jets, is considered. No significant deviation is observed from predicted background and upper limits at 95% confidence level are set on the branching ratios of top quark decays, $B(t \to uH) < 0.47\%$ and $B(t \to cH) < 0.47\%$ [378], which are similar to the combined limits on all decay channels ob-

tained with the full data set at 8 TeV [379]. More recently, a search for the signature of flavor-changing neutral current interactions of top quarks and Higgs bosons has been performed. corresponding to an integrated luminosity of 137 fb^{-1} at 13 TeV. Multivariate machine learning techniques have been used to separate signal and standard model background processes. No significant excess above the background prediction is observed, and upper limits on the $t \to Hq$ branching fractions are derived through a binned fit to the diphoton invariant mass spectrum. The observed 95% confidence level upper limits are found to be 1.9×10^{-4} for $\Gamma(t \to Hu)$ and 7.3×10^{-4} for $\Gamma(t \to Hc)$.

ATLAS has presented results on the search for single top-quark production via FCNC's in strong interactions using data collected at $\sqrt{s}$=8 TeV and corresponding to an integrated luminosity of 20.3 fb^{-1}. Flavor-changing-neutral-current events are searched for in which a light quark (u or c) interacts with a gluon to produce a single top quark, either with or without the associated production of another light quark or gluon. Candidate events of top quarks decaying into leptons and jets are selected and classified into signal- and background-like events using a neural network. The observed 95% C.L. limit is $\sigma_{qq\to t} \times B(t \to Wb) < 3.4$ pb that can be interpreted as limits on the branching ratios, $B(t \to ug) < 4 \cdot 10^{-5}$ and $B(t \to cg) < 1.7 \cdot 10^{-4}$ [380]. ATLAS has set limits on the coupling of a top quark, a photon, and an up or charm quark using 81 fb^{-1} of data 13 TeV. Events with a photon, an electron or muon, a b-tagged jet, and missing transverse momentum are selected. The data are consistent with the background-only hypothesis, and limits are set on the strength of the $tq\gamma$ coupling in an effective field theory. These are also interpreted as 95% CL upper limits on $t \to u\gamma$ branching ratio via a left-handed (right-handed) interaction of 2.8×10^{-5} (6.1×10^{-5}) and on the $t \to c\gamma$ branching ratio for of 22×10^{-5} (18×10^{-5}) [381]. Constraints on FCNC couplings of the top quark can also be obtained from searches for anomalous single top-quark production in e^+e^- collisions, via the process $e^+e^- \to \gamma, Z^* \to t\overline{q}$ and its charge-conjugate ($q = u, c$), or in $e^{\pm}p$ collisions, via the process $e^{\pm}u \to e^{\pm}t$. For a leptonic W decay, the topology is at least a high-p_T lepton, a high-p_T jet and missing E_T, while for a hadronic W-decay, the topology is three high-p_T jets. Limits on the cross section for this reaction have been obtained by the LEP collaborations [382] in e^+e^- collisions, and by H1 [383] and ZEUS [384] in $e^{\pm}p$ collisions. When interpreted in terms of branching ratios in top decay [385, 386], the LEP limits lead to typical 95% C.L. upper bounds of $B(t \to qZ) < 0.137$. Assuming no coupling to the Z boson, the 95% C.L. limits on the anomalous FCNC coupling $\kappa_\gamma < 0.13$ and < 0.27 by ZEUS and H1, respectively, are stronger than the CDF limit of $\kappa_\gamma < 0.42$, and improve over LEP sensitivity in that domain. The H1 limit is slightly weaker than the ZEUS limit due to an observed excess of five-candidate events over an expected background of 3.2±0.4. If this excess is attributed to FCNC top-quark production, this leads to a total cross section of $\sigma(ep \to e + t + X, \sqrt{s} = 319 \text{ GeV}) < 0.25$ pb [383, 387].

61.3.3.2 *New Physics in Top-Quark decays*

The large sample of top quarks produced at the Tevatron and the LHC allows to measure or set stringent limits on the branching ratios of rare top-quark decays. For example, the existence of a light H^+ can be constrained by looking for $t \to H^+b$ decay, in particular with tau-leptons in the final state (for more information see the review "Higgs Bosons: theory and searches").

A first class of searches for new physics focuses on the structure of the Wtb vertex. Using up to 2.7 fb^{-1} of data, DØ has measured the Wtb coupling form factors by combining information from the W-boson helicity in top-quark decays in $t\bar{t}$ events and single top-quark production, allowing to place limits on the left-handed and right-handed vector and tensor couplings [388–390].

ATLAS has published the results of a search for CP-violation in the decay of single top quarks produced in the t-channel where the top quarks are predicted to be highly polarized, using the lepton+jets final state [391]. The data analyzed are from pp collisions at $\sqrt{s} = 7$ TeV and correspond to an integrated luminosity of 4.7 fb^{-1}. In the Standard Model, the couplings at the Wtb vertex are left-handed, right-handed couplings being absent. A forward-backward asymmetry with respect to the normal to the plane defined by the W-momentum and the top-quark polarization has been used to probe the complex phase of a possibly non-zero value of the right-handed coupling, signaling a source of CP-violation beyond the SM. The measured value of the asymmetry is $0.031 \pm 0.065(stat.)^{+0.029}_{-0.031}(syst.)$ in good agreement with the Standard Model.

A second class of searches focuses on FCNC's in the top-quark decays. Both, CDF and DØ, have provided the first limits for FCNC's in Run I and II. The most recent results from CDF give $B(t \to qZ) < 3.7\%$ and $B(t \to q\gamma) < 3.2\%$ at the 95% C.L. [392] while DØ [393, 394] sets $B(t \to qZ)(q = u, c \text{ quarks }) < 3.2\%$) at 95% C.L., $B(t \to gu) < 2.0 \cdot 10^{-4}$, and $B(t \to gc) < 3.9 \cdot 10^{-3}$ at the 95% C.L. At the LHC, CMS has used a sample at a center-of-mass energy of 8 TeV corresponding to 19.7 fb^{-1} of integrated luminosity to perform a search for flavor changing neutral current top-quark decay $t \to Zq$. Events with a topology compatible with the decay chain $t\bar{t} \to Wb + Zq \to \ell\nu\ b + \ell\ell q$ are searched for. There is no excess seen in the observed number of events relative to the SM prediction; thus no evidence for flavor changing neutral current in top-quark decays is found. A combination with a previous search at 7 TeV excludes a $t \to Zq$ branching fraction greater than 0.05% at the 95% confidence level [395]. CMS has also performed a search for the production of a single top quark in association with a Z boson in the same data set at 8 TeV. Final states with three leptons (electrons or muons) and at least one jet are investigated. Exclusion limits at 95% confidence level on the branching fractions are found to be $B(t \to uZ) < 0.022\%$ and $B(t \to cZ) < 0.049\%$ [396].

The ATLAS collaboration has also searched for FCNC processes in 36.1 fb^{-1} of $t\bar{t}$ events at a center-of-mass energy of 13 TeV, with one top quark decaying through FCNC ($t \to qZ$) and the other through the SM dominant mode ($t \to bW$). Only the decays of the Z boson to charged leptons and leptonic W boson decays were considered as signal, leading to a final state topology characterized by the presence of three isolated leptons, at least two jets and missing transverse energy from the undetected neutrino. No evidence for an FCNC signal was found. An upper limit on the $t \to qZ$ branching ratio of $B(t \to Zu(c)) < 1.7(2.4) \times 10^{-4}$ is set at the 95% confidence level [397]. The ATLAS collaboration has also searched for a tqZ coupling, in a study that includes events where a single top quark is produced as $gq \to tZ$ (with $q = u, c$) and top-quark pair events, with one top quark decaying through the $t \to qZ$ channel, 139 fb^{-1} of data at 13 TeV. The analysis selects events with three leptons (electrons or muons), a b-tagged jet, possible additional jets and missing transverse momentum. The data are consistent with the background-only hypothesis and 95% confidence-level limits on the branching ratios are set. These are 6.2×10^{-5} (13×10^{-5}) for $t \to Zu$ ($t \to Zc$) for a left-handed coupling, and 6.6×10^{-5} (12×10^{-5}) in the case of a right-handed coupling [398].

Another search for FCNCs is the interactions of a top-quark to a Higgs boson and a light parton, tqH, $q = u, c$. The CMS collaboration has performed a search using a sample at a center-of-mass energy of 13 TeV corresponding to 35.9 fb^{-1} of integrated luminosity, [399], combining single top quark FCNC production in association with the Higgs boson ($pp \to tH$), and top quark pair production with FCNC decay of the top quark ($t \to qH$). The combined analysis sets an upper limit on the $t \to u/cH$ branching ratios of $B(t \to u/cH) < 0.47\%$ at 95% confidence level. The ATLAS collaboration considers $t \to qH$, $q = u, c$ with 36.1 fb^{-1} of $t\bar{t}$ events at $\sqrt{s} = 13$ TeV. A combined measurement including $H \to bb$ and $H \to \tau\tau$ modes yields a 95% C.L. upper limit of 0.11% and 0.12% on the branching ratios of $B(t \to cH)$ and $B(t \to uH)$, respectively [400].

61.4 Outlook

Top-quark physics at hadron colliders has developed into precision physics. Various properties of the top quark have been measured with high precision, where the LHC has by now surpassed the Tevatron precision and reach in the majority of relevant observables. Several $\sqrt{s}$-dependent physics quantities, such as the production cross-section, have been measured at several energies at the Tevatron and the LHC. Up to now, all measurements are consistent with the SM predictions and allow stringent tests of

the underlying production mechanisms by strong and weak interactions. Given the very large event samples available at the LHC, top-quark properties will be further determined in $t\bar{t}$ as well as in electroweak single top-quark production. At the Tevatron, the $t-$ and $s-$channels for electroweak single top-quark production have been measured separately. At the LHC, quick progress has been achieved in the last years making all three relevant channels measured with more than 5 sigma significance. Furthermore, $t\bar{t}\gamma$, $t\bar{t}Z$, and $t\bar{t}W$ together with $t\bar{t}H$ associated production have started to provide key information on the top-quark electroweak couplings. Corresponding effective field theory (EFT) fits for the coupling extraction are being developed. At the same time various models of physics beyond the SM involving top-quark production are being constrained. While a majority of the Run-II data recorded at 13 TeV has been analysed or is in an advanced stage, the beginning of the Run-III at $\sqrt{s} = 13.6$ to 14 TeV and an expected integrated luminosity of $160 - 200$ fb^{-1}, doubling the Run-I plus Run-II data set, is immanent. With the first results to be released, top-quark physics has the potential to shed light on open questions and new aspects of physics at the TeV scale.

62. Form Factors for Semileptonic Kaon ($K_{\ell 3}$), Radiative Pion ($\pi_{\ell 2\gamma}$) and Kaon ($K_{\ell 2\gamma}$) Decays

Revised August 2021 by M.A. Bychkov (Virginia U.) and G. D'Ambrosio (INFN, Napoli).

62.1 $\pi^{\pm}_{\ell 2\gamma}$ and $K^{\pm}_{\ell 2\gamma}$ Form Factors

The radiative decays, $\pi^{\pm} \to l^{\pm}\nu\gamma$ and $K^{\pm} \to l^{\pm}\nu\gamma$, with l standing for an e or a μ, and γ for a real or virtual photon (e^+e^- pair), provide a powerful tool to investigate the hadronic structure of pions and kaons. The structure-dependent part SD_i of the amplitude describes the emission of photons from virtual hadronic states, and is parametrized in terms of form factors V, A, (vector, axial vector), in the standard description [1–4]. Note that in the Listings and some literature, equivalent nomenclature F_V and F_A for the vector and axial form factors is often used. Exotic, non-standard contributions like $i = T, S$ (tensor, scalar) have also been considered. Apart from the SD terms, there is also the Inner Bremsstrahlung amplitude, IB, corresponding to photon radiation from external charged particles and described by Low theorem in terms of the physical decay $\pi^{\pm}(K^{\pm}) \to l^{\pm}\nu$. Experiments try to optimize their kinematics so as to minimize the IB part of the amplitude.

The SD amplitude in its standard form is given as

$$M(\mathrm{SD}_V) = \frac{-eG_F U_{qq'}}{\sqrt{2}m_P}\epsilon^{\mu} l^{\nu} V^P \epsilon_{\mu\nu\sigma\tau} k^{\sigma} q^{\tau} \tag{62.1}$$

$$M(\mathrm{SD}_A) = \frac{-ieG_F U_{qq'}}{\sqrt{2}m_P}\epsilon^{\mu} l^{\nu}\{A^P[(qk-k^2)g_{\mu\nu} - q_\mu k_\nu] + R^P k^2 g_{\mu\nu}\}\,, \tag{62.2}$$

which contains an additional axial form factor R^P which only can be accessed if the photon remains virtual. $U_{qq'}$ is the Cabibbo-Kobayashi-Maskawa mixing-matrix element; ϵ^{μ} is the polarization vector of the photon (or the effective vertex, $\epsilon^{\mu} = (e/k^2)\overline{u}(p_-)\gamma^{\mu}v(p_+)$, of the e^+e^- pair); $\ell^{\nu} = \overline{u}(p_\nu)\gamma^{\nu}(1-\gamma_5)v(p_\ell)$ is the lepton-neutrino current; q and k are the meson and photon four-momenta ($k = p_+ + p_-$ for virtual photons); and P stands for π or K.

For decay processes where the photon is real, the partial decay width can be written in analytical form as a sum of IB, SD, and IB/SD interference terms INT [1, 4]:

$$\begin{aligned}\frac{d^2\Gamma_{P\to\ell\nu\gamma}}{dxdy} &= \frac{d^2\left(\Gamma_{\mathrm{IB}} + \Gamma_{\mathrm{SD}} + \Gamma_{\mathrm{INT}}\right)}{dxdy} \\ &= \frac{\alpha}{2\pi}\Gamma_{P\to\ell\nu}\frac{1}{(1-r)^2}\Bigg\{\mathrm{IB}(x,y) \\ &+ \frac{1}{r}\left(\frac{m_P}{2f_P}\right)^2\Big[(V+A)^2\mathrm{SD}^+(x,y) + (V-A)^2\mathrm{SD}^-(x,y)\Big] \\ &+ \epsilon_P\frac{m_P}{f_P}\Big[(V+A)\mathrm{S}^+_{\mathrm{INT}}(x,y) + (V-A)\mathrm{S}^-_{\mathrm{INT}}(x,y)\Big]\Bigg\}.\end{aligned} \tag{62.3}$$

Here

$$\begin{aligned}\mathrm{IB}(x,y) &= \left[\frac{1-y+r}{x^2(x+y-1-r)}\right]\left[x^2 + 2(1-x)(1-r) - \frac{2xr(1-r)}{x+y-1-r}\right] \\ \mathrm{SD}^+(x,y) &= (x+y-1-r)\Big[(x+y-1)(1-x) - r\Big] \\ \mathrm{SD}^-(x,y) &= (1-y+r)\Big[(1-x)(1-y) + r\Big] \\ \mathrm{S}^+_{\mathrm{INT}}(x,y) &= \left[\frac{1-y+r}{x(x+y-1-r)}\right]\Big[(1-x)(1-x-y) + r\Big] \\ \mathrm{S}^-_{\mathrm{INT}}(x,y) &= \left[\frac{1-y+r}{x(x+y-1-r)}\right]\Big[x^2 - (1-x)(1-x-y) - r\Big]\end{aligned} \tag{62.4}$$

where $x = 2E_\gamma/m_P$, $y = 2E_\ell/m_P$, $r = (m_\ell/m_P)^2$, f_P is the meson decay constant, and ϵ_P is +1 for pions and -1 for kaons. The structure dependent terms SD^+ and SD^- are shown in Fig. 1. The SD^- term is maximized in the same kinematic region where overwhelming IB term dominates (along $x + y = 1$ diagonal). Thus experimental yields with less background are dominated by SD^+ contribution and proportional to $A^P + V^P$ making simultaneous precise determination of the form factors difficult.

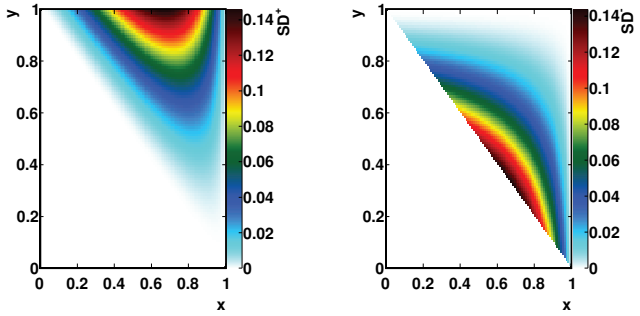

Figure 62.1: Components of the structure dependent terms of the decay width. Left: SD^+, right: SD^-

Recently, formulas 62.3 and 62.4 have been extended to describe polarized distributions in radiative meson and muon decays [5].

The "helicity" factor r is responsible for the enhancement of the SD over the IB amplitude in the decays $\pi^{\pm} \to e^{\pm}\nu\gamma$, while $\pi^{\pm} \to \mu^{\pm}\nu\gamma$ is dominated by IB. Interference terms are important for the decay $K^{\pm} \to \mu^{\pm}\nu\gamma$ [6], but contribute only a few percent correction to pion decays. However, they provide the basis for determining the signs of V and A. Radiative corrections to the decay $\pi^+ \to e^+\nu\gamma$ have to be taken into account in the analysis of the precision experiments. They make up to 4% corrections in the total decay rate [7]. In $\pi^{\pm} \to e^{\pm}\nu e^+e^-$ and $K^{\pm} \to \ell^{\pm}\nu e^+e^-$ decays, all three form factors, V^P, A^P, and R^P, can be determined [8, 9].

Theoretically, the first non-trivial χPT contributions to A^P and V^P appear at $\mathcal{O}(p^4)$ [4], respectively from Gasser-Leutwyler coefficients, L_i's, and the anomalous lagrangian:

$$A^P = \frac{4\sqrt{2}M_P}{F_\pi}(L^r_9 + L^r_{10}), \quad V^P = \frac{\sqrt{2}M_P}{8\pi^2 F_\pi}. \tag{62.5}$$

In case of the kaon $A^K = 0.042$ and $V^K = 0.096$. $\mathcal{O}(p^6)$ contributions to A^K can be predicted accurately: they are flat in the momentum dependence and shift the $\mathcal{O}(p^4)$ value to 0.034. $\mathcal{O}(p^6)$ contributions to V^K are model dependent and can be approximated by a form factor linearly dependent on momentum. For example, when looking at the spread of results obtained within two different models, the constant piece of this linear form factor is shifted to 0.078 ± 0.005 [1, 2, 4].

We give the experimental $\pi^{\pm}$ form factors V^{π}, A^{π}, and R^{π} in the Listings. In the $K^{\pm}$ Listings, we give the extracted sum $A^K + V^K$ and difference $A^K - V^K$, as well as V^K, A^K and R^K. In particular KLOE has measured for the constant piece of the form factor $A^K + V^K = 0.125 \pm 0.007 \pm 0.001$ [10] while ISTRA+, $V^K - A^K = 0.21 \pm 0.04 \pm 0.04$ [11].

The pion vector form factor, V^{π}, is related via CVC (Conserved Vector Current) to the $\pi^0 \to \gamma\gamma$ decay width. The constant term is given by $|V^{\pi}(0)| = (1/\alpha)\sqrt{2\Gamma_{\pi^0\to\gamma\gamma}/\pi m_{\pi^0}}$ [3]. The resulting value, $V^{\pi}(0) = 0.0259(9)$, has been confirmed by calculations based on chiral perturbation theory (χPT) [4], and by two experiments given in the Listings.

A recent experiment by the PIBETA collaboration [12] obtained a $V^{\pi}(0)$ that is in excellent agreement with the CVC hypothesis. It also measured the slope parameter a in $V^{\pi}(s) = V^{\pi}(0)(1 + a\cdot s)$, where $s = (1 - 2E_\gamma/m_\pi)$, and E_γ is the gamma energy in the pion rest frame: $a = 0.095 \pm 0.058$. A functional dependence on s is expected for all form factors. It becomes non-negligible in the

case of $V^\pi(s)$ when a wide range of photon momenta is recorded; proper treatment in the analysis of K decays is mandatory.

The form factor, R^P, can be related to the electromagnetic radius, r_P, of the meson [2]: $R^P = \frac{1}{3} m_P f_P \langle r_P^2 \rangle$ using PCAC (Partial Conserved Axial vector Current).

In lowest order χPT, the ratio A^π/V^π is related to the pion electric polarizability $\alpha_E = [\alpha/(8\pi^2 m_\pi f_\pi^2)] \times A^\pi/V^\pi$ [13]. Direct experimental and theoretical status of pion polarizability studies currently is not settled. Most recent theoretical predictions from χPT at $\mathcal{O}(p^6)$ [14] and experimental results from COMPASS collaboration [15] favor a small value of pion polarizability $\alpha_\pi \sim (2 \div 3) \times 10^{-4}\,\mathrm{fm}^3$. Dispersive analysis of $\gamma\gamma \to \pi^+\pi^-$ crossection [16] and experimental results from MAMI collaboration [17] report a much larger value of $\alpha_\pi \sim 6 \times 10^{-4}\,\mathrm{fm}^3$. Precise measurement of the pion form factors by PIBETA collaboration favors smaller values of polarizability $\alpha_\pi = 2.7^{+0.6}_{-0.5} \times 10^{-4}\,\mathrm{fm}^3$.

Several searches for the exotic form factors F_T^π, F_T^K (tensor), and F_S^K (scalar) have been pursued in the past. In particular, F_T^π has been brought into focus by experimental as well as theoretical work [18]. New high-statistics data from the PIBETA collaboration have been re-analyzed together with an additional data set optimized for low backgrounds in the radiative pion decay. In particular, lower beam rates have been used in order to reduce the accidental background, thereby making the treatment of systematic uncertainties easier and more reliable. The PIBETA analysis now restricts F_T^π to the range $-5.2 \times 10^{-4} < F_T^\pi < 4.0 \times 10^{-4}$ at a 90% confidence limit [12]. This result is in excellent agreement with the most recent theoretical work [4].

Precision measurements of radiative pion and kaon decays are effective tools to study QCD in the non-perturbative region and are of interest beyond the scope of radiative decays. Meanwhile other processes such as $\pi^+ \to e^+\nu$ that seem to be better suited to search for new physics at the precision frontier are currently studied. The advantages of such process are the very accurate and reliable theoretical predictions and the more straightforward experimental analysis.

62.2 $K^\pm_{\ell 3}$ and $K^0_{\ell 3}$ Form Factors

Assuming that only the vector current contributes to $K \to \pi\ell\nu$ decays, we write the matrix element as

$$M \propto f_+(t)\left[(P_K + P_\pi)_\mu \bar{\ell}\gamma_\mu(1+\gamma_5)\nu\right] + f_-(t)\left[m_\ell \bar{\ell}(1+\gamma_5)\nu\right] , \quad (62.6)$$

where P_K and P_π are the four-momenta of the K and π mesons, m_ℓ is the lepton mass, and f_+ and f_- are dimensionless form factors which can depend only on $t = (P_K - P_\pi)^2$, the square of the four-momentum transfer to the leptons. If time-reversal invariance holds, f_+ and f_- are relatively real. $K_{\mu 3}$ experiments, discussed immediately below, measure f_+ and f_-, while K_{e3} experiments, discussed further below, are sensitive only to f_+ because the small electron mass makes the f_- term negligible.

62.2.1 $K_{\mu 3}$ *Decays*

Analyses of $K_{\mu 3}$ data frequently assume a linear dependence of f_+ and f_- on t, *i.e.*,

$$f_\pm(t) = f_\pm(0)\left[1 + \lambda_\pm (t/m^2_{\pi^+})\right] . \quad (62.7)$$

Most $K_{\mu 3}$ data are adequately described by formula 62.7 for f_+ and a constant f_- (*i.e.*, $\lambda_- = 0$).

There are two equivalent parametrizations commonly used in these analyses: $\lambda_+, \xi(0)$ parametrization and λ_+, λ_0 parametrization.

Older analyses of $K_{\mu 3}$ data often introduce the ratio of the two form factors

$$\xi(t) = f_-(t)/f_+(t) . \quad (62.8)$$

The $K_{\mu 3}$ decay distribution is then described by the two parameters λ_+ and $\xi(0)$ (assuming time reversal invariance and $\lambda_- = 0$).

More recent $K_{\mu 3}$ analyses have parametrized in terms of the form factors f_+ and f_0, which are associated with vector and scalar exchange, respectively, to the lepton pair. f_0 is related to f_+ and f_- by

$$f_0(t) = f_+(t) + \left[t/(m_K^2 - m_\pi^2)\right] f_-(t) . \quad (62.9)$$

Here $f_0(0)$ must equal $f_+(0)$. The earlier assumption that f_+ is linear in t and f_- is constant leads to f_0 linear in t:

$$f_0(t) = f_0(0)\left[1 + \lambda_0 (t/m^2_{\pi^+})\right] . \quad (62.10)$$

With the assumption that $f_0(0) = f_+(0)$, the two parametrizations, $(\lambda_+, \xi(0))$ and (λ_+, λ_0) are equivalent as long as correlation information is retained. (λ_+, λ_0) correlations tend to be less strong than $(\lambda_+, \xi(0))$ correlations.

Since the 2006 edition of the *Review* [19], we no longer quote results in the $(\lambda_+, \xi(0))$ parametrization. We have removed many older low statistics results from the Listings. See the 2004 version of this note [20] for these older results, and the 1982 version [21] for additional discussion of the $K^0_{\mu 3}$ parameters, correlations, and conversion between parametrizations.

More recent high-statistics experiments have included a quadratic term in the expansion of $f_+(t)$,

$$f_+(t) = f_+(0)\left[1 + \lambda_+^{'}(t/m^2_{\pi^+}) + \frac{\lambda_+^{''}}{2}(t/m^2_{\pi^+})^2\right] . \quad (62.11)$$

If there is a non-vanishing quadratic term, then λ_+ of formula 62.7 represents the average slope, which is then different from $\lambda_+^{'}$. Our convention is to include the factor $\frac{1}{2}$ in the quadratic term, and to use m_{π^+} even for K^+_{e3} and $K^+_{\mu 3}$ decays. We have converted other's parametrizations to match our conventions, as noted in the beginning of the "$K^\pm_{\ell 3}$ and $K^0_{\ell 3}$ Form Factors" sections of the Listings.

There are two alternatives to the Taylor parametrization: The Pole Parametrization and Dispersive Parametrization.

The pole model describes the t-dependence of $f_+(t)$ and $f_0(t)$ in terms of the exchange of the lightest vector and scalar K^* mesons with masses M_V and M_S, respectively:

$$f_+(t) = f_+(0)\left[\frac{M_V^2}{M_V^2 - t}\right] , \quad f_0(t) = f_0(0)\left[\frac{M_S^2}{M_S^2 - t}\right] . \quad (62.12)$$

The Dispersive Parametrization approach, valid in a much wider kinematic range and able to describe at the same time τ-decay data, [22] uses dispersive techniques and the known low-energy K-π phases to parametrize the vector and scalar form factors:

$$f_+(t) = f_+(0)\exp\left[\frac{t}{m_\pi^2}(\Lambda_+ + H(t))\right]; \quad (62.13)$$

$$f_0(t) = f_+(0)\exp\left[\frac{t}{(m_K^2 - m_\pi^2)}\,(ln[C] - G(t))\right], \quad (62.14)$$

where Λ_+ is the slope of the vector form factor, and $\ln C = \ln[f_0(m_K^2 - m_\pi^2)]$ is the logarithm of the scalar form factor at the Callan-Treiman point. The functions $H(t)$ and $G(t)$ are dispersive integrals.

62.2.2 K_{e3} *Decays*

Analysis of K_{e3} data is simpler than that of $K_{\mu 3}$ because the second term of the matrix element assuming a pure vector current [formula 62.6 above] can be neglected. Here f_+ can be assumed to be linear in t, in which case the linear coefficient λ_+ of formula 62.7 is determined, or quadratic, in which case the linear coefficient $\lambda_+^{'}$ and quadratic coefficient $\lambda_+^{''}$ of formula 62.11 are determined.

If we remove the assumption of a pure vector current, then the matrix element for the decay, in addition to the terms in formula 62.6, would contain

$$+2m_K\, f_S\, \bar{\ell}(1+\gamma_5)\nu + (2f_T/m_K)(P_K)_\lambda (P_\pi)_\mu\, \bar{\ell}\,\sigma_{\lambda\mu}(1+\gamma_5)\nu , \quad (62.15)$$

where f_S is the scalar form factor, and f_T is the tensor form factor. In the case of the K_{e3} decays where the f_- term can be neglected, experiments have yielded limits on $|f_S/f_+|$ and $|f_T/f_+|$.

For K_{e3} data, we determine best values for the three parametrizations: linear (λ_+), quadratic ($\lambda_+^{'}$, $\lambda_+^{''}$) and pole (M_V). For $K_{\mu 3}$ data, we determine best values for the three parametrizations: linear (λ_+, λ_0), quadratic ($\lambda_+^{'}$,$\lambda_+^{''}$, λ_0) and pole (M_V, M_S). We then assume $\mu-e$ universality so that we can combine K_{e3} and $K_{\mu 3}$ data, and again determine best values for the three parametrizations: linear (λ_+, λ_0), quadratic ($\lambda_+^{'}$,$\lambda_+^{''}$, λ_0), and pole (M_V, M_S). When there is more than one parameter, fits are done including input correlations. Simple averages suffice in the two K_{e3} cases where there is only one parameter: linear (λ_+) and pole (M_V).

A comprehensive global analysis of the semileptonic kaon decay data and its effect on the CKM unitarity debate can be found in [23, 24]. An update on experimental data including NA48/2 newest results can be found in [25].

Both KTeV and KLOE see an improvement in the quality of their fits relative to linear fits when a quadratic term is introduced, as well as when the pole parametrization is used. The quadratic parametrization has the disadvantage that the quadratic parameter $\lambda_+^{''}$ is highly correlated with the linear parameter $\lambda_+^{'}$, in the neighborhood of 95%, and that neither parameter is very well determined. The pole fit has the same number of parameters as the linear fit, but yields slightly better fit probabilities, so that it would be advisable for all experiments to include the pole parametrization as one of their choices.

The "Kaon Particle Listings" show the results with and without assuming μ-e universality. The "Meson Summary Tables" show all of the results assuming μ-e universality, but most results not assuming μ-e universality are given only in the Listings.

63. Spectroscopy of Light Meson Resonances

Written August 2021 by C. Amsler (Stefan Meyer Inst.), S. Eidelman (Budker Inst., Novosibirsk; Novosibirsk U.), A. Masoni (INFN, Cagliari) and G. Venanzoni (INFN, Pisa).

63.1 Introduction

According to the constituent quark model, a light meson consists of a color singlet quark-antiquark pair made of the u, d, or s quarks and the $\overline{u}$, $\overline{d}$, or $\overline{s}$ antiquarks, grouped into a flavor multiplet of SU(3). However, additional mesons made of bound gluons (glueballs) could exist in the same mass range, suggested by the self coupling of gluons in QCD. Multiquark structures are also possible, such as quark-antiquark pairs with an excited gluon (hybrid mesons). Tetraquarks are compact color singlets of diquark-antidiquark pairs ($qq\overline{q}\overline{q}$) or 'molecular' bound states of two mesons ($q\overline{q}q\overline{q}$). More complex systems such as $qqq\overline{q}\overline{q}\overline{q}$ (baryonia) are also predicted.

Fundamentals on the constituent quark model on light and heavy mesons and baryons (including hadrons with charm and bottom quarks), and on predictions from lattice gauge theories, are described in 'Quark Model' in this issue of the *Review of Particle Physics*, henceforth called the *Review*. In the present text we describe the experimental spectrum of light mesons and their classifications within the constituent quark model, with emphasis on states exhibiting properties incompatible with $q\bar{q}$ structures. The discussion is driven by the results entered in the database of the *Review*. The spectrum of kaon excitations is much less clear cut and therefore deferred to a future edition, when further data might become available. More detailed discussions on exotic mesons – including those involving the c and b quarks – can be found in Refs. [1–7] and in 'Heavy Non-$q\bar{q}$ Mesons' of the *Review*. For more information on the meson (and baryon) spectrum of light (and heavy) quarks we refer to the textbook [8].

Figure 63.1 shows the mass spectrum of $q\bar{q}$ mesons. The mass (vertical axis) increases with orbital excitations ℓ (horizontal axis) and radial excitation n. In the quark model one uses the notation nS, nP, nD... for the radial excitations ($n = 1$ for the ground states), in contrast to the usual $1s$, $2p$, $3d$... notation in atomic physics. Each box represents an SU(3) nonet containing multiplets of the isospin i, three isovectors, two strange isodoublets, and two isosinglets (one SU(3) singlet and one SU(3) octet). The spin, parity [$P = -(-1)^{\ell}$] and C-parity [$C = (-1)^{\ell+s}$] take the possible values $J^{PC} = 0^{++}$ (scalar), 0^{-+} (pseudoscalar), 1^{--} (vector), $1^{+\pm}$ (axial- or pseudovector), 2^{++} (tensor), etc. Therefore mesons with the *exotic* quantum numbers 0^{--}, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, etc. cannot be $q\bar{q}$ states. Note that the C-parity is defined only for the electrically neutral non-strange nonet members.

The two isosinglets in each nonet mix with an angle θ close to the *ideal* value of 35.3° for the 1^{--}, $1^{+\pm}$, 2^{++} and 3^{--} nonets, in which case the isosinglets decouple to $u\overline{u}+d\overline{d}$ and $s\overline{s}$. The orbital excitations $\ell \geq 1$ consist of four nonets for each value of n, since $j = \ell$ for antiparallel quark spins and $j = \ell-1, \ell$ or $\ell+1$ for parallel spins. Since the C-parity is not defined for strange mesons, the K_{1A} and K_{1B} in the axial vector 1^{++} and 1^{+-} nonets of fig. 63.1 are mathematical constructs which mix to give the observed $K_1(1270)$ and $K_1(1400)$ mesons.

As described in more detail below (section 63.2), it is hard to accommodate all the known scalar mesons in the lower $q\bar{q}$ nonets: The light scalar mesons $a_0(980)$, $K_0^*(700)$ (also known as κ), the $f_0(500)$ (also known as σ), and the $f_0(980)$, not shown in the figure, could build the lightest nonet, but could also be two-meson resonances or tetraquarks (section 63.8). Furthermore, the ground state glueball expected below 2 GeV will mix with the $q\bar{q}$ isoscalar scalar mesons (section 63.3.1). The pseudoscalar slot labeled $\eta(1440)$ may consist of two states (section 63.4). The status of vector meson excitations is described in section 63.5. The axial-vector meson $f_1(1420)$ could be replaced in the 1^{++} nonet by the $f_1(1510)$ which, however, needs confirmation (see the *Listings* and section 63.6). Mesons with exotic quantum numbers are discussed in section 63.7.

63.2 Scalar mesons

Scalar mesons decay dominantly into pairs of pseudoscalar mesons ($\pi\pi$, $K\overline{K}$, $\pi\eta$, $\eta\eta$ or $\eta\eta'$). The widths tend to be large for those decaying into $\pi\pi$, due to the absence of angular momentum barrier and the large available phase space. Identifying broad overlapping states is not straightforward. Furthermore, the onset of the $K\overline{K}$, $\eta\eta$ or $\eta\eta'$ thresholds distorts the line shapes and produces cusps. This requires high statistics data and the use of coupled channel analyses taking into account unitarity and analyticity (see 'Resonances' in the *Review*). The SU(3) classification is also not easy, because the ground state scalar glueball and multiquark states are predicted to exist below 2 GeV.

Two isovector scalars are known, the $a_0(980)$ and the $a_0(1450)$. Five isoscalar resonances are established: the very broad $f_0(500)$, the $f_0(980)$, the broad $f_0(1370)$, and the comparatively narrow $f_0(1500)$ and $f_0(1710)$. The strange partners are the $K_0^*(700)$ and the $K_0^*(1430)$. The $f_0(500)$ and $K_0^*(700)$ deserve a separate treatment and can be found in 'Scalar Mesons below 1 GeV', which contains more details on the $a_0(980)$ and $f_0(980)$, briefly reviewed in section 63.8.

The $a_0(1450)$ was first reported by the Crystal Barrel experiment in $\bar{p}p$ annihilation with stopped antiprotons [9] (see [10] for a review of Crystal Barrel results). Its mass of about 1450 MeV is not far from that of the $a_2(1320)$ meson. An isovector scalar, possibly the $a_0(1450)$ (albeit at a lower mass of 1317 MeV) is observed by Belle in $\gamma\gamma$ collisions leading to $\eta\pi^0$ [11]. The state interferes destructively with the non-resonant background. Its $\gamma\gamma$ coupling is comparable to that of the $a_2(1320)$, in accord with simple predictions (see *e.g.* [12]). A contribution from $a_0(1450) \to K\overline{K}$ is also found in the CLEO-c analysis of $D^{\pm} \to K^+K^-\pi^{\pm}$ [13] and $D^0 \to K_S^0K^{\pm}\pi^{\mp}$ from LHCb [14].

The $f_0(1370)$ and $f_0(1500)$ were observed by Crystal Barrel [15–17] and by WA102 in central production with 450 GeV protons [18,19]. They decay mostly into 2π and 4π. The $f_0(1500)$ was also observed to decay into $\eta\eta$ [20–22] and $\eta\eta'$ [23]. All data agree that the 4π decay mode represents about half of the $f_0(1500)$ decay width, but is dominant for $f_0(1370)$.

The determination of the $\pi\pi$ coupling of the very broad $f_0(1370)$ is complicated by its interference with the $f_0(500)$ and $f_0(1500)$. Its existence is questioned by COMPASS from $\pi^-p \to \pi^-\pi^-\pi^+p$ data [24]. In $\overline{B}_s^0 \to J/\psi(1S)\pi^+\pi^-$ from LHCb a strong scalar contribution from the $f_0(1370)$ was initially observed [25], although new data require the $f_0(500)$ and $f_0(1500)$, without any need for the $f_0(1370)$ [26]. In $\overline{B}^0 \to J/\psi(1S)\pi^+\pi^-$ the $\pi\pi$ mass spectrum does not show any significant scalar component above ∼1.2 GeV [27] (an analysis that is however challenged in [28]). $D^0 \to \pi^+\pi^-\pi^+\pi^-$ data from CLEO-c also require a contribution from $f_0(500)f_0(1370) \to 4\pi$ [29]. A broad 2π signal is also observed by BaBar around 1400 MeV in the decay $B^{\pm} \to \pi^{\pm}\pi^{\pm}\pi^{\mp}$ [30] which is attributed to the $f_0(1370)$, but could also be due to the $f_0(1500)$.

In Refs. [31, 32] the $f_0(1370)$ and $f_0(1710)$ (together with the $f_2(1270)$ and $f_2'(1525)$) are interpreted as bound systems of two vector mesons. This view is challenged in Ref. [33] where in a covariant formalism, e.g. the $f_2(1270)$ does not appear as a $\rho\rho$ bound state. Photoproduction data of the $f_2(1270)$ in $\gamma p \to \pi^0\pi^0p$ from CLAS [34], as a function of momentum trans-

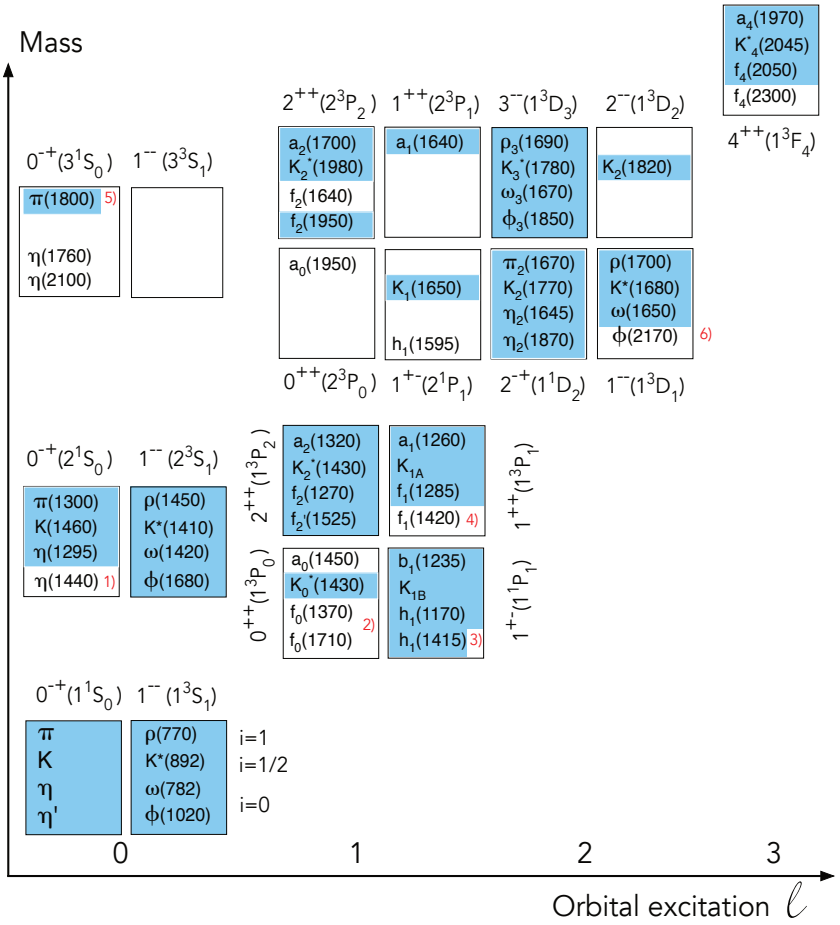

Figure 63.1: The mesons made of the u, d, and s light quarks are organised in $J^{PC}(n^{2s+1}\ell_j)$ nonets with isospin i. The established mesons (which appear in the *Summary Table* of the *Review*) are shown in the dark (blue) areas. The white areas contain those omitted in the *Summary Table* but reported in the *Listings*, or the established ones with a tentative nonet classification. States with the same J^{PC} mix, such as the 2^3S_1 and 1^3D_1 mesons. The states become broad and overlap with increasing masses, which complicates the determination of the resonance parameters *e.g.* mass, width and spin. For a complete list of mesons see the *Listings*.
[1] The $\eta(1440)$ stands for the $\eta(1405)$ and the $\eta(1475)$, section 63.4.
[2] The classification of the scalar nonet is controversial. Alternative schemes involve the $f_0(1500)$ and the light scalars below 1 GeV, section 63.2.
[3] Considered established, but more data would be desirable.
[4] An alternative to the $f_1(1420)$ is the $f_1(1510)$, section 63.6.
[5] The $\pi(1800)$ has also been proposed as a hybrid meson, section 63.7.
[6] The $\phi(2170)$ has also been proposed as a tetraquark state, section 63.8.

fer, also disagree with predictions [35] for the $f_2(1270)$ to be a $\rho\rho$ bound state.

While the $K\bar{K}$ decay branching ratio of the $f_0(1500)$ is small [18] [36], the $f_0(1710)$ decays dominantly into $K\overline{K}$. The $f_0(1710)$ is not observed in $p\bar{p}$ annihilation at rest [36] and only weakly produced in $p\bar{p}$ annihilation in flight [37], with a rate strongly suppressed compared to that of the $f_0(1500)$ (∼7%). For comparison, the rate for the $(s\bar{s})$ $f_2'(1525)$ is about 9% that of the $(u\bar{u}+d\bar{d})$ $f_2(1270)$, as expected from the OZI rule [37]. On the other hand the $f_0(1370)$ does not couple strongly to $K\bar{K}$ [18]. This suggests an $n\bar{n}$ structure $(u\bar{u}+d\bar{d})$ for the $f_0(1370)$ and $s\bar{s}$ for the $f_0(1710)$. The $f_0(1500)$ would also qualify as an $n\bar{n}$ state (see 63.3.1), although it is very narrow compared to the other states. Occam's razor principle therefore suggests that the $f_0(1370)$, $a_0(1450)$, and the $f_0(1710)$ are in the same SU(3) flavor nonet, the $f_0(1370)$ and $a_0(1450)$ being the two (mostly) $n\bar{n}$ states, and the $f_0(1710)$ the (dominantly) $s\bar{s}$ one. It is important to note that the spectrum of scalar mesons above the $f_0(1710)$ is not well established: The reported ones in the *Listings* need experimental confirmation and are not included in the *Summary Table*.

According to [38] there is mounting evidence for the existence of two scalar nonets and one glueball below 2 GeV: Table 63.1 shows a proposed classification scheme. The low mass nonet is made of four-quark states which recombine at large distances to become meson-meson resonances, while the ground state 1^3P_0 $q\bar{q}$ nonet lies in the 1400 MeV region, see Ref. [1] for a review and Ref. [39] for the $f_0(500)$. The nature of the $f_0(1500)$ is discussed along this scheme in section 63.3.1.

Other schemes have been proposed, for example a tetraquark for the $f_0(1500)$ [40] or flavor octets for the $f_0(1500)$ and $f_0(1710)$ [3]. In Ref. [41] the $a_0(1450)$, $f_0(1370)$, $f_0(1500)$ and $K_0^*(1430)$ are radial excitations of the scalar nonet below 1 GeV. In Ref. [42] the light and heavy scalar nonets in Table 63.1 are interpreted as mixing of two tetraquark nonets. In the unitarized quark model with coupled $q\bar{q}$ and meson-meson channels, the scalars below 1 GeV are manifestations of bare $q\bar{q}$ confinement states, mass shifted from the 1.4 GeV region and distorted by the strong $^3P_0$ coupling to S-wave two-meson decay channels [43, 44]. Thus, in these models the light scalar nonet comprising the light and heavy scalar nonets shown in Table 63.1 are manifestations of the same bare input states (see also [45]). Surprisingly for a state decaying strongly into 2π and 4π, the $f_0(1370)$ is assumed to be an $s\bar{s}$ state in Ref. [46]. The $f_0(1500)$ is then a radial excitation and the glueball lies around 1700 MeV.

Table 63.1: Tentative classification of scalar mesons (see the text). The 1^3P_0 ground state $q\bar{q}$ nonet is listed in the bottom half. The third isoscalar $f_0(1500)$ is discussed in section 63.3.1.

	Γ [MeV]	isospin i	structure
$a_0(980)$	~ 50	1	$K\bar{K}, qq\bar{q}\bar{q}$
$f_0(980)$	~ 50	0	$K\bar{K}, qq\bar{q}\bar{q}$
$f_0(500)$	~ 800	0	$\pi\pi, qq\bar{q}\bar{q}$
$K_0^*(700)$	~ 600	$\frac{1}{2}$	$K\pi, qq\bar{q}\bar{q}$
$a_0(1450)$	265	1	$u\bar{d}, d\bar{u}, d\bar{d} - u\bar{u}$
$f_0(1370)$	~ 400	0	$d\bar{d} + u\bar{u}$
$f_0(1710)$	125	0	$s\bar{s}$
$K_0^*(1430)$	294	$\frac{1}{2}$	$u\bar{s}, d\bar{s}, s\bar{u}, s\bar{d}$

63.3 Glueballs

Lattice calculations, QCD sum rules, flux tube, and constituent glue models agree that the lightest glueball has quantum numbers $J^{PC} = 0^{++}$ and the first excited state 2^{++}. Lattice calculations predict for the ground state (0^{++}) a mass around 1600 – 1700 MeV [47–50], while the 2^{++} state lies around 2300 MeV. For more information on lattice calculations see 'Quark Model' in the *Review* and fig. 15.3 therein for an example of mass spectrum. These predictions were made in the quenched approximation, neglecting $q\bar{q}$ loops. However quenched predictions and full QCD calculations lead to small mass shifts (see 'Quark Model' and fig. 15.15 therein).

Heavier glueballs with quantum numbers 0^{-+}, 2^{-+}, 1^{+-}, etc. are predicted above 2500 MeV and the lowest exotic ones (with exotic quantum numbers such as 0^{+-} and 2^{+-}) are expected above 4000 MeV [50]. In holographic QCD the 0^{-+} is predicted to be very broad [51] and the 1^{+-} is at least as broad as its width [52]. Calculations of the three lowest scalar and pseudoscalar glueballs masses in pure Yang-Mills theory are in quantitative agreement with lattice results [53]. The lightest glueballs lie in the same mass region as ordinary isoscalar $q\bar{q}$ states, in the mass range of the $1^3P_0(0^{++})$, $2^3P_2(2^{++})$, $3^3P_2(2^{++})$, and $1^3F_2(2^{++})$ $q\bar{q}$ states. Therefore, mixing of glueballs with nearby $q\bar{q}$ states of the same quantum numbers leads to supernumerary isoscalar state in the $q\bar{q}$ nonets (however, see Ref. [54] discussed in section 63.3.1).

Among the signatures naively expected for glueballs are (i) isoscalar states that do not fit into $q\bar{q}$ nonets, (ii) enhanced production in gluon-rich channels such as central production and radiative $J/\psi(1S)$ decay, (iii) decay branching fractions incompatible with SU(3) predictions for $q\bar{q}$ states, and (iv) reduced $\gamma\gamma$ couplings. However, mixing effects with isoscalar $q\bar{q}$ mesons [47, 55–63] and decay form factors [64] can obscure these simple signatures.

According to SU(3) the decay branching ratios for $q\bar{q}$ mesons and pure glueballs are different, and therefore useful to determine the internal structures of mesons. For pure glueballs with flavor symmetric couplings the decay ratios are $\pi\pi : K\bar{K} : \eta\eta : \eta\eta' = 3 : 4 : 1 : 0$, apart from phase space factors. The partial widths for the decay of a scalar (or a tensor) meson into a pair of pseudoscalar mesons are given in Fig. 63.2 (for a derivation see e.g. [8]).

The decay of a $q\bar{q}$ meson into a pair of mesons involves the creation of a $q\bar{q}$ pair, and SU(3) symmetry assumes that the matrix elements for the creation of $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ pairs are equal. (The generalization to unequal $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ couplings is given in Ref. [55].) An excellent fit to the tensor meson decay widths is obtained with $\beta \simeq 0.5$ GeV/c, $\theta_V \simeq 26$ ° and $\theta_P \simeq -17$ ° [55].

Note that the assumption of flavor symmetric couplings may not apply in models describing the scalar glueball by a dilaton field, which lead to mass dependent couplings [65, 66] (see Ref. [67] which predicts that a scalar glueball above 1 GeV would be unobservably wide).

Another way to determine the flavor contents of neutral mesons is the decay $B \to J/\psi(1S)X$ which filters out the $d\bar{d}$ content of X, while $B_s^0 \to J/\psi(1S)X$ selects its $s\bar{s}$ component [68].

63.3.1 *Scalar glueballs*

One of the three isoscalars, the $f_0(1370)$, $f_0(1500)$ or $f_0(1710)$, appears to be supernumerary. The branching ratios in Fig. 63.2 can be used to deduce the structures of these states, assuming that they are $q\bar{q}$. The comparison of decay branching ratios from Crystal Barrel annihilation and WA102 central collision data shows that the $f_0(1500)$ is compatible with an $n\bar{n}$ structure, while the $f_0(1710)$ is mostly $s\bar{s}$ [12]. However, the close vicinity of the very broad $n\bar{n}$ $f_0(1370)$, its narrow width, enhanced production at low transverse momentum transfer in central collisions [69–71] and absence in $\gamma\gamma$ collisions (see below) favor the $f_0(1500)$ to be the supernumerary non-$q\bar{q}$ state. According to [55, 60] the $f_0(1370)$ and $f_0(1710)$ would be dominantly $\bar{q}q$ states mixing with glue, while the $f_0(1500)$ would be dominantly a glueball mixing with $q\bar{q}$ states. Its suppressed $K\bar{K}$ decay would be due to interferences with the $f_0(1370)$ and $f_0(1710)$. In the analogous mixing scheme of Ref. [72], which uses central production data from WA102 and the hadronic $J/\psi(1S)$ decay data from BES [73,74], glue is shared between the $f_0(1370)$ (mainly $n\bar{n}$), $f_0(1500)$(mainly glue) and $f_0(1710)$ (dominantly $s\bar{s}$). This agrees with the analyses [55, 60]. In the mixing scheme of Ref. [75] the QCD spectral sum rule also leads to a large gluonic component in the $f_0(1500)$ (satisfying the observed strong $\pi\pi$ and $f_0(500)f_0(500) \to 4\pi$ decays).

However, not everybody agrees that the strong $K\bar{K}$ signal is indicative of an $s\bar{s}$ structure for the $f_0(1710)$. The $f_0(1710)$ could still be the glueball, since the two-gluon coupling to $n\bar{n}$ appears to be suppressed by chiral symmetry [76], thus $K\bar{K}$ would be enhanced compared to $\pi\pi$. It was argued that chiral symmetry constraints in a multichannel analysis imply that the $f_0(1710)$ is an unmixed scalar glueball [77]. However, this view is challenged in [78].

The $K\bar{K}$ decay is also naturally enhanced in the extended linear sigma model with a dilaton as glueball [65] and in the holographic model of [66, 79] which both prefer the $f_0(1710)$ as the glueball. For a scalar glueball Ref. [66] finds a strong enhancement of the decays into $K\bar{K}$ and $\eta\eta$, in fairly close agreement with the measured branching ratios of the $f_0(1710)$, while Ref. [79] predicts the (so far not measured) rate into $\eta\eta'$ to be very small.

In $\gamma\gamma$ collisions leading to K_SK_S [80] and K^+K^- [81] a spin-0 signal is observed at the $f_0(1710)$ mass (together with a dominant spin-2 component), while the $f_0(1500)$ is not observed in $\gamma\gamma \to K\bar{K}$ nor $\pi^+\pi^-$ [82]. The $f_0(1500)$ is also not observed by Belle in $\gamma\gamma \to \pi^0\pi^0$, although a shoulder is seen which could also be due to the $f_0(1370)$ [83]. The absence of $f_0(1500)$ signal in the $\pi\pi$ channel in $\gamma\gamma$ collisions does not favor an $\overline{n}n$ interpretation for the $f_0(1500)$. The upper limit for $\Gamma_{2\gamma}$ (< 1.4 keV) in $\pi^+\pi^-$ [12]) excludes a large $n\overline{n}$ content, and hence points to a mainly $s\overline{s}$ content [12], which contradicts the small $K\overline{K}$ decay branching ratio of the $f_0(1500)$ [18, 36, 84]. Belle finds that in $\gamma\gamma \to K_SK_S$ collisions the 1500 MeV region is dominated by the $f_2'(1525)$. The $f_0(1710)$ is also observed with a production rate × branching ratio compatible with an $s\bar{s}$ state [85]. Note, however, that the $\gamma\gamma$ couplings of glueballs are sensitive to glue mixing with $q\bar{q}$ [72]. Ref. [63] predicts the glueball $\gamma\gamma$ partial width in the few keV range (comparable to that of $q\bar{q}$ mesons) due to couplings of vector mesons to γ via VDM.

Alternative assignments for the scalar glueball have been proposed: In Ref. [57] the gluonic signal is distributed over $f_0(1370)$, $f_0(1500)$ and another broad isoscalar around 1530 MeV, while the gluonic contribution to the $f_0(1710)$ is small. As mentioned already, in Ref. [47, 65, 66] the $f_0(1710)$ is the glueball state, as in Ref. [61], where the $f_0(1500)$ is the $q\bar{q}$ octet state degenerate with the $a_0(1450)$. In the generalized linear sigma model [86] the $a_0(980)$ is dominantly a tetraquark and $a_0(1450)$ a $q\bar{q}$ state. The $f_0(980)$, $f_0(1370)$ and $f_0(1500)$ (or $f_0(1710)$) are dominantly tetraquark, $q\bar{q}$ and glue.

In Ref. [59] the $f_0(500)$ and $f_0(1370)$ are signals from a single broad resonance proposed as the scalar glueball. The ground state scalar nonet then consists of the $f_0(980)$, $a_0(980)$, $K_0^*(1430)$, $f_0(1500)$ and $f_0(1710)$ [62]. The $f_0(980)$ and $f_0(1500)$ mix (similarly to the η and η' in the pseudoscalar nonet), while the $f_0(1500)$ mixes with a glueball in the 500 – 1000 MeV mass range, which is identified as the $f_0(500)$. A reanalysis of the CERN-Munich

Isospin	Decay channel	γ^2
0	$\pi\pi$	$3\cos^2\alpha$
	$K\overline{K}$	$(\cos\alpha - \sqrt{2}\sin\alpha)^2$
	$\eta\eta$	$(\cos\alpha\cos^2\phi - \sqrt{2}\sin\alpha\sin^2\phi)^2$
	$\eta\eta'$	$\frac{1}{2}\sin^2 2\phi\ (\cos\alpha + \sqrt{2}\sin\alpha)^2$

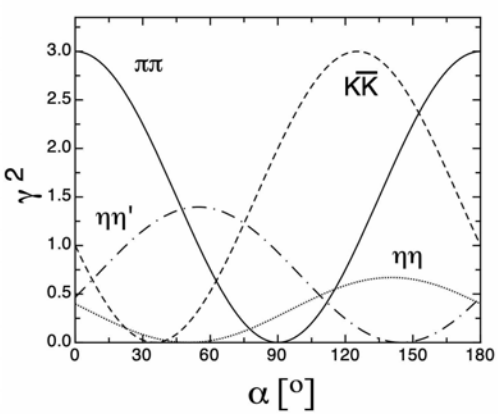

Figure 63.2: Left: SU(3) couplings γ^2 for scalar (or tensor) $q\bar{q}$ meson decays. The angles α and ϕ are defined as $\alpha = 54.7^\circ + \theta$ and $\phi = 54.7^\circ + \theta_P$, where θ is the mixing angle of the decaying isoscalars and θ_P the mixing angle in the 0^{++} (2^{++}) meson nonet. The partial decay width is given by $\Gamma = C \times \gamma^2 \times |F(q)|^2 \times q$, where C is a nonet constant, q the momentum of the decay products and $F(q)$ a form factor which may be taken as $|F(q)|^2 = q^{2\ell} \times \exp(-q^2/8\beta^2)$ with β= 0.5 GeV/c, and where ℓ is the relative angular momentum between the decay products ($\ell = 0$ for scalars and $\ell = 2$ for tensors). Right: SU(3) couplings as a function of mixing angle α for isoscalar decays for $\theta_P = -17.3^\circ$ (from [55]).

data shows no signal for the $f_0(1370)$ decaying into $\pi\pi$, in contrast to [54, 87]. However, in this scheme the $K_0^*(700)$ and the $a_0(1450)$ are also left out.

In Ref. [88], a large K^+K^- scalar signal reported by Belle in B decays into $KK\bar{K}$ [89], compatible with the $f_0(1500)$, is explained as due to constructive interference of a flavor octet with a broad glueball background. However, the Belle data are inconsistent with the BaBar measurements which show instead a broad scalar at this mass for B decays into both $K^\pm K^\pm K^\mp$ [90] and $K^+K^-\pi^0$ [91].

The $f_0(1500)$ is observed by BESII in $J/\psi(1S) \to \gamma\pi\pi$ [92] and by BESIII in $J/\psi(1S) \to \gamma\eta\eta$ [93] with a much smaller rate than for the $f_0(1710)$, which would speak against a glueball interpretation of the former, although the systematic errors are large. Also, the $f_0(1500)$ appears at a lower mass and the $f_0(1710)$ at a higher mass than the accepted values. However, the coupled channel analysis of more data on radiative $J/\psi(1S)$ decay from BESIII [54] (described in the next paragraph) finds comparable contributions from $f_0(1500)$ and $f_0(1710)$ with a preference for $\pi\pi$ decay over $K\bar{K}$ for the former and $K\bar{K}$ over $\pi\pi$ for the latter.

The authors of Ref. [54] have analyzed the high statistics data from $J/\psi(1S)$ radiative decays into $\pi^0\pi^0$, $K_S^0K_S^0$, $\eta\eta$ and $\omega\phi$ from BESIII, including data on $\pi\pi$, $\eta\eta$ and $\eta\eta'$ from the CERN SPS, BNL data on $\pi\pi \to K_S^0K_S^0$ and $\bar{p}p$ annihilation data from LEAR into various final states. The coupled channel analysis requires ten scalar mesons, the established ones in the *Review* and the four isoscalars $f_0(2020, 2100, 2200, 2330)$ so far omitted from the *Summary Table*. As a new feature, the $f_0(1710)$ splits into two states, one at about 1700 MeV, the former $f_0(1710)$, and a new one around 1770 MeV being mandatory to obtain a good fit. A broad (∼370 MeV) enhancement is observed in $J/\psi(1S)$ radiative decays around 1865 MeV, attributed to the contribution of glue distributed among the scalar mesons, with a very strong contribution from the new 1770 MeV state [94]. In this model there are no supplementary states as the glue 'fragments' between the various isoscalars.

Ref. [95] reports on a very recent re-analysis of the BESIII $J/\psi(1S)$ radiative decay data into $\pi^0\pi^0$ and $K_S^0K_S^0$. A good fit is obtained with only two scalar resonances below 2 GeV, the $f_0(1500)$ and $f_0(1710)$. The latter couples much more strongly to both channels, which points to a sizeable glueball component.

63.3.2 *Tensor glueballs*

Above the well known $f_2(1270)$ and $f_2'(1525)$ $q\bar{q}$ mesons, the $f_2(1640)$ and $f_2(1950)$ are tentatively assigned to the 2^3P_2 nonet (see Fig. 63.1). The broad $f_2(1950)$ has been observed by several experiments, *e.g.* in central production [19] and in $\bar{p}p$ annihilation in flight [96] and is often identified as the ground state of the pomeron [97, 98]. Three further isoscalar tensors are established, the $f_2(2010)$, $f_2(2300)$ and $f_2(2340)$, which are in the range of the 1^3F_2 and 3^3P_2 nonets, and in the expected region for the 2^{++} glueball. The large $\phi\phi$ cross section in $\bar{p}p$ just above threshold [99] could be due to the production of the 2^{++} glueball, in accord with earlier observations in π^-N reactions [100, 101] and in central collisions [102].

The $f_2(2010)$, $f_2(2300)$ and $f_2(2340)$ have been observed by BESIII in $J/\psi(1S) \to \gamma\phi\phi$ [103]. The production rate of a tensor glueball in $J/\psi(1S)$ radiative decay has been calculated in quenched lattice QCD to be large (around 1%) [104] and is claimed by BESIII [103] to be compatible with their rates measured in $J/\psi(1S) \to f_2(2340)$, $f_2(2340) \to \eta\eta$ [93], and $f_2(2340) \to \phi\phi$ [103]. The relatively narrow $f_2(2300)$ with a measured width of 149 MeV [101] is preferred by the holographic QCD model of Ref. [105]. However, the tensor glueball is predicted to be much broader (600-900 MeV) by the holographic model of Ref. [106].

There is no evidence for a narrow meson, $f_J(2220)$ (a tensor candidate) in $\bar{p}p$ annihilation (see the note under the $f_J(2220)$ in the 2004 issue of the *Review*). The measured partial width to $\bar{p}p$ in radiative $J/\psi(1S)$ decay [107] is too large and inconsistent with the upper limit from $\bar{p}p$ annihilation into $\pi\pi$ [108].

63.4 Pseudoscalar mesons

We now deal with the first radial excitations of the 0^{-+} nonet (Fig. 63.1). The $\pi(1300)$ is a very broad resonance (200–600 MeV) decaying into 3π. The $K(1460)$ was recently confirmed with high statistics data from LHCb in $D^0 \to K3\pi$ decays [109] and has become an established kaon excitation. The first observation of an isoscalar resonance around 1425 MeV – the E-meson – was made in $p\bar{p}$ annihilation at rest into $E\pi^+\pi^-$, $E \to K\overline{K}\pi$ [110]. This state was reported to decay into $a_0(980)\pi$ and $K^*(892)\overline{K}$ with roughly equal contributions. An isoscalar state, the ι meson, was observed in radiative $J/\psi(1S)$ decay into $K\overline{K}\pi$ [111–113] and $\gamma\rho$ [114], and was considered at that time as a glueball candidate, owing to its strong signal in radiative $J/\psi(1S)$ decay. The E and ι were later assumed to be the same state, called $\eta(1440)$.

The $\eta(1295)$ has been observed in various production mechanisms, in π^-p experiments [115–118], and in $\bar{p}p$ annihilation [84,119,120]. In $J/\psi(1S)$ radiative decay, the $\eta(1295)$ signal is also evident in the 0^{-+} $\eta\pi\pi$ wave of the DM2 data [121]. Also BaBar reports a signal around 1295 MeV in B decays into $\eta\pi\pi K$ [122]. Let us therefore assume in the following that the $\eta(1295)$ is one of the isoscalars in this nonet.

However, two isoscalars were later observed in this mass region, the $\eta(1405)$ and $\eta(1475)$. The former decays mainly into $a_0(980)\pi$ (or direct $K\overline{K}\pi$) and the latter mainly into $K^*(892)\overline{K}$. The simultaneous observation of two pseudoscalars is reported in

three production mechanisms: $\pi^- p$ [115, 123], radiative $J/\psi(1S)$ decay [121, 124], and $\overline{p}p$ annihilation at rest [125–128]. All of them give values for the masses, widths, and decay modes that are in reasonable agreement. (However, Ref. [121] favors a state decaying into $K^*(892)\overline{K}$ at a lower mass than the state decaying into $a_0(980)\pi$.) In $J/\psi(1S)$ radiative decay, the $\eta(1405)$ decays into $K\overline{K}\pi$ through $a_0(980)\pi$, and hence a signal is also expected in the $\eta\pi\pi$ mass spectrum. This was indeed observed by MARK III in $\eta\pi^+\pi^-$ [129], which reported a mass of 1400 MeV, in line with the existence of the $\eta(1405)$ decaying into $a_0(980)\pi$. Two states were also reported by BES: Around 1452 MeV BESII observed a $K\bar{K}\pi$ enhancement in $J/\psi(1S) \to \omega K\bar{K}\pi$ but not in $J/\psi(1S) \to \phi K\bar{K}\pi$ [130], while BESIII reported a 52 MeV broad state in $\psi(2S) \to \omega K^* K$ [131], both left without J^{PC} determination.

The $K\overline{K}\pi$ and $\eta\pi\pi$ channels were studied in $\gamma\gamma$ collisions by L3 [132]. (For the 2γ couplings of glueballs and $q\bar{q}$ mesons see [63,133,134].) The analysis led to a clear $\eta(1475)$ signal in $K\overline{K}\pi$, decaying into $K^*\overline{K}$, well identified in the untagged data sample, where spin 1 resonances are not allowed. At the same time, L3 did not observe the $\eta(1405)$, neither in $K\overline{K}\pi$ nor in $\eta\pi\pi$ [132]. On the other hand, CLEO-II did not observe any pseudoscalar signal with tagged γ's in $\gamma\gamma \to \eta(1475) \to K^0_S K^\pm\pi^\mp$ [135], with an upper limit slightly smaller than the signal observed by L3. After the CLEO-II result L3 performed a further analysis with full statistics [136], confirming their previous evidence for the $\eta(1475)$. The CLEO upper limit [135] for $\Gamma_{\gamma\gamma}$, and the L3 results [136], are consistent with the world average for the $\eta(1475)$ width. BaBar [122] also reported the $\eta(1475)$ in B decays into $K\bar{K}^*$ recoiling against a K, while upper limits only were given for the $\eta(1405)$.

Hence, in radiative $J/\psi(1S)$ decay, $\pi^- p$ and $\overline{p}p$ annihilation at rest two isoscalar signals are observed in the 1400 – 1500 MeV mass region, while the $\eta(1405)$ is not seen in $\gamma\gamma$ interactions nor in B decays. The $\eta(1475)$ could be the first radial excitation of the η', with the $\eta(1295)$ being the first radial excitation of the η. Ideal mixing, suggested by the $\eta(1295)$ and $\pi(1300)$ mass degeneracy, would then imply that the second isoscalar in the nonet is mainly $s\bar{s}$, and hence couples to $K^*\overline{K}$, in agreement with properties of the $\eta(1475)$. Also, its width agrees with the expected one for the radially excited $s\bar{s}$ state [64, 69]. A study of radial excitations of pseudoscalar mesons [137] also favors the $s\bar{s}$ interpretation of the $\eta(1475)$. However, due to the strong kinematical suppression in $\eta(1405) \to K^*\overline{K}$ the data are not sufficient to exclude a sizeable $s\bar{s}$ admixture also in the $\eta(1405)$.

The supernumerary isoscalar $\eta(1405)$ would be a candidate for the 0^{-+} glueball in the fluxtube model [138], in which the 0^{++} glueball is also naturally related to a 0^{-+} glueball with mass degeneracy broken in QCD. However, this scenario is not favored by lattice gauge theories which predict the 0^{-+} state above 2 GeV [48,139] (see 'Quark model' in this issue of the *Review*). Nevertheless, the pseudoscalar glueball could lie at a lower mass than predicted from lattice calculation [140], see also Refs. [141–143]. A detailed review of the experimental situation on the pseudoscalar glueball is available in Ref. [144].

Here also, there are alternative explanations. The mere existence of the $\eta(1295)$ is questioned in Refs. [3, 145], in which the authors also propose a single pseudoscalar meson at 1440 MeV, the first radial excitation of the η. According to Ref. [3] the splitting of the 1440 MeV state into $\eta(1405)$ and $\eta(1475)$ is due to nodes in the decay amplitudes, which differ in $\eta\pi\pi$ and $K^*(892)\overline{K}$. The splitting could also be due to a triangle singularity, hence the manifestation of one state only (Fig. 63.3) [146–148]. In Ref. [149], using the triangle singularity approach of [146], the authors conclude that the BESIII results can be reproduced either with the $\eta(1405)$ or the $\eta(1475)$, or by a mixture of these two states.

To summarise this section, the experimental data on the 1400 — 1500 MeV region span several decades, various production mechanisms and decay modes, with models for data analysis evolving with time. A comprehensive coherent picture of all available data is therefore difficult. We believe that there is sufficient evidence to consider the 0^{-+} nonet with the $\eta(1440)$ in fig. 63.1 as established. Whether one or two different states – $\eta(1405)$ and $\eta(1475)$ – exist is an open question, in which case the $\eta(1405)$ would be supernumerary. There is a wide number of experimental results indicating the presence of two separate states but, as mentioned above, data are also consistent with one state only. Theoretical interpretations of the most recent data are not able to lift the ambiguity.

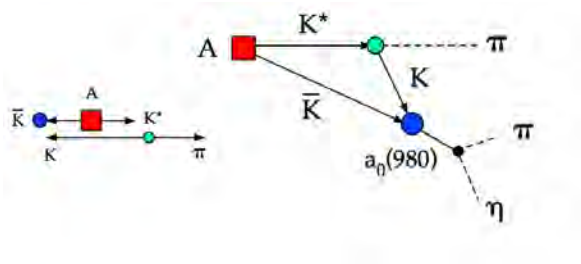

Figure 63.3: Triangle singularity: a state A decays into $K^*\overline{K}$. The K from K^* decay catches up with the $\overline{K}$ and excites the $a_0(980)$ resonance which in turn decays into $\eta\pi$. This mechanism can lead to two distinct peaks (depending on the width of A), one in $K^*\overline{K}$ and the other via rescattering in $\eta\pi\pi$. Similarly, the virtual $K^*\overline{K}$ loop can couple to $f_0(980)$ which, decaying into $\pi\pi$, leads to a peak in the 3π final state.

63.5 Vector mesons

In this section we restrict ourselves to the more interesting isovector spectrum which contains broad and overlapping states.

63.5.1 *The* $\rho(770)$ *meson*

The determination of the parameters of the $\rho(770)$ is beset with many difficulties because of its large width. The line shape depends on the production process and is not described by a relativistic Breit-Wigner function with a P-wave width, but requires some additional shape parameter. This dependence on parameterization was demonstrated long ago [150]. Bose-Einstein correlations are another source of shifts in the $\rho(770)$ line shape, particularly in multiparticle final-state systems [151].

The same model dependence afflicts any other source of resonance parameters, such as the energy dependence of the phase shift δ_1^1, or the pole position. It is, therefore, not surprising that a study of $\rho(770)$ dominance in the decays of the η and η' reveals the need for specific dynamical effects, in addition to the $\rho(770)$ pole [152, 153].

The cleanest determination of the $\rho(770)$ mass and width comes from e^+e^- annihilation and τ-lepton decays. ALEPH data [154] showed that the charged $\rho(770)$ parameters measured from τ-lepton decays are consistent with those of the neutral one determined from e^+e^- data [155]. This conclusion is qualitatively supported by the later studies of CLEO [156] and Belle [157]. However, a comparison of the two-pion mass spectrum in τ decays from OPAL [158], CLEO [156], and ALEPH [159, 160], and the $e^+e^- \to \pi^+\pi^-$ cross section from CMD-2 [161, 162], showed significant discrepancies between the two shapes which can be as high as 10% above the ρ meson mass [163, 164]. This discrepancy remains after measurements of the two-pion cross section in e^+e^- annihilation at KLOE [165–168], SND [169,170], BaBar [171] and, more recently BESIII [172]. The effect is not accounted for by isospin breaking [173–176], but the accuracy of its calculation may be overestimated [177, 178].

This problem seems to be solved after a recent analysis in [179], which showed that after correcting the τ data for the missing ρ–γ mixing contribution, besides the other known isospin symmetry violating corrections, the $\pi\pi$ isospin 1 part of the hadronic vacuum polarization contribution to the muon $g-2$ is fully compatible between τ based and e^+e^- based evaluations. The global fit of the whole set of the ρ, ω, and ϕ decays, taking into account mixing effects in the hidden local symmetry model, also showed consistency of the data on τ decays to two pions and e^+e^- annihilation [180, 181]. However, because of the progress in e^+e^- data, the τ input is now less precise and less reliable due to additional theoretical uncertainties [182] decreasing the importance of τ decay for the determination of the $\rho(770)$ parameters.

63.5.2 *The* $\rho(770)$ *excitations*

In our 1988 edition, we replaced the $\rho(1600)$ entry with two new ones, the $\rho(1450)$ and the $\rho(1700)$, because there was emerging evidence that the 1600-MeV region actually contains two ρ-like resonances. This possibility was pointed out by a theoretical analysis [183] on the consistency of the 2π and 4π electromagnetic form factors and the $\pi\pi$ scattering length. A consistent picture of $e^+e^- \to 2\pi, 4\pi$ and diffractive photoproduction is obtained with two resonances [184]. The existence of the $\rho(1450)$ was supported by the analysis of $\eta\rho^0$ mass spectra obtained in photoproduction and e^+e^- annihilation [185], as well as that of $e^+e^- \to \omega\pi$ [186].

The analysis of [184] was further extended by [187, 188] to include new data on 4π-systems produced in e^+e^- annihilation, and in τ decays ($\tau \to 4\pi$ and $e^+e^- \to 4\pi$ are related by the Conserved Vector Current hypthesis). These systems were successfully analyzed using interfering contributions from two ρ-like states, and from the tail of the $\rho(770)$ two-body decay. While specific conclusions on $\rho(1450) \to 4\pi$ were obtained, little could be said about the $\rho(1700)$. Independent evidence for two 1^- states is provided by [189] in 4π electroproduction at $\langle Q^2\rangle = 1$ (GeV/c)^2, and by [190] in a high-statistics sample of the $\eta\pi\pi$ system in $\pi^- p$ charge exchange.

This scenario with two overlapping resonances is supported by other data. DM2 [191] measured the pion form factor in the interval 1.35–2.4 GeV, and observed a deep minimum around 1.6 GeV. The best fit was obtained with the hypothesis of ρ-like resonances at 1420 and 1770 MeV, with widths of about 250 MeV. DM2 [192] found that the $e^+e^- \to \eta\,\pi^+\,\pi^-$ cross section is better fitted with two fully interfering Breit-Wigners, with parameters in fair agreement with those of [184] and [191]. These results can be considered as a confirmation of the $\rho(1450)$.

Decisive evidence for the $\pi\pi$ decay mode of both $\rho(1450)$ and $\rho(1700)$ comes from $\overline{p}p$ annihilation at rest [193]. It has been shown that these resonances possess a $K\overline{K}$ decay mode [84, 194, 195]. This decay mode has also been studied in three-body hadronic B decays [196]. High-statistics studies of the decays $\tau \to \pi\pi\nu_\tau$ [154, 156], and $\tau \to 4\pi\nu_\tau$ [197] also require the $\rho(1450)$, but are not sensitive to the $\rho(1700)$, being too close to the τ mass. A recent very-high-statistics study of the $\tau \to \pi\pi\nu_\tau$ from Belle [157] reports the first observation of both $\rho(1450)$ and $\rho(1700)$ in τ decays. A clear picture of the two $\pi^+\pi^-$ resonances interfering with the $\rho(770)$ in e^+e^- annihilation was also reported by BaBar using the ISR (Initial State Radiation) method [198].

The structure of these ρ states is not yet completely clear. The authors of Refs. [64,199] claim that $\rho(1450)$ has a mass consistent with radial $2S$, but its decays show characteristics of hybrids, and suggest that this state may be a $2S$-hybrid mixture. Hybrid states could have a 4π decay mode dominated by the $a_1\pi$ [200]. Such behavior has been observed by [201] in $e^+e^- \to 4\pi$ in the energy range 1.05–1.38 GeV, and by [197] in $\tau \to 4\pi$ decays. CLEO [202] and Belle [203] observe the $\rho(1450) \to \omega\pi$ decay mode in B-meson decays, however, do not find $\rho(1700) \to \omega\pi^0$. A similar conclusion is made by [204, 205], who studied the process $e^+e^- \to \omega\pi^0$ and do not observe a statistically significant signal of the $\rho(1700)$. Various decay modes of the $\rho(1450)$ and $\rho(1700)$ are observed in $\overline{p}n$ and $\overline{p}p$ annihilation [206, 207], but no definite conclusions can be drawn. More data should be collected to clarify the nature of the ρ states, particularly in the energy range above 1.6 GeV.

We now list under a separate entry the $\rho(1570)$, the $\phi\pi$ state with $J^{PC} = 1^{--}$ earlier observed by [208] – referred to as $C(1480)$) – and recently confirmed by [209] and [210]. While [211] shows that it may be a threshold effect, Refs. [187] and [212] suggest two independent vector states with this decay mode. The $C(1480)$ has not been seen in the $\overline{p}p$ [213] and e^+e^- [214, 215] experiments. However, the sensitivity of the two latter is an order of magnitude lower than that of [209]. Note that [209] can not exclude that their observation is due to an OZI-suppressed decay mode of the $\rho(1700)$.

Several observations on the $\omega\pi$ system in the 1200 MeV region [216–222] may be interpreted in terms of either $J^P = 1^-$ $\rho(770) \to \omega\pi$ production [223], or $J^P = 1^+$ $b_1(1235)$ production [221, 222]. We argue that no special entry for a $\rho(1250)$ is needed. The LASS amplitude analysis [224] showing evidence for $\rho(1270)$ is preliminary and needs confirmation. However, evidence for the $\rho(1250)$ from a reanalysis of elastic scattering data is claimed in Ref. [225]. For completeness, the relevant observations are listed under the $\rho(1450)$.

Recently Ref. [226] reported a very broad 1^{--} resonance-like K^+K^- state in $J/\psi \to K^+K^-\pi^0$ decays. Its pole position corresponds to mass of 1576 MeV and width of 818 MeV. Its exotic structure (molecular or multiquark) is suggested [227–229], while in Refs. [230] and [231] this is explained by the interference between the $\rho(1450)$ and $\rho(1700)$. The latter statement is qualitatively supported by BaBar [232] and SND [233]. We quote [226] as $X(1575)$ in the section "Further States."

Evidence for ρ-like mesons decaying into 6π was first noted by [234] in the analysis of $e^+e^- \to 6\pi$ [235, 236] and diffractive photoproduction [237]. The authors of Ref. [234] argued that two states at about 2.1 and 1.8 GeV exist: while the former is a candidate for the $\rho(2150)$, the latter could be a manifestation of the $\rho(1700)$ distorted by threshold effects. BaBar reported observations of the new decay modes of the $\rho(2150)$ in the channels $\eta'(958)\pi^+\pi^-$, $f_1(1285)\pi^+\pi^-$ [238] and $\pi^+\pi^-$ [239]. The decay of the $\rho(2150)$ into K^+K^- has been observed by BESIII [240] and confirmed by BaBar [241]. The relativistic quark model [242] predicts the 2^3D_1 state with $J^{PC} = 1^{--}$ at 2.15 GeV which can be identified with the $\rho(2150)$.

Under $\rho(1900)$ we list various observations of irregular behavior of the cross sections near the $N\bar{N}$ threshold. Dips of various width around 1.9 GeV were reported by the E687 Collaboration (a narrow one in the $3\pi^+3\pi^-$ diffractive photoproduction [243, 244]), by the FENICE experiment (a narrow structure in the R value [245]), by BaBar in ISR (a narrow structure in $e^+e^- \to \phi\pi$ final state [209], but much broader in $e^+e^- \to 3\pi^+3\pi^-$ and $e^+e^- \to 2(\pi^+\pi^-\pi^0)$ [246]), by CMD-3 (also a rather broad dip in $e^+e^- \to 3\pi^+3\pi^-$ [247]). A dedicated scan of the $N\bar{N}$-threshold region by CMD-3 confirms this effect in the $e^+e^- \to 3\pi^+3\pi^-$ and $e^+e^- \to K^+K^-\pi^+\pi^-$ final states, but does not see it in the cross section of $e^+e^- \to 2\pi^+2\pi^-$ [248]. Most probably, these structures emerge as a threshold effect due to the opening of the $N\bar{N}$ channel [249–251]. A similar enhancement is observed by BESIII in $e^+e^- \to \Lambda\bar{\Lambda}$ near the $\Lambda\bar{\Lambda}$ threshold [252].

63.6 Axial-vector mesons

The $J^{PC} = 1^{++}$ nonet consists of the isovector $a_1(1260)$, the isoscalars $f_1(1285)$ and $f_1(1420)$, and the K_{1A}, which is a superposition of the physical states $K_1(1270)$ and $K_1(1400)$ with a mixing angle of about 35° [253]. The nonet mixing angle $\theta_{1^{++}}$ is around 23°. The orthogonal combination – the K_{1B} – belongs to the 1^{+-} nonet with a mixing angle $\theta_{1^{+-}}$ of about 28° [253].

The mass region above 1400 MeV is rather complex [254–256]. The $f_1(1420)$ was first reported in $\pi^- p$ reactions at 4 GeV/c, decaying into $K^*\overline{K}$ [257]. The $f_1(1420) \to K\overline{K}\pi$ was also observed in a reanalysis of the MARK III data [124], and a C=+1 state seen in tagged $\gamma\gamma$ collisions [258]. Axial-vector mesons are not observed in $\overline{p}p$ annihilation at rest in liquid hydrogen, which proceeds dominantly through S-wave annihilation. However, in gaseous hydrogen, P-wave annihilation is enhanced and the $f_1(1420)$ is indeed observed, decaying into $K^*\overline{K}$ [126]. The $f_1(1420)$, decaying into $K\overline{K}\pi$, is also seen in pp central production, together with the $f_1(1285)$. The latter decays via $a_0(980)\pi$, and the former only via $K^*\overline{K}$. The $K^0_S K^0_S \pi^0$ decay mode of the $f_1(1420)$ establishes unambiguously C=+1. Neither central production [259] nor $\pi^- p$ interactions at 100 GeV [117] find any evidence for a $\eta\pi\pi$ decay mode of the $f_1(1420)$.

The $f_1(1285)$ has been suggested to be a $K^*\overline{K}$ molecule [260]. However, LHCb has determined the 1^{++} nonet mixing angle to be consistent with a mostly $n\bar{n}$ structure for the $f_1(1285)$ from $\overline{B}^0/\overline{B}^0 \to J/\psi(1S)f_1(1285)$, independent of the identity of its isoscalar partner [261]. The mixing angle $\theta_{1^{++}} = 24°$ agrees with that of Ref. [253] quoted above. The ratio of $\overline{B}^0/\overline{B}^0_s$ decay rates also excludes the tetraquark interpretation of the $f_1(1285)$ [261]. This is consistent with earlier determinations assuming that the $f_1(1420)$ is the other isoscalar in the nonet [262].

A resonance candidate decaying into 3π had been reported earlier by COMPASS at 1420 MeV in $\pi^- p \to \pi^-\pi^-\pi^+ p$ [263, 264].

The signal appeared as a clear peak in the 1^{++} $f_0(980)\pi$ P-wave and had the expected phase motion of a new resonance, called the $a_1(1420)$. However, the signal appears to originate from a triangle singularity: the decay of the $a_1(1260)$ into $K^*(\to K\pi)\bar{K}$ is followed by rescattering into the $f_0(980)\pi$ channel, $f_0(980) \to \pi\pi$ (see the caption of fig. 63.3) [265]. Accordingly, this entry has been removed from the *Listings* in the *Review*.

A similar triangle singularity is proposed for the $f_1(1420)$, resulting from the $K^*\overline{K}$ and $a_0(980)\pi$ decay modes of the $f_1(1285)$ [266]. The $f_1(1420)$ was also suggested to be a hybrid $q\bar{q}g$ meson [267] or a $K^*\overline{K}$ molecule, due to the proximity of the $K^*\overline{K}$ threshold [268]. Indeed, the $f_1(1420)$ is not seen in K^-p [269], which argues against the $f_1(1420)$ being the $s\bar{s}$ member of the 1^{++} nonet. In this case the $s\bar{s}$ partner of the $f_1(1285)$ could be the $f_1(1510)$ which is, however, not well established [270].

The $f_1(1510)$ was seen to decay into $K\bar{K}\pi$ in K^-p interactions at 4 and 11 GeV/c, recoiling against a Λ [269,271], which points to an $s\bar{s}$ state. Evidence was also reported in π^-p interactions, based on the phase motion of the 1^{++} $K^*\overline{K}$ wave [256]. A somewhat broader 1^{++} signal is observed in $J/\psi(1S) \to \gamma\eta\pi^+\pi^-$ [272] and a small signal in $J/\psi(1S) \to \gamma\eta'\pi^+\pi^-$ [273]. However, there is no evidence for the $f_1(1510)$ in other K^-p experiments [274,275], while the $f_1(1420)$ is observed in K^-p but not in π^-p [274]. The $f_1(1510)$ is not seen in central collisions [276], nor in $\gamma\gamma$ collisions [277], although surprisingly for an assumed $s\bar{s}$ meson, a signal is reported in 4π decays [278]. Given this confusing experimental situation, the meson classification in the 1^{++} nonet is not entirely settled.

63.7 Hybrid mesons

Hybrids may be viewed as $q\bar{q}$ mesons with a vibrating gluon flux tube. In contrast to glueballs, they can have isospin 0 or 1 and be electrically charged. The mass spectrum of hybrids with exotic (non-$q\bar{q}$) quantum numbers was predicted in Ref. [279], while Ref. [280] also deals with non-exotic quantum numbers. The ground-state hybrids with quantum numbers (0^{-+}, 1^{-+}, 1^{--}, and 2^{-+}) are expected around 1.7 to 1.9 GeV. Lattice calculations predict that the hybrid with exotic quantum numbers 1^{-+} lies at a mass of 1.9 ± 0.2 GeV [281,282]. Most hybrids are expected to be rather broad, but some can be as narrow as 100 MeV [283]. They prefer to decay into a pair of S- and P-wave mesons. The lattice study in [284, 285], based on full QCD with pion masses around 400 MeV, finds that several of the high-lying states observed in their spectrum show significant overlap with gluon rich source terms interpreted as hybrid states. A very broad 1^{-+} structure is predicted by a recent lattice calculation [286]. The main decay mode is $b_1(1235)\pi$ (a pair of S- and P-wave mesons), while other modes, such as $\rho\pi$, $\eta\pi$ and $\eta'\pi$, are suppressed by at least an order of magnitude. For an experimental and theoretical review on hybrid mesons see [4, 287].

There are currently two 1^{-+} candidates, the $\pi_1(1400)$ and $\pi_1(1600)$. The ∼350–400 MeV broad $\pi_1(1400)$, was reported in $\pi^-p \to \eta\pi^-p$ [288,289] and in $\pi^-p \to \eta\pi^0n$ [290]. It was observed as an interference between the angular momentum $L = 1$ and $L = 2$ $\eta\pi$ amplitudes, leading to a forward/backward asymmetry in the $\eta\pi$ angular distribution. This state had been reported earlier in π^-p reactions [291], but ambiguous solutions in the partial wave analysis were pointed out [292, 293]. A resonating 1^{-+} contribution to the $\eta\pi$ P-wave is also required in the Dalitz plot analysis of $\bar{p}n$ annihilation into $\pi^-\pi^0\eta$ [294], and in $\bar{p}p$ annihilation into $\pi^0\pi^0\eta$ [295]. Mass and width are consistent with the results of Ref. [288]. A coupled channel re-analysis of the $\pi^0\pi^0\eta$, $\pi^0\eta\eta$ and $K^+K^-\pi^0$ Crystal Barrel data at 900 MeV/c, supplemented with data from other collaboration in $\pi\pi \to \pi\pi, K\bar{K}, \eta\eta$ and $\eta\eta'$, leads to a single 1^{-+} ∼600 MeV broad state with a pole around 1400 MeV, decaying into $\eta\pi^0$ [296]. Ref. [297] suggested for the production in π^-p that a Deck-generated $\eta\pi$ background from final state rescattering in $\pi_1(1600)$ decay could mimic $\pi_1(1400)$, a mechanism that is, however, absent in $\bar{p}p$ annihilation.

The $\pi_1(1600)$, decaying into $\rho\pi$, was reported by COMPASS with 190 GeV pions hitting a lead target [298,299]. It had already been observed in π^-p interactions in the decay modes $\eta'\pi$ [300], $f_1(1285)\pi$ [301], and $\omega\pi\pi$ [302], $b_1(1235)\pi$, but not $\eta\pi$ [303]. A strong enhancement in the 1^{-+} $\eta'\pi$ wave, compared to $\eta\pi$, was reported at this mass in [304]. The enhancement is also observed by COMPASS in $\pi^-p \to \eta'\pi$ but in $\eta\pi$ a peak appears at 1400 MeV and in $\eta'\pi$ at 1600 MeV [305]. A coupled channel analysis of the $\eta\pi$ and $\eta'\pi$ COMPASS data leads to a single pole at 1564 ± 89 MeV, with a width of 492 ± 115 MeV [306]. Furthermore, a combined analysis of the COMPASS and Crystal Barrel data at 900 MeV/c leads to compatible results, a single pole around 1623 MeV, with a width of about 455 MeV, although a two-pole scenario cannot be completely excluded [307]. The predicted width from the lattice calculation [286] is compatible with the COMPASS result.

Hybrid candidates with the non-exotic quantum numbers 0^{-+}, 1^{--}, and 2^{-+} have also been reported: the $\pi(1800)$ is somewhat narrow if interpreted as the second radial excitation of the pion. It decays mostly into a pair of S- and P-wave mesons [308,309], in line with expectations for 0^{-+} hybrid mesons. The evidence for 1^{--} hybrids in e^+e^- annihilation and in τ decays has been discussed in [200]. The near degeneracy of the $\eta_2(1645)$ and $\pi_2(1670)$ suggests ideal mixing in the 2^{-+} $q\bar{q}$ nonet, and hence, the second isoscalar, presumably the $\eta_2(1870)$, should be mainly $s\bar{s}$. However, the $\eta_2(1870)$ is also observed in $\bar{p}p$ annihilation and decays mainly into $a_2(1320)\pi$ and $f_2(1270)\pi$ [310], with a relative rate compatible with a hybrid state [280]. Evidence for another exotic $\pi_1(2015)$ has been claimed in π^-p interactions [301, 302].

Summarizing, there is evidence for a very broad 1^{-+} enhancement in the 1400–1600 MeV region which consists in one or perhaps two exotic states, the lowest one seemingly favored by $\bar{p}p$ annihilation data, the highest one by high energy π^-p data. As isovectors, $\pi_1(1400)$ and $\pi_1(1600)$ cannot be glueballs. The coupling to $\eta\pi$ of the former points to a four-quark state [311], while the $\eta'\pi$ coupling of the latter is favored for hybrid states [312,313]. The mass of $\pi_1(1600)$ is not far below the lattice and flux tube model predictions.

63.8 Tetraquark states

The existence of multiquark states was suggested a long time ago, based on duality arguments [314, 315]. The most prominent tetraquark candidates are the $a_0(980)$ and $f_0(980)$ [316–318]. A remarkable prediction for the existence of low-lying four quarks states is based on color hyperfine splitting. The lowest ground state ($L = 0$) tetraquark multiplet is predicted to be a scalar nonet. The scalar nonet lies just below 1 GeV when one assumes as mass scale the hyperfine color splitting between the ρ and the π (for a simple derivation see [8]). Assuming the classification in Table 63.1 one then gets the nonet structures

$$
\begin{aligned}
|a_0(980)\rangle &= |us\bar{d}\bar{s}\rangle, \frac{1}{\sqrt{2}}|(u\bar{u} - d\bar{d})s\bar{s}\rangle, |\bar{u}\bar{s}ds\rangle,\\
|f_0(980)\rangle &= \frac{1}{\sqrt{2}}|(u\bar{u} + d\bar{d})s\bar{s}\rangle,\\
|f_0(500)\rangle &= |\bar{u}\bar{d}ud\rangle,\\
|K_0^*(700)\rangle &= |\bar{s}\bar{d}ud\rangle, |\bar{s}\bar{u}ud\rangle \quad \text{and} \quad |\bar{u}\bar{d}us\rangle, |\bar{u}\bar{d}ds\rangle.
\end{aligned}
$$

The two isoscalars are expected to mix with the angle φ:

$$
\begin{aligned}
|f_0(980)\rangle &= \cos\varphi|s\bar{s}\rangle + \sin\varphi|n\bar{n}\rangle,\\
|f_0(500)\rangle &= -\sin\varphi|s\bar{s}\rangle + \cos\varphi|n\bar{n}\rangle.
\end{aligned} \tag{63.1}
$$

Whether these mesons are really tetraquark states or $q\bar{q}$ mesons, is still an open issue. The $f_0(980)$ is strongly produced in D_s^+ decay [320], which suggests a large $s\bar{s}$ component, due to the Cabibbo-favored $c \to s$ coupling. However, the mainly $n\bar{n}$ $f_0(1370)$ is also strongly produced in D_s^+ decay, hence additional graphs must contribute [321].

The relative branching ratios for $\bar{B}^0$ and $\bar{B}_s^0 \to J/\psi(1S)f_0(500)$ and $J/\psi(1S)f_0(980)$ can be used to probe the $q\bar{q}$ or tetraquark natures of the $f_0(500)$ and $f_0(980)$, as proposed in Refs. [319,322]. LHCb observes the $f_0(980)$ in $\bar{B}_s^0$ decays, but not the $f_0(500)$ [26], as would be expected for tetraquarks (see Table 63.2). In contrast, LHCb also observes the $f_0(500)$ in $\bar{B}^0$ decays, but not the $f_0(980)$ with an upper limit eight standard deviations below the predicted value for a tetraquark state [27]. However, these contradicting findings have been challenged by a dispersive analysis [323], using

Table 63.2: Coupling amplitudes for $\bar{B}^0$ and $\bar{B}^0_s$ decays into $J/\psi(1S)f_0(500)/f_0(980)$, depending on the $q\bar{q}$ or tetraquark structures of the $f_0(500)$ and $f_0(980)$ (from [319] where illustrative decay diagrams can be found). The angle φ is defined in Eq. 63.1.

	$\bar{B}^0$		$\bar{B}^0_s$	
	$f_0(980)$	$f_0(500)$	$f_0(980)$	$f_0(500)$
$q\bar{q}$	$\sin\varphi/\sqrt{2}$	$\cos\varphi/\sqrt{2}$	$\cos\varphi$	$\sin\varphi$
$qq\bar{q}\bar{q}$	$1/\sqrt{2}$	1	$\sqrt{2}$	0

a model independent inclusion of hadronic final state interactions, in which a substantial $f_0(980)$ contribution is nevertheless found in $\bar{B}^0$-decays, thus still leaving the tetraquark structure as an open possibility.

The $f_0(980)$ and $a_0(980)$ could also be $K\overline{K}$ molecular states [324–326], being close to the $K\overline{K}$ threshold and decaying strongly into $K\overline{K}$. For $q\bar{q}$ states, the expected $\gamma\gamma$ widths [327, 328] are not significantly larger than for molecular states [327, 329] and both predictions are consistent with data. Radiative decay of the $\phi(1020)$ into $a_0(980)$ and $f_0(980)$ were proposed to disentangle compact (tetraquark) structures from hadronic molecules. Following Refs. [330, 331] the data from KLOE [332, 333], CMD-2 [334] and SND [335] seem to favor these mesons to be tetraquark states. This is also supported by a BESIII analysis of $J/\psi(1S) \to \gamma\pi^0\pi^0$ data [336] and by a measurement of $a_0(980) - f_0(980)$ mixing at BESIII [337]. In Ref. [38] these states are made of four-quark cores and virtual $K\bar{K}$ clouds at the periphery, a view that is challenged in Ref. [338] showing that radiative ϕ decay data are consistent with molecular structures of light scalars.

As mentioned already, the $f_0(1500)$ [40] and the $f_1(1285)$ [319] have been proposed as tetraquarks, the latter also as $K^*\overline{K}$ molecule [260], together with the $f_1(1420)$ [268].

Another potential candidate for a tetraquark is the $\phi(2170)$. As an excited $q\bar{q}$ state of the $\phi(1020)$, this meson should decay strongly into K^+K^- and $K^0_SK^0_L$, and also $K^*\bar{K}^*$. However, these decays are not observed. Hence, based on its observed decay into $f_0(980)\phi(1020)$ this meson could be $ss\bar{s}\bar{s}$, see Ref. [339] where relative decay rates into various channels are predicted for both $q\bar{q}$ and tetraquark structures of the $f_0(980)$. However Refs. [340,341] claim that the $\phi(2170)$ may not be a good candidate for the $ss\bar{s}\bar{s}$ state, but could qualify as an $su\bar{s}\bar{u}$ tetraquark [341].

More information on the $a_0(980)$, $f_0(980)$, $f_0(500)$ and $K^*_0(700)$ is provided by 'Scalar Mesons below 1 GeV' in the *Review*.

63.9 Baryonia

Nucleon-antinucleon ($N\bar{N}$) bound states and resonances (baryonium) were predicted a long time ago [342, 343], based on the strongly attractive $N\bar{N}$ meson exchange potential, which is obtained from the NN one by multiplying with the G-parity of the exchanged meson. Several candidates had been reported in the seventies by experiments at CERN, BNL and KEK, some of them being indisputably statistically significant (for details on the model and on experiments, see [344, 345] and references therein). Most potential models predict a sequence of deeply bound isoscalar baryonia with quantum numbers $J^{PC} = 2^{++}$, 1^{--} and 0^{++}, the latter being the mostly bound [346, 347]. The $f_2(1565)$ which is observed in $\bar{p}p$ annihilation only [348, 349], is a good candidate for the 2^{++} $\bar{p}p$ bound state.

Enhancements close to the $\bar{p}p$ threshold have also been reported in B decays [350–352]. The strong signal in $J/\psi(1S) \to \gamma\bar{p}p$ [353–355] could be due to a 0^{-+} baryonium [356], but could also be generated by the $N\bar{N}$ final state interaction [357–360]. The strong energy dependence of the cross section in $e^+e^- \to \bar{p}p$ [361, 362] and $\bar{p}p \to e^+e^-$ [363] is attributed to the $N\bar{N}$ final state interaction [364] (see also our comments on the $\rho(1900)$ at the end of section 63.5.2). Alternative explanations to baryonia have been proposed for the signals in $B \to \bar{p}pK$, such as the dynamics of the fragmentation mechanism [351].

63.10 Conclusions

The ground states nonets 1^1S_0, 1^3S_1, 1^1P_1, 1^3P_2, 1^1D_2 and 1^3D_3 (see fig. 63.1) are complete and established (although more data are desirable for the $h_1(1415)$ in the 1^1P_1 nonet). There are uncertainties and ambiguities in all other nonets . In the pseudoscalar sector the mere existence of the $\eta(1295)$ (possibly the radial excitation of the η) has been questioned. The $\eta(1440)$ consists of two states, one at 1405 MeV, the other at 1475 MeV, which could also be the manifestation of a single state decaying into two different final states. In this case the 1475 one could be the radial excitation of the η' and the 1405 state the pseudoscalar ground state glueball predicted a long time ago by the bag model, although the lattice puts it above 2 GeV. In the 1^{++} nonet two isoscalars – the $f_1(1420)$ and $f_1(1510)$ – compete for the $s\bar{s}$ slot, the former perhaps being exotic, and the latter not being very well established. The first radial excitation 2^3S_1 is complete, but questions have been raised as to the nature of the $\rho(1450)$ and its relation to the $\rho(1700)$. The classification of scalar mesons is not settled with the ones below 1 GeV being tetraquark states or part of the ground state nonet. The nature of the scalars in the 1.5 – 1.8 GeV region is unclear, obscured by the interference with the ground state scalar glueball predicted in this mass region by most theoretical models. For example, the $f_0(1500)$ and the $f_0(1710)$ could be $q\bar{q}$ states ($n\bar{n}$ and $s\bar{s}$, respectively) or made of gluons mixed with $q\bar{q}$. The $f_0(1500)$ or alternatively the $f_0(1710)$ have been proposed as mostly gluonic. Scalar mesons above the $f_0(1710)$ need experimental confirmation. The 1.4 - 1.6 GeV mass region is populated by one or two broad isovector states with exotic (1^{-+}) quantum numbers, the $\pi_1(1400)$ and $\pi_1(1600)$. The mass of latter is not far below theoretical predictions. Above 1.8 GeV mesons are broad and overlap, which complicates the data analyses. This makes the classification difficult, in particular the identification of the 2^{++} glueball.

Acknowledgements

We thank Paolo Gauzzi, Bertram Kopf, Mikhail Mikhasenko and Anton Rebhan for carefully reading the manuscript, and for their detailed and constructive suggestions. We have also benefitted from several reviews published earlier in the *Review of Particle Physics*, jointly with Thomas Gutsche, Christoph Hanhart and Stefan Spanier, which have been merged into the current article.

64. Scalar Mesons below 1 GeV

Revised August 2021 by S. Eidelman (Budker Inst., Novosibirsk; Novosibirsk U.), T. Gutsche (Tübingen U.), C. Hanhart (Jülich), R.E. Mitchell (Indiana U.) and S. Spanier (Tennessee U.).

64.1 Introduction

In contrast to the vector and tensor mesons, the identification of the scalar mesons is a long-standing puzzle. Scalar resonances are difficult to resolve because some of them have large decay widths, which cause a strong overlap between resonances and background. In addition, in some cases, several decay channels open up within a short mass interval (*e.g.* at the $K\bar{K}$ and $\eta\eta$ thresholds), producing cusps in the line shapes of the nearby resonances. Furthermore, one expects non-$q\bar{q}$ scalar objects, such as hadronic molecules and multiquark states, in the mass range of interest (for reviews see, *e.g.*, Refs. [1–5]).

Light scalars are produced, for example, in πN scattering on polarized/unpolarized targets, $p\bar{p}$ annihilation, central hadronic production, $J/\psi(1S)$, B-, D- and K-meson decays, $\gamma\gamma$ formation, and ϕ radiative decays. Especially for the lightest scalar mesons simple parameterizations like Breit-Wigner functions and variants thereof fail — this is demonstrated explicitly on the example of the $f_0(500)$ or σ, e.g., in Ref. [6]. Accordingly, more advanced theory tools are necessary to extract the resonance parameters from data. In the analyses available in the literature, fundamental properties of the amplitudes such as unitarity, analyticity, Lorentz invariance, and chiral and flavor symmetry are implemented at different levels of rigor. Especially, chiral symmetry implies the appearance of zeros, the so-called Adler zeros, close to the threshold in elastic S-wave scattering amplitudes involving soft (pseudo) Goldstone bosons [7,8], which may be shifted or removed in associated production processes [9]. Moreover, especially for the lightest non-strange and strange scalar resonance precision extractions of pole parameters get complicated by the presence of both left-hand cuts as well as circular cuts [5]. The methods employed are the K-matrix formalism, the N/D-method, the Dalitz-Tuan ansatz, unitarized quark models with coupled channels, effective chiral field theories and the linear sigma model, *etc.* Dynamics near the lowest two-body thresholds in some analyses are described by crossed channel (t, u) meson exchange or with an effective range parameterization instead of, or in addition to, resonant features in the s-channel. Dispersion theoretical approaches are applied to pin down the location of resonance poles for the low mass states [10–15].

The mass and width of a resonance are found from the position of the nearest pole in the process amplitude (T-matrix or S-matrix) at an unphysical sheet of the complex energy plane, traditionally labeled as

$$\sqrt{s_{\rm Pole}} = M - i\,\Gamma/2\ . \qquad (64.1)$$

It is important to note that in general the pole of a Breit-Wigner parameterization does not agree with the S- or T-matrix pole. For a detailed discussion of this issue we refer to the review on *Resonances* in this Review of Particle Physics (RPP).

In this review we present proposed values for the mass parameters of the scalar resonances below 1 GeV. Note that those are labeled as 'our estimate' — it is not an average over the quoted analyses, but is chosen to include the bulk of the analyses. An averaging procedure is not justified, since the analyses use overlapping or sometimes even identical data sets so that they are not statistically independent.

On this note, we discuss the light scalars below 1 GeV organized in the *Listings* under the entries $K_0^*(700)$ (or κ) with isospin $I = 1/2$, $a_0(980)$ with $I = 1$, as well as $f_0(500)$ (or σ) and $f_0(980)$ both with $I = 0$. The $I = 2$ $\pi\pi$ and $I = 3/2$ $K\pi$ partial waves do not have any resonances.

64.2 The $K_0^*(700)$, also known as κ ($I = 1/2$)

The $K_0^*(700)$ shows up as a pole in the low energy πK scattering, although its presence and properties are difficult to establish, since it appears to have a very large width ($\Gamma \approx 500$ MeV) and resides close to the $K\pi$ threshold. Hadronic D- and B-meson decays provide additional data points in the vicinity of the $K\pi$ threshold and are discussed in detail in the *Review on Multibody Charm Analyses* in this RPP. With a few exceptions discussed there, the three- or more-hadron final states are usually treated as non-interacting two-body systems. Precision information from semileptonic D decays, where the strongly interacting two-particle final states could be treated without approximation, is not available. BES II [16] (re-analyzed in [17]) finds a $K_0^*(700)$-like structure in $J/\psi(1S)$ decays to $\bar{K}^{*0}(892)K^+\pi^-$ where $K_0^*(700)$ recoils against the $K^*(892)$. The decay $\tau^- \to K_S^0\pi^-\nu_\tau$ can be considered clean with respect to final-state interactions and is studied by Belle [18], with $K_0^*(700)$ parameters fixed to those of Ref. [16].

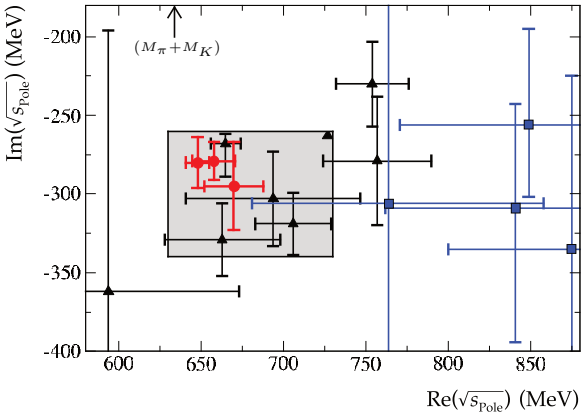

Figure 64.1: Location of the $K_0^*(700)$ (or κ) poles in the complex energy plane. Red circles denote the results of the most sophisticated analyses based on dispersion relations (see text for details), poles extracted from Breit-Wigner fits are shown as blue squares, while all other analyses quoted in the *Listings* are denoted by black triangles. The corresponding references are given in the listing. The arrow shows the location of the πK thresholds. The grey box indicates the ranges extracted as 'our estimate' of the pole locations.

Some authors find a $K_0^*(700)$ pole in their phenomenological analysis (see, *e.g.*, [19–28]), while others do not need to include it in their fits (see, *e.g.*, [29–33]). All works including constraints from chiral symmetry at low energies naturally find a light $K_0^*(700)$ below 800 MeV, see, *e.g.*, [34–39]. The analysis of Ref. [14,40] is based on the Roy-Steiner equations, which include analyticity and crossing symmetry constraints. Ref. [15] uses the Padé method to extract pole parameters after refitting scattering data constrained to satisfy forward dispersion relations. All three arrive at compatible pole positions for the $K_0^*(700)$ that are consistent with the pole parameters deduced from other theoretical methods. Due to their large uncertainties, the pole locations deduced from the Breit-Wigner fits appear to be just about consistent with the other determinations, but the real parts of all those analyses lie systematically too high. Moreover, phase shifts extracted from the Breit-Wigner functions for the $K_0^*(700)$ are very different from the known scalar πK phase shifts. The various poles are shown in in Fig. 64.1. The compilation in this figure justifies the pole parameters of the $K_0^*(700)$, which we quote as 'our estimate', namely,

$$\sqrt{s^{\kappa}_{\rm Pole}} = (630 - 730) - i(260 - 340)\ \text{MeV}\ . \qquad (64.2)$$

For an extensive discussion about the πK system in general and the κ meson in particular, see Ref. [41].

64.3 The $a_0(980)$ ($I = 1$)

The $a_0(980)$ couples strongly to the channels $\pi\eta$ and $K\bar{K}$. Independent of any model, the $K\bar{K}$ component must be large in the $a_0(980)$ wave function, since the mass of the $a_0(980)$ lies very close to the opening of the $K\bar{K}$ channel, to which it strongly couples [42,43]. This generates a pronounced cusp-like behavior in the resonant amplitude and to reveal its true coupling constants the presence of the $K\bar{K}$ channel cannot be ignored. All listed $a_0(980)$

measurements agree on a mass position value near 980 MeV, but the width deduced from the imaginary part of the pole location has values between 50 and 100 MeV, mostly due to the different models. For example, the analysis of the $p\bar{p}$ annihilation data [42] using a unitary K-matrix description finds a width determined from the T-matrix pole of 92 ± 8 MeV. Note that the width of the $a_0(980)$ line shape is typically smaller than what could be expected from the pole location.

The relative coupling $K\bar{K}/\pi\eta$ is determined indirectly from $f_1(1285)$ [44–46] or $\eta(1410)$ decays [47–49], from the line shape observed in the $\pi\eta$ decay mode [50–53], or from the coupled-channel analysis of the $\pi\pi\eta$ and $K\bar{K}\pi$ final states of $p\bar{p}$ annihilation at rest [42].

There are different recent extractions of the $a_0(980)$ pole location. Refs. [36, 37, 39, 54] use unitarized chiral perturbation theory. Ref. [55] used a similar formalism to extract the pole of the $a_0(980)$, employing the amplitude fixed in Ref. [56]. A dispersion theoretical approach to the isovector scalar $\pi\eta - K\bar{K}$ system is presented in Ref. [57] that may be refined further from studies of heavy meson decays [58]. Those efforts lead to a rather precise determination of the $a_0(980)$ pole location [59]. A value consistent for the mass parameter, but with a larger width, is found in a recent analysis of 1996 LEAR data for $\bar{p}p$ annihilation in flight employing a K-matrix [60]. The poles extracted in Refs. [39, 42, 53, 55, 59, 60] are shown in Fig. 64.2 together with the range of acceptable pole parameters extracted from this compilation, namely,

$$\sqrt{s_{\rm Pole}^{a_0(980)}} = (960 - 1030) - i(20 - 70)\ \text{MeV} \qquad (64.3)$$

indicated by the box.

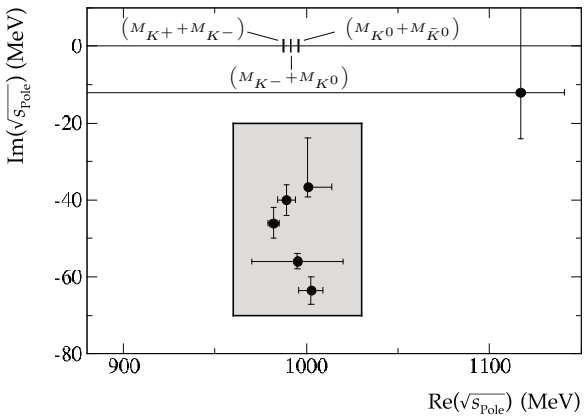

Figure 64.2: Location of the $a_0(980)$ poles from different extractions in the complex energy plane. The corresponding references are given in the *Listings*. Also shown are the thresholds for the K^+K^- and $K^0\bar{K}^0$ channels, relevant for $a_0(980)^0$, and for the K^-K^0 channel, relevant for the $a_0(980)^-$. The grey box indicates the ranges extracted as 'our estimate' of the pole locations.

64.4 The $f_0(500)$, also known as σ-meson ($I = 0$)

For discussions of the $\pi\pi$ S wave below the $K\bar{K}$ threshold and on the long history of the $f_0(500)$, which was suggested in linear sigma models more than 50 years ago, see the review [5]. Information on the $\pi\pi$ S-wave phase shift $\delta_J^I = \delta_0^0$ was already extracted many years ago from πN scattering [61–63], and near the $\pi\pi$ threshold from K_{e4} decays [64]. The kaon decays were later revisited leading to consistent data with very much improved statistics [65, 66]. The reported $\pi\pi \to K\bar{K}$ cross sections [67–70] have large uncertainties. The πN data have been analyzed in combination with high-statistics data (see entries labeled as RVUE for reanalyses of the data). The $2\pi^0$ invariant mass spectra, extracted from $p\bar{p}$ annihilation at rest into $3\pi^0$ [71, 72] and into $5\pi^0$ [73] and from central pp collision [74] do not show a distinct resonance structure below 900 MeV, but these data are consistently described with the standard solution for the $\pi\pi$ scalar isoscalar S-wave extracted from high energy $\pi N \to \pi\pi N$ data [62, 75], which allows for the existence of the broad $f_0(500)$. An enhancement is observed in the $\pi^+\pi^-$ invariant mass near threshold in the decays $D^+ \to \pi^+\pi^-\pi^+$ [76–78] and $J/\psi(1S) \to \omega\pi^+\pi^-$ [79, 80], and in $\psi(2S) \to J/\psi(1S)\pi^+\pi^-$ with very limited phase space [81, 82].

The precise $f_0(500)$ (or σ) pole is difficult to establish because of its large width. The $\pi\pi$ scattering amplitude shows an unusual energy dependence due to the presence of the Adler zero in the unphysical regime close to the threshold [7, 8], required by chiral symmetry. However, most of the analyses listed under $f_0(500)$ agree on a pole position near $(500 - i\,250)$ MeV). In particular, analyses of $\pi\pi$ data that include unitarity, are consistent with the near threshold $\pi\pi$ data from K_{e4} decays, and the chiral symmetry constraints from Adler zeroes and/or scattering lengths find a light $f_0(500)$, see, *e.g.*, [83, 84].

Precise pole positions with an uncertainty of less than 20 MeV (see our table for the T-matrix pole in the *Listings*) were extracted using the Roy equations, which are twice subtracted dispersion relations derived from crossing symmetry and analyticity. In Ref. [11] the subtraction constants were fixed to the S-wave scattering lengths a_0^0 and a_0^2 derived from matching the Roy equations and two-loop chiral perturbation theory [10]. The only additional relevant input to fix the $f_0(500)$ pole turned out to be the $\pi\pi$-wave phase shifts at some higher energy point, chosen as 800 MeV. The analysis was improved further in Ref. [13]. Alternatively, in Ref. [12] Roy equations were used as constraints for a fit to the data. In that reference also once-subtracted Roy–like equations, called GKPY equations, were used, since the extrapolation into the complex plane based on the twice-subtracted equations leads to larger uncertainties, mainly due to the limited experimental information on the isospin 2 $\pi\pi$ scattering length. Ref. [85] uses Padé approximants for the analytic continuation. All these extractions find consistent results. Using analyticity and unitarity only to describe data from $K_{2\pi}$ and K_{e4} decays, Ref. [86] finds consistent values for the pole position and the scattering length a_0^0. The importance of the $\pi\pi$ scattering data for fixing the $f_0(500)$ pole is nicely illustrated by comparing analyses of $\bar{p}p \to 3\pi^0$ omitting [71, 87] or including [72, 88] information on $\pi\pi$ scattering: while the former analyses find an extremely broad structure above 1 GeV, the latter find $f_0(500)$ masses of the order of 400 MeV.

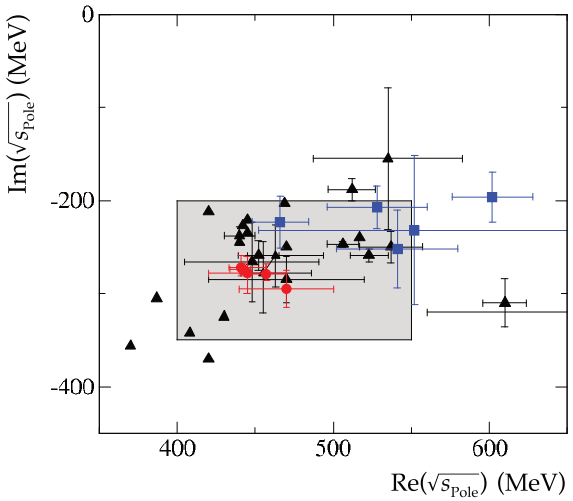

Figure 64.3: Location of the $f_0(500)$ (or σ) poles in the complex energy plane. Circles denote the recent analyses based on Roy(-like) dispersion relations, poles extracted from Breit-Wigner fits are shown as blue squares, while all other analyses are denoted by triangles. The corresponding references are given in the *Listings*. The grey box indicates the ranges extracted as 'our estimate' of the pole locations.

From Fig. 64.3 we read the range of pole positions for the $f_0(500)$, namely,

$$\sqrt{s^{\sigma}_{\rm Pole}} = (400-550) - i(200-350)\ \text{MeV}\ . \qquad (64.4)$$

The plot contains the poles from Refs. [24, 35, 37, 39, 52, 54, 61, 72, 78, 81–84, 86, 88–107] as well as the advanced dispersion analyses [10–13, 85]. The extracted $f_0(500)$ pole position is very sensitive to the high accuracy low energy $\pi\pi$ scattering data [65, 66]. In fact, all analyses consistent with those data find poles within the accepted range indicated in the figure. As in case of the $K_0^*(700)$, poles extracted from Breit-Wigner analyses are shown as blue squares. Again we see that those poles have the tendency to appear at higher masses, although here the effect is not as pronounced as in case of the $K_0^*(700)$. One should not take this as an indication that using Breit-Wigners is justified in case of the $f_0(500)$, since $\pi\pi$ phase shifts extracted from Breit-Wigners are in strong discrepancy with the scattering phase shifts.

If one uses just the most advanced dispersive analyses of Refs. [10–13], shown as solid dots in Fig. 64.3 to determine the pole location of the $f_0(500)$, the range narrows down to [5]

$$\sqrt{s^{\sigma}_{\rm Pole}} = (449^{+22}_{-16}) - i(275\pm 12)\ \text{MeV}\ , \qquad (64.5)$$

which is labeled as 'conservative dispersive estimate' in this reference.

Besides $\pi\pi$, the only other decay channel of the $f_0(500)$ is two photons. Due to the large full width of the $f_0(500)$ an extraction of its two-photon width directly from data is not possible. Thus, the values for $\Gamma(\gamma\gamma)$ quoted in the literature as well as the in *Listings* are based on the expression in the narrow width approximation [108] $\Gamma(\gamma\gamma) \simeq \alpha^2|g_\gamma|^2/(4\text{Re}(\sqrt{s^{\sigma}_{\rm Pole}}))$, where g_γ is derived from the residue at the $f_0(500)$ pole to two photons and α denotes the electromagnetic fine-structure constant (see also the review on *Resonances* in this issue of the RPP). The explicit form of the expression may vary between different authors due to different definitions of the coupling constant, however, the expression given for $\Gamma(\gamma\gamma)$ is free of ambiguities. According to Refs. [109–112], the data for $f_0(500) \to \gamma\gamma$ are consistent with what is expected for a two step process of $\gamma\gamma \to \pi^+\pi^-$ via pion exchange in the t- and u-channel, followed by a final state interaction $\pi^+\pi^- \to \pi^0\pi^0$. The same conclusion is drawn in Ref. [113], where the bulk part of the $f_0(500) \to \gamma\gamma$ decay width is dominated by re-scattering. Therefore, it might be difficult to learn anything new about the nature of the $f_0(500)$ from its $\gamma\gamma$ coupling. For the most recent work on $\gamma\gamma \to \pi\pi$, see Refs. [54,86–88,95–108,111–116]. There are strong indications (*e.g.*, [117–147]) that the $f_0(500)$ pole cannot be classified as a $q\bar{q}$ state.

64.5 The $f_0(980)$ $(I = 0)$

The $f_0(980)$ couples predominantly to the $\pi\pi$ and $K\bar{K}$ channels and its signal overlaps strongly with the background represented mainly by the $f_0(500)$ and the $f_0(1370)$. This can lead to a dip in the $\pi\pi$ spectrum at the $K\bar{K}$ threshold. It changes from a dip into a peak structure in the $\pi^0\pi^0$ invariant mass spectrum of the reaction $\pi^- p \to \pi^0\pi^0 n$ [121], with increasing four momentum transfer to the $\pi^0\pi^0$ system, which means increasing the $a_1(1260)$ exchange contribution in the amplitude, while the π exchange decreases. Also when a $(u\bar{u} + d\bar{d})$ source is switched to a $s\bar{s}$ source, as it appears when moving from $B_d \to J/\psi(1S)\pi\pi$ to $B_s \to J/\psi(1S)\pi\pi$, the f_0 signal switches from a dip to a peak [135]. The $f_0(500)$ and the $f_0(980)$ are also observed in the data for radiative ϕ decays $(\phi \to f_0\gamma)$ from SND [122,123], CMD2 [124], and KLOE [125,126].

Unitarized chiral perturbation theory was employed to extract the pole of the $f_0(980)$ in Refs. [36, 37, 39, 54, 55]. Two different dispersive analyses were used in Ref. [12] to simultaneously pin down the pole parameters of both the $f_0(500)$ and the $f_0(980)$. The poles extracted in Refs. [12, 13, 39, 55, 60, 91, 148] are shown in Fig. 64.4, together with the range of acceptable pole parameters extracted from this compilation, namely,

$$\sqrt{s^{f_0(980)}_{\rm Pole}} = (980-1010) - i(20-35)\ \text{MeV} \qquad (64.6)$$

indicated by the box. A disclaimer is important here: Both the poles of $a_0(980)$ and of $f_0(980)$ are located very close to the kaon thresholds, with the charged and neutral thresholds being 8 MeV apart — to illustrate this point the pertinent thresholds are shown explicitly in Figs. 64.2 and 64.4. This observation lead to the prediction of an enhanced a_0-f_0 mixing [149–152]. On the other hand, all analyses employed in the pole determinations quoted above are done assuming isospin symmetry. Future studies need to show the impact of isospin violation on the extraction of the $a_0(980)/f_0(980)$ pole parameters.

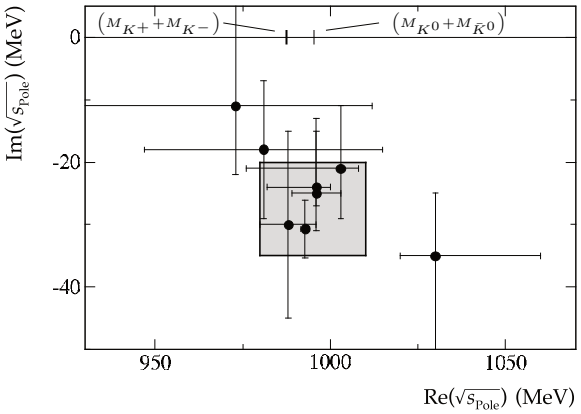

Figure 64.4: Location of the $f_0(980)$ poles from different extractions in the complex energy plane. The corresponding references are given in the *Listings*. Also shown are the thresholds for the K^+K^- and $K^0\bar{K}^0$ channels. The grey box indicates the ranges extracted as 'our estimate' of the pole locations.

Analyses of $\gamma\gamma \to \pi\pi$ data [127–129] underline the importance of the $K\bar{K}$ coupling of the $f_0(980)$, while the resulting two-photon width of the $f_0(980)$ cannot be determined precisely [130]. The prominent appearance of the $f_0(980)$ in the semileptonic D_s decays and decays of B and B_s mesons implies a dominant $(\bar{s}s)$ component: those decays occur via weak transitions that alternatively result in $\phi(1020)$ production. Ratios of decay rates of B and/or B_s mesons into $J/\psi(1S)$ plus $f_0(980)$ or $f_0(500)$ were proposed to allow for an extraction of the flavor mixing angle and to probe the tetraquark nature of those mesons within a certain model [131,132]. The resulting phenomenological fits of the LHCb collaboration [133, 134] lead the authors to conclude that their data are incompatible with a model where $f_0(500)$ and $f_0(980)$ are formed from two quarks and two antiquarks (tetraquarks). However, a dispersive analysis of the same data that allows for a model independent inclusion of the hadronic final state interactions in Ref. [135] puts into question the conclusions of Ref. [133].

64.6 Interpretation of the scalars below 1 GeV

In the literature, many structures are discussed for the light scalar mesons, such as conventional $q\bar{q}$ mesons, compact $(qq)(\bar{q}\bar{q})$ structures (tetraquarks), or meson-meson bound states (hadronic molecules). In reality, there can be superpositions of these components, and one often depends on models to determine the dominant one. Although we have seen progress in recent years, this question remains open. Here, we mention some of the present conclusions.

The $f_0(980)$ and $a_0(980)$ are often interpreted as compact tetraquark states [144–147, 153] or $K\bar{K}$ bound states [154]. The insight into their internal structure using two-photon widths [123, 155–161] is not conclusive. The $f_0(980)$ appears as a peak structure in $J/\psi(1S) \to \phi\pi^+\pi^-$ and in D_s decays without $f_0(500)$ background, while being nearly invisible in $J/\psi(1S) \to \omega\pi^+\pi^-$. Based on that observation it is suggested that $f_0(980)$ has a large $s\bar{s}$ component, which according to Ref. [162] is surrounded by a virtual $K\bar{K}$ cloud (see also Ref. [163]). Data on radiative decays $(\phi \to f_0\gamma$ and $\phi \to a_0\gamma)$ from SND, CMD2, and KLOE (see above) are consistent with a prominent role of kaon loops. This

observation is interpreted as evidence for a compact four-quark structure of the light scalars in Ref. [164], while it is claimed to point at a molecular nature in Ref. [165, 166]. Details of this controversy are given in the comments [167, 168]; see also Ref. [169]. There is now a rather broad consensus that the states $f_0(980)$ and $a_0(980)$, together with the $f_0(500)$ and the $K_0^*(700)$, form a nonet of predominantly four-quark states, where at larger distances the quarks recombine into a pair of pseudoscalar mesons creating a meson cloud (see, *e.g.,* Ref. [170]). Different QCD sum rule studies [171–176] do not agree on a tetraquark configuration for the same particle group.

Models that start directly from chiral Lagrangians, either in non-linear [36, 39, 83, 165] or in linear [177–183] realization, predict the existence of the $f_0(500)$ meson near 500 MeV. Here the $f_0(500)$, $a_0(980)$, $f_0(980)$, and $K_0^*(700)$ (in some models the $K_0^*(1430)$) would form a nonet (not necessarily $q\bar{q}$). In the linear sigma models the lightest pseudoscalars appear as their chiral partners.

In the non-linear approaches of Refs. [36] and [83] the above resonances together with the low mass vector states are generated starting from chiral perturbation theory predictions near the first open channel, and then by extending the predictions to the resonance regions, using unitarity and analyticity.

Ref. [177] uses a framework with explicit resonances that are unitarized and coupled to the light pseudoscalars in a chirally invariant way. Evidence for a dominant non-$\bar{q}q$ nature of the lightest scalar resonances is derived from their mixing scheme. In Ref. [178] the scheme is extended and applied to the decay $\eta' \to \eta\pi\pi$, which leads to the same conclusions. In Ref. [184] the large N_c behavior of the poles was studied to identify the nature of the resonances generated from scattering equations. This lead to the observation that, while the light vector states behave consistent with what is predicted for $\bar{q}q$ states, the light scalars behave very differently. This finding provides strong support for a dominant non-$\bar{q}q$ nature of the light scalar resonances. Note, the more refined study of Ref. [117] which found, in the case of the $f_0(500)$, indications for a subdominant $\bar{q}q$ component located around 1 GeV in addition to a dominant non-$\bar{q}q$ nature. Additional support for the dominant non-$q\bar{q}$ nature of the $f_0(500)$ is given in Ref. [185], where the connection between the pole of resonances and their Regge trajectories is analyzed. All works including constraints from chiral symmetry at low energies naturally find a light $K_0^*(700)$ below 800 MeV and a $f_0(500)$ below 600 MeV, see, *e.g.*, [34–39]. In these works the $K_0^*(700)$, $f_0(500)$, $f_0(980)$, and $a_0(980)$ appear to form a nonet [35, 38]. Additional evidence for this assignment is presented in Ref. [13], where the couplings of the nine states to $\bar{q}q$ sources are compared. The same low mass scalar nonet was also found earlier in the unitarized quark model of Ref. [94].

There are, however, alternative interpretations of the light scalars. For example Ref. [186] (for a more recent, condensed discussion of the idea see Ref. [187]), also builds on chiral symmetry, but expands around an infrared fixed point such that the $f_0(500)$ appears as a QCD dilaton with a mass driven by the QCD scale anomaly. The phenomenology studied in that work appears consistent with this proposal. In Ref. [91, 113, 188, 189] data on $\pi\pi - \bar{K}K$ scattering, as well as $\gamma\gamma \to \pi\pi$, are analysed and the authors conclude that especially the $f_0(500)$ should have a significant gluon content.

A model independent method to identify hadronic molecules goes back to a proposal by Weinberg [190] (an extension of the formalism to virtual states is provided in Ref. [191]), which was shown to be equivalent to the pole counting arguments of [149–152, 192–197] in Ref. [195]. The formalism allows one to extract the amount of molecular component in the wave function from the effective coupling constant of a physical state to a nearby continuum channel. It can be applied to near threshold states only and provides strong evidence that the $f_0(980)$ is predominantly a $\bar{K}K$ molecule, while the situation turns out to be less clear for the $a_0(980)$ (see also Refs. [159, 161]). This is in line with the findings of Ref. [55], which reports an important role of the $\pi\eta$ channel to the formation of the $a_0(980)$ in addition to the $\bar{K}K$ channel, while the $f_0(980)$ also in this work appears to be predominantly a $\bar{K}K$ molecule. The relevance of both the $\bar{K}K$ and the $\pi\eta$ channels in a dynamically generated $a_0(980)$ was also pointed out in the description of the $\chi_{c1} \to \eta\pi^+\pi^-$ and $D_s^+ \to \pi^+\pi^0\eta$ reactions [198, 199]. Further insights into $a_0(980)$ and $f_0(980)$ are expected from their mixing [149]. The corresponding signal predicted in Refs. [150,151] was recently observed at BES III [196]. In order to get a quantitative understanding of those data, in addition to the mixing mechanism itself, some detailed understanding of the production mechanism seems necessary [152].

In the unitarized quark model with coupled $q\bar{q}$ and meson-meson channels, the light scalars are interpreted as additional manifestations of bare $q\bar{q}$ confinement states, strongly mass shifted from the 1.3 - 1.5 GeV region and very distorted due to the strong $^3P_0$ coupling to S-wave two-meson decay channels [197,200]. Thus, in these models the light scalar nonet comprising the $f_0(500)$, $f_0(980)$, $K_0^*(700)$, and $a_0(980)$, as well as the nonet consisting of the $f_0(1370)$, $f_0(1500)$ (or $f_0(1710)$), $K_0^*(1430)$, and $a_0(1450)$, respectively, are seen as two manifestations of the same bare input states (see also Ref. [201]). It should not remain unmentioned, however, that the heavier nonet lies rather close to the input nonet and that the light scalar one emerges only, once the coupling to the two-meson channels is switched on, again highlighting that the meson-meson interaction is indispensable for the light scalars.

Acknowledgement

The authors would like to thank Claude Amsler, Eberhard Klempt, Mikhail Mikhasenko, and Jose Ramon Pelaez for helpful input and discussions in the preparation of the review.

65. Rare Kaon Decays

Revised August 2021 by L. Littenberg (BNL) and G. Valencia (Monash U.).

65.1 Introduction

There are several useful reviews on rare kaon decays and related topics [1–13]. Activity in rare kaon decays can be divided roughly into four categories:

1. Searches for explicit violations of the Standard Model (SM)
2. The golden modes: $K \to \pi\nu\bar{\nu}$
3. Other constraints on SM parameters
4. Studies of strong interactions at low energy.

The paradigm of Category 1 is the lepton flavor violating decay $K_L \to \mu e$. Category 2 includes the two modes that can be calculated with negligible theoretical uncertainty, $K^+ \to \pi^+\nu\bar{\nu}$ and $K_L \to \pi^0\nu\bar{\nu}$. These modes can lead to precision determinations of CKM parameters or, in combination with other measurements of these parameters, they can constrain new interactions. They constitute the main focus of the current experimental kaon program. The search for new light particles through the reaction $K \to \pi X^0$ is a byproduct of these measurements. Category 3 is focused on decays with charged leptons, such as $K_L \to \pi^0\ell^+\ell^-$ or $K_L \to \ell^+\ell^-$ where $\ell \equiv e, \mu$. These modes are sensitive to CKM parameters, but they suffer from multiple hadronic uncertainties that can be addressed, at least in part, through a systematic study of the peripheral modes indicated in Fig. 65.1.

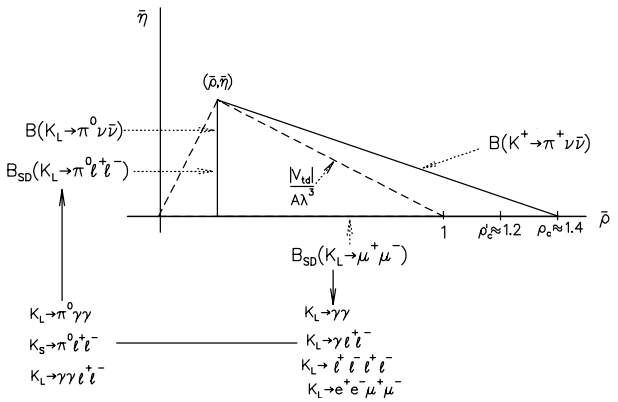

Figure 65.1: Role of rare kaon decays in determining the unitarity triangle. The solid arrows point to auxiliary modes needed to interpret the main results, or potential backgrounds to them.

The interplay between Categories 3-4 and their complementarity to Category 2 is illustrated in the figure. Category 4 includes reactions like $K^+ \to \pi^+\ell^+\ell^-$ where long distance contributions are dominant and which constitute a testing ground for the ideas of chiral perturbation theory. Other decays in this category are $K_L \to \pi^0\gamma\gamma$ and $K_L \to \ell^+\ell^-\gamma$. The former is important in understanding a CP-conserving contribution to $K_L \to \pi^0\ell^+\ell^-$, whereas the latter could shed light on long distance contributions to $K_L \to \mu^+\mu^-$.

65.2 Explicit violations of the Standard Model

Much activity has focussed on searches for lepton flavor violation (LFV). This is motivated by the fact that many extensions of the minimal Standard Model violate lepton flavor and by the potential to access very high energy scales. For example, the tree-level exchange of a LFV vector boson of mass M_X that couples to left-handed fermions with electroweak strength and without mixing angles yields $\mathrm{B}(K_L \to \mu e) = 4.7 \times 10^{-12}(148\ \mathrm{TeV}/M_X)^4$ [2]. This simple dimensional analysis may be used to read from Table 65.1 that the reaction $K_L \to \mu e$ is already probing scales of over 100 TeV. Table 65.1 summarizes the present experimental situation vis-à-vis LFV. The decays $K_L \to \mu^\pm e^\mp$ and $K^+ \to \pi^+ e^\mp \mu^\pm$ (or $K_L \to \pi^0 e^\mp \mu^\pm$) provide complementary information on potential family number violating interactions, since the former is sensitive to parity-odd couplings and the latter is sensitive to parity-even couplings.

Limits on certain lepton-number violating (LNV) kaon decays also have been obtained, with special interest arising from their role in constraining possible extensions of the neutrino sector [14, 15], and we list those in the table as well. Related searches in μ and τ processes are discussed in our section "Tests of Conservation Laws."

Table 65.1: Searches for lepton flavor and lepton number violation in K decay

LFV mode	90% CL upper limit	Experiment	Yr./Ref.	Type
$K^+ \to \pi^+ e^- \mu^+$	1.3×10^{-11}	BNL-865	2005/ [16]	LFV
$K^+ \to \pi^+ e^+ \mu^-$	6.6×10^{-11}	NA62	2021/ [17]	LFV
$K_L \to \mu e$	4.7×10^{-12}	BNL-871	1998/ [18]	LFV
$K_L \to \pi^0 e\mu$	7.6×10^{-11}	KTeV	2008/ [19]	LFV
$K_L \to \pi^0\pi^0 e\mu$	1.7×10^{-10}	KTeV	2008/ [19]	LFV
$K^+ \to \pi^- e^+ e^+$	5.3×10^{-11}	NA62	2022/ [20]	LNV
$K^+ \to \pi^-\pi^0 e^+ e^+$	8.5×10^{-10}	NA62	2022/ [20]	LNV
$K^+ \to \pi^- \mu^+ \mu^+$	4.2×10^{-11}	NA62	2019/ [21]	LNV
$K_L \to e^\pm e^\pm \mu^\mp \mu^\mp$	4.12×10^{-11}	KTeV	2003/ [22]	LNV
$K^+ \to \pi^- \mu^+ e^+$	4.2×10^{-11}	NA62	2021/ [17]	LNFV

65.3 The golden modes: $K \to \pi\nu\bar{\nu}$

In the SM, the decay $K^+ \to \pi^+\nu\bar{\nu}$ is dominated by one-loop diagrams with top-quark intermediate states while long-distance contributions are known to be quite small [23–25]. This permits a precise calculation of this rate in terms of SM parameters. Studies of this process are thus motivated by the possibility of detecting non-SM physics when comparing with the results of global fits [26, 27].

The branching ratio can be written in a compact form that exhibits the different ingredients that go into the calculation [28],

$$\mathrm{B}\left(K^+ \to \pi^+\nu\bar{\nu}(\gamma)\right) = \kappa_+(1+\Delta_{\mathrm{EM}})\left[\left(\frac{\mathrm{Im}(V_{ts}^\star V_{td})}{\lambda^5}X_t\right)^2 + \left(\frac{\mathrm{Re}(V_{cs}^\star V_{cd})}{\lambda}P_c + \frac{\mathrm{Re}(V_{ts}^\star V_{td})}{\lambda^5}X_t\right)^2\right]. \quad (65.1)$$

The parameters in Eq. 65.1 incorporate the *a priori* unknown hadronic matrix element in terms of the very well-measured K_{e3} rate [23] in κ_+; long distance QED corrections in Δ_{EM} [29]; the Inami-Lim function for the short distance top-quark contribution [30] including NLO QCD corrections [31, 32] and the two-loop electroweak correction [28], all in X_t; and the charm-quark contributions due to short distance effects including NNLO QCD corrections [33, 34] and NLO electroweak corrections via P_c [35], which also includes certain long distance dubbed $\delta P_{c,u}$ [25, 36].

An interesting approximate way to cast this result in terms of the CKM parameters λ, V_{cb}, $\bar{\rho}$ and $\bar{\eta}$ (see our Section on "The Cabibbo-Kobayashi-Maskawa mixing matrix") [9] is:

$$\mathrm{B}(K^+ \to \pi^+\nu\bar{\nu}) \approx 1.6 \times 10^{-5}|V_{cb}|^4[(\sigma\bar{\eta})^2 + (\rho_c - \bar{\rho})^2] \quad (65.2)$$

where $\rho_c \approx 1.45$ and $\sigma \equiv \frac{1}{(1-\frac{1}{2}\lambda^2)^2}$. Thus, $\mathrm{B}(K^+ \to \pi^+\nu\bar{\nu})$ determines an ellipse in the $\bar{\rho}$, $\bar{\eta}$ plane with center $(\rho_c, 0)$ and semiaxes $\approx \frac{1}{|V_{cb}|^2}\sqrt{\frac{\mathrm{B}(K^+\to\pi^+\nu\bar{\nu})}{1.6\times10^{-5}}}$ and $\frac{1}{\sigma|V_{cb}|^2}\sqrt{\frac{\mathrm{B}(K^+\to\pi^+\nu\bar{\nu})}{1.6\times10^{-5}}}$.

BNL-787 observed two candidate events [37, 38] in the clean high π^+ momentum and one event [39] in the low-momentum region. The successor experiment BNL-949 observed one more in the high-momentum region [40] and three more in the low-momentum region [41], yielding a branching ratio of $(1.73^{+1.15}_{-1.05}) \times 10^{-10}$ [42].

The NA62 experiment, performed with in-flight decays at CERN, aims to reach a sensitivity of $\sim 10^{-12}$ per event. NA62 was commissioned in 2015 and has taken data in 2016, 2017 and 2018. They recently published results from the 2016-18 runs [43]. Twenty candidate events were observed, including an estimated background of 7.03, yielding $\mathrm{B}(\mathrm{K}^+ \to \pi^+\nu\overline{\nu}) = (10.6^{+4.0}_{-3.4}|_{\mathrm{stat}} \pm 0.9_{\mathrm{sys}}) \times 10^{-11}$. NA62 will continue taking data in 2021 with improvements to the detector.

Using the latest CKMfitter input (Dec. 2019) [26], we estimate $\mathrm{B}(K^+ \to \pi^+\nu\overline{\nu})_{SM} = (8.1 \pm 0.4) \times 10^{-11}$, near the lower end of the measurements of BNL-787/949 and NA62. Current parametric uncertainty in the CKM angles can result in numbers with central values differing from this one by up to 10% [44].

The second golden mode is the neutral counterpart to our preceeding discussion: $K_L \to \pi^0\nu\overline{\nu}$. It is dominantly CP-violating and free of hadronic uncertainties [23, 45, 46]. In the Standard Model, this mode is dominated by an intermediate top-quark state and does not suffer from the small uncertainty associated with the charm-quark intermediate state that affects $K^+ \to \pi^+\nu\overline{\nu}$. The branching ratio is given by Ref. [9]:

$$\mathrm{B}(K_L \to \pi^0\nu\overline{\nu}) = \kappa_L \left(\frac{\mathrm{Im}(V_{ts}^\star V_{td})}{\lambda^5} X_t \right)^2 \approx 7.6 \times 10^{-5} |V_{cb}|^4 \overline{\eta}^2 \ . \tag{65.3}$$

As with the charged mode, the hadronic matrix element can be related to that measured in $K_{\ell 3}$ decay and is parameterized in κ_L.

Our estimate for the branching ratio within the SM, using the latest CKMfitter input (Dec. 2019) [26], is $(2.8 \pm 0.2) \times 10^{-11}$. Similarly to the charged kaon case, parametric uncertainty in the CKM angles can result in a central value that differs from this one by up to almost 20% [44].

Grossman and Nir (GN) [47] pointed out that, in a nearly model-independent manner, the two golden modes satisfy the relation $\mathrm{B}(K_L \to \pi^0\nu\overline{\nu}) \lesssim 4.3\ \mathrm{B}(K^+ \to \pi^+\nu\overline{\nu})$. Using the BNL 787/949 90% CL bound on $K^+ \to \pi^+\nu\overline{\nu}$, GN then predict $B(K_L \to \pi^0\nu\overline{\nu}) < 1.46 \times 10^{-9}$. Using instead the latest NA62 result, the GN upper bound becomes $B(K_L \to \pi^0\nu\overline{\nu}) < 8.14 \times 10^{-10}$ [13].

The KOTO experiment at J-PARC, whose initial goal is to observe this decay, has been running since 2013 and in 2018 published a 90% CL upper limit of 3.0×10^{-9} [48], based on their 2015 data. They have run every year since, making incremental improvements to the experimental configuration between runs. In 2021 they published a result on the data taken between 2016 and 2018 in which three events were observed in the signal region [49]. Studies revealed two backgrounds previously unanticipated at the current level of sensitvity (7.2×10^{-10}/event), one from halo $K_L \to \gamma\gamma$ and a larger one from charged kaons produced by K_L interactions in the downstream collimator, followed by $K^\pm \to \pi^0 e^\pm \nu_e$ where the $e^\pm$ goes backwards and is not observed. These constituted more than 90 % of the expected background of 1.22 events. Conservatively assuming the three events were due to background, they extracted a 90% CL upper limit of 4.9×10^{-9}. Subsequent hardware and analysis improvements are expected to greatly reduce these backgrounds in future data collection. An increase of 3-5 in sensitivity is anticipated from runs planned in the next three years.

The current theoretical and experimental situation for the golden modes is summarized in Fig. 65.2. The red area corresponds to the 1σ SM prediction we obtain with the latest input available from CKMfitter (December 2019) [26]. The yellow region shows the result established by the combined BNL-787 and BNL-949 results, whereas the green region marks the new NA62 result for $K^+ \to \pi^+\nu\overline{\nu}$. The black shaded region marks the GN exclusion, which lies significantly above the SM expectation leaving a large window for discovery of new physics contributions by experiments seeking to measure $\mathrm{B}(K_L \to \pi^0\nu\overline{\nu})$. The 90% CL upper bound on this mode from the KOTO result published in 2018 [48] is shown as a dashed orange line, and is seen to still lie in the GN excluded zone.

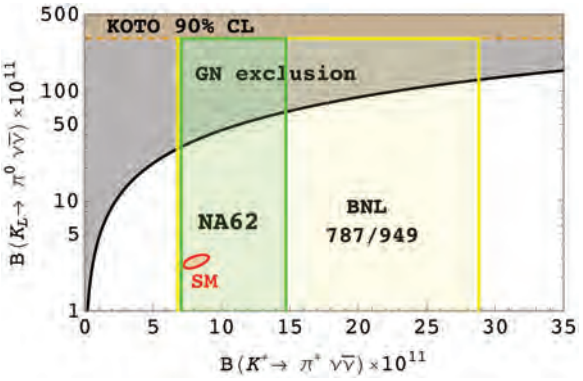

Figure 65.2: Summary of current situation for the golden modes $K \to \pi\nu\overline{\nu}$. The red ellipse shows the 1σ SM prediction with input from CKMfitter; the green (yellow) region corresponds to the NA62 (BNL787/949) 1σ measurement; and the dashed orange line marks the 90% CL KOTO upper bound. The black shaded region shows the GN exclusion.

Much theoretical work has explored beyond the SM scenarios that can populate this window as well as their correlations with other rare processes outside kaon physics. Although it would be relatively straightforward to establish the existence of new physics by observing deviations from their SM values in the $K \to \pi\nu\overline{\nu}$ modes, it would take much more extensive global fits to pinpoint the origin of any such deviation. Partial summaries with references focusing on quark flavor physics can be found in Refs. [9, 50–54]. Different possibilities emphasizing an interpretation of these modes as $K \to \pi + E_{\mathrm{miss}}$ can be found in Refs. [55–57].

There is a subtlety in converting the GN bound extracted from measurements of $K^+ \to \pi^+\nu\overline{\nu}$ into an upper bound for $K_L \to \pi^0\nu\overline{\nu}$ as applied to KOTO [58]. This is due to a lack of sensitivity of the charged kaon experiments to a kinematic window near the pion mass. New physics appearing through a two body mode $K^+ \to \pi^+ X^0$, for an invisible X^0 with mass near the pion mass, has a much weaker constraint. The situation is illustrated in Fig. 65.3 which shows the BNL787/949 [42] and NA62 [59] 90% c.l. limits on $K^+ \to \pi^+ X^0$ as a function of m_{X^0} assuming X^0 is stable. The implied GN bound for $K_L \to \pi^0 X^0$, $B(K_L \to \pi^0 X^0) \lesssim 4.3 B(K^+ \to \pi^+ X^0)$ is shown as a blue line and can be compared with the actual KOTO [48] constraint on $K_L \to \pi^0 X^0$ in red. Notice that the upper bound derived from NA62 is lower than that derived from BNL787/949 except for a small mass window. For $120 \lesssim m_{X^0} \lesssim 150$ MeV, KOTO already has better sensitivity than that implied by the GN bound in this case. The possibility of new physics in this scenario has generated much theoretical speculation [60–70].

The search for a new light particle X^0 in $K^+ \to \pi^+ X^0$ has a long tradition covering both long-lived particles (*e.g.*, hyperphoton, axion, familon, *etc.*), and short-lived ones that decay to muon, electron, photon or neutrino pairs. The longstanding 90% CL upper limit on $K^+ \to \pi^+ X^0$ from BNL787/949 7.3×10^{-11} [40] for the case of massless X^0 has been slightly improved by NA62 to 5×10^{-11} as can be read from Fig. 65.3. These limits can also be reinterpreted in connection with a dark photon [71] or dark Z [72], and in this context NA48/2 also constrained the mode $B(K^\pm \to \pi^\pm A' \to \pi^\pm e^+ e^-)$ [73]. Complementary searches for new light particles in kaon experiments use modes with two pions and include the KTeV bound $B(K_L \to \pi^0\pi^0 X^0 \to \pi^0\pi^0\mu^+\mu^-) < 1 \times 10^{-10}$ [74] and the E391a bound $B(K_L \to \pi^0\pi^0 X^0 \to \pi^0\pi^0\gamma\gamma) < 2.4 \times 10^{-7}$ [75].

Neutrino pair modes with one extra pion, $K \to \pi\pi\nu\overline{\nu}$, are similarly dominated by short distance contributions in the SM [76–78]. Even though they are theoretically clean, they occur with very

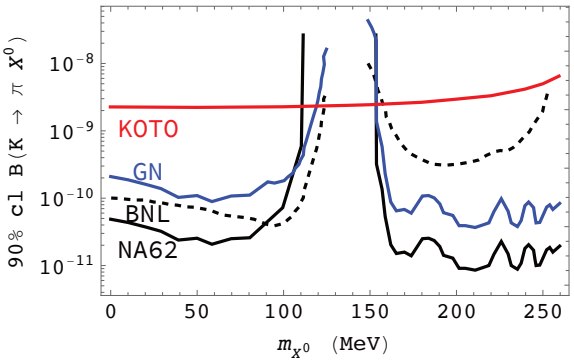

Figure 65.3: Summary of current situation for $K \to \pi X^0$. The solid (dashed) black line shows the exclusion limit for $K^+ \to \pi^+ X^0$ from NA62 (BNL787/949) assuming X^0 is stable. The blue line marks the constraint implied for $K_L \to \pi^0 X^0$ by the Grossman-Nir relation and the red line marks the current KOTO limit on $K^+ \to \pi^+ X^0$.

low rates with branching ratios of order 10^{-13}. The current best bound comes from KEK-391a, $B(K_L \to \pi^0\pi^0\nu\bar{\nu}) < 8.1 \times 10^{-7}$ at 90% CL [79]. There is also a bound for the charged kaon mode $B(K^+ \to \pi^+\pi^0\nu\bar{\nu}) < 4.3 \times 10^{-5}$ at 90% CL [80] from BNL-787. New physics contributions to these modes are discussed in [81].

65.4 Other constraints on Standard Model parameters

The decay $K_L \to \mu^+\mu^-$ has a short distance contribution sensitive to the CKM parameter $\overline{\rho}$, given by [5]:

$$\mathrm{B_{SD}}(K_L \to \mu^+\mu^-) \approx 2.7 \times 10^{-4} |V_{cb}|^4 (\rho_c' - \overline{\rho})^2 \qquad (65.4)$$

where ρ_c' depends on the charm quark mass and is approximately 1.2. This decay, however, is dominated by a long-distance contribution from a two-photon intermediate state. The absorptive (imaginary) part of the long-distance component is determined by the measured rate for $K_L \to \gamma\gamma$ to be $\mathrm{B_{abs}}(K_L \to \mu^+\mu^-) = (6.64 \pm 0.07) \times 10^{-9}$; and it almost completely saturates the observed rate $\mathrm{B}(K_L \to \mu^+\mu^-) = (6.84 \pm 0.11) \times 10^{-9}$ [82]. The difference between the observed rate and the absorptive component can be attributed to the (coherent) sum of the short-distance amplitude and the real part of the long-distance amplitude. The latter cannot be derived directly from experiment [83], but can be estimated with certain assumptions [84, 85].

By contrast, the decay $K_L \to e^+e^-$ is completely dominated by long distance physics and is easier to estimate. The result, $B(K_L \to e^+e^-) \sim 9 \times 10^{-12}$ [83, 86], is in good agreement with the BNL-871 measurement, $(8.7^{+5.7}_{-4.1}) \times 10^{-12}$ [87].

The mode $K_S \to \mu^+\mu^-$ has a short distance contribution proportional to the square of the CKM parameter $\bar{\eta}$ entering at the 10^{-13} level [10]. It also has long distance contributions arising from the two photon intermediate state which result in a rate $B(K_S \to \mu^+\mu^-)_{LD} = 5.1 \times 10^{-12}$ [10]. There is a 90% CL limit $B(K_S \to \mu^+\mu^-) < 2.1 \times 10^{-10}$ from LHCb [88, 89]. The interplay between $K_L \to \mu^+\mu^-$ and $K_S \to \mu^+\mu^-$ has been the subject of [90,91], and it has been pointed out that a measurement of time-dependent interference effects could be used to extract information on CKM angles from $K \to \mu^+\mu^-$ measurements [92].

The decay $K_L \to \pi^0 e^+e^-$ is sensitive to the CKM parameter η through its CP-violating component. There are both direct and indirect CP-violating amplitudes that can interfere. The direct CP-violating amplitude is short distance dominated and has been calculated in detail within the SM [5]. The indirect CP-violating amplitude can be inferred from a measurement of $K_S \to \pi^0 e^+e^-$. The complete CP-violating contribution to the rate can be written as [93–95]:

$$\mathrm{B_{CPV}} \approx \left[15.7|a_S|^2 \pm 1.4 \left(\frac{|V_{cb}|^2\overline{\eta}}{10^{-4}} \right) |a_S| + 0.12 \left(\frac{|V_{cb}|^2\overline{\eta}}{10^{-4}} \right)^2 \right] \times 10^{-12} \qquad (65.5)$$

where the three terms correspond to the indirect CP violation, the interference, and the direct CP violation, respectively. The parameter a_S has been extracted by NA48/1 from a measurement of $K_S \to \pi^0 e^+e^-$ with the result $|a_S| = 1.06^{+0.26}_{-0.21} \pm 0.07$ [96], as well as from a measurement of $K_S \to \pi^0\mu^+\mu^-$ with the result $|a_S| = 1.54^{+0.40}_{-0.32} \pm 0.06$ [97]. With current constraints on the CKM parameters, and assuming a positive sign for the interference term [95, 98], this implies that $\mathrm{B_{CPV}}(K_L \to \pi^0 e^+e^-) \approx (3.1 \pm 0.9) \times 10^{-11}$, where the three contributions to the central value from indirect, interference and direct CP violation are $(1.76, 0.9, 0.45) \times 10^{-11}$ respectively. It should be noted that more recent studies suggest a much larger uncertainty in the value of a_S [99].

$K_L \to \pi^0 e^+e^-$ also has a CP-conserving component dominated by a two-photon intermediate state. This component can be decomposed into an absorptive and a dispersive part. The absorptive part can be extracted from the measurement of the low $m_{\gamma\gamma}$ region of the $K_L \to \pi^0\gamma\gamma$ spectrum. The rate and the shape of the distribution $d\Gamma/dm_{\gamma\gamma}$ in $K_L \to \pi^0\gamma\gamma$ are well described in chiral perturbation theory in terms of three (*a priori*) unknown parameters [100–103].

Both KTeV and NA48 have studied the mode $K_L \to \pi^0\gamma\gamma$, reporting similar results. KTeV finds $B(K_L \to \pi^0\gamma\gamma) = (1.29 \pm 0.03_{\mathrm{stat}} \pm 0.05_{\mathrm{sys}}) \times 10^{-6}$ [104], while NA48 finds $B(K_L \to \pi^0\gamma\gamma) = (1.36 \pm 0.03_{\mathrm{stat}} \pm 0.03_{\mathrm{sys}} \pm 0.03_{\mathrm{norm}}) \times 10^{-6}$ [105]. Both experiments are consistent with a negligible rate in the low $m_{\gamma\gamma}$ region, suggesting a very small CP-conserving component $B_{\mathrm{CP}}(K_L \to \pi^0 e^+e^-) \sim \mathcal{O}(10^{-13})$ [95, 103, 105]. There remains some model dependence in the estimate of the dispersive part of the CP-conserving $K_L \to \pi^0 e^+e^-$ [95].

The related process, $K_L \to \pi^0\gamma e^+e^-$, is potentially an additional background to $K_L \to \pi^0 e^+e^-$ in some region of phase space [106]. This process has been observed with a branching ratio of $(1.62 \pm 0.14_{\mathrm{stat}} \pm 0.09_{\mathrm{sys}}) \times 10^{-8}$ [107].

The decay $K_L \to \gamma\gamma e^+e^-$ constitutes the dominant background to $K_L \to \pi^0 e^+e^-$. It was first observed by BNL-845 [108], and subsequently confirmed with a much larger sample by KTeV [109]. It has been estimated that this background will enter at about the 10^{-10} level [110, 111], comparable to or larger than the signal level. Because of this, the observation of $K_L \to \pi^0 e^+e^-$ at the SM level will depend on background subtraction with good statistics. Possible alternative strategies are discussed in Ref. [95] and references cited therein.

The 90% CL upper bound for the process $K_L \to \pi^0 e^+e^-$ is 2.8×10^{-10} [111]. For the closely related muonic process, the published upper bound is $\mathrm{B}(K_L \to \pi^0\mu^+\mu^-) \leq 3.8 \times 10^{-10}$ [112], compared with the SM prediction of $(1.9 \pm 0.5) \times 10^{-11}$. The latter assumes positive interference between the direct- and indirect-CP violating components and includes a CP-conserving component which contributes about 30% of the total [10, 113].

A study of $K_L \to \pi^0\mu^+\mu^-$ has indicated that it might be possible to extract the direct CP-violating contribution by a joint study of the Dalitz plot variables and the components of the μ^+ polarization [114]. The latter tends to be quite substantial so that large statistics may not be necessary.

Combined information from $K_L \to \pi^0\ell^+\ell^-$ as well as $K_L \to \mu^+\mu^-$ complements the $K \to \pi\nu\overline{\nu}$ measurements in constraining physics beyond the SM [115].

65.5 Other long distance dominated modes

The decays $K^+ \to \pi^+\ell^+\ell^-$ ($\ell = e$ or μ) have received considerable attention. The rate and spectrum have been measured for

both the electron and muon modes [116–121]. A review of the theoretical status of these modes can be found in [99, 122].

Ref. [93, 94] has proposed a parameterization inspired by chiral perturbation theory, which provides a successful description of data but indicates the presence of large corrections beyond leading order. More work is needed to fully understand the origin of these large corrections. The mode $K^+ \to \pi^+\pi^0 e^+ e^-$, analyzed by NA48/2 [123], is also dominated by long distance physics but it has been argued that measuring asymmetries can provide information on the short distance components [124]. The current status of these modes is discussed in [125].

The decay $K^+ \to \pi^+\gamma\gamma$ can be predicted in terms of one unknown parameter to leading order in χPT resulting in a correlation between the rate and the diphoton mass spectrum [126]. Certain important corrections at the next order are also known [127]. The rate was first measured by E787 [128], and NA48/2 [129] has obtained a more precise result with a 6% error, as well as the corresponding spectrum fits. The most recent, and precise, result is from NA62 based on a sample of 232 events [130] but is still insufficient to distinguish between the leading order and next order χPT parameterizations. The NA48 and NA62 results have been combined in [131].

Much information has been recorded by KTeV and NA48 on the rates and spectrum for the Dalitz pair conversion modes $K_L \to \ell^+\ell^-\gamma$ [132, 133], and $K_L \to \ell^+\ell^-\ell'^+\ell'^-$ for $\ell, \ell' = e$ or μ [22, 134]. All these results are used to test hadronic models and should eventually help unravel the underlying physics in $K_L \to \mu^+\mu^-$ [85, 90, 135].

66. *CPT* Invariance Tests in Neutral Kaon Decay

Revised August 2021 by M. Antonelli (INFN, Frascati), G. D'Ambrosio (INFN, Napoli) and M.S. Sozzi (Pisa U.).

CPT theorem is based on three assumptions: quantum field theory, locality, and Lorentz invariance, and thus it is a fundamental probe of our basic understanding of particle physics. Strangeness oscillation in $K^0-\overline{K}^0$ system, described by the equation

$$i\frac{d}{dt}\begin{bmatrix}K^0\\ \overline{K}^0\end{bmatrix} = [M - i\Gamma/2]\begin{bmatrix}K^0\\ \overline{K}^0\end{bmatrix} ,$$

where M and Γ are hermitian matrices (see PDG review [1], references [2,3], and KLOE paper [4] for notations and previous literature), allows a very accurate test of CPT symmetry; indeed since CPT requires $M_{11} = M_{22}$ and $\Gamma_{11} = \Gamma_{22}$, the mass and width eigenstates, $K_{S,L}$, have a CPT-violating piece, δ, in addition to the usual CPT-conserving parameter ϵ:

$$K_{S,L} = \frac{1}{\sqrt{2\left(1+|\epsilon_{S,L}|^2\right)}}\left[\left(1+\epsilon_{S,L}\right)K^0 \pm \left(1-\epsilon_{S,L}\right)\overline{K}^0\right]$$

$$\epsilon_{S,L} = \frac{-i\Im\left(M_{12}\right) - \frac{1}{2}\Im\left(\Gamma_{12}\right) \mp \frac{1}{2}\left[M_{11} - M_{22} - \frac{i}{2}\left(\Gamma_{11}-\Gamma_{22}\right)\right]}{m_L - m_S + i(\Gamma_S-\Gamma_L)/2}$$

$$\equiv \epsilon \pm \delta. \tag{66.1}$$

Using the phase convention $\Im(\Gamma_{12}) = 0$, we determine the phase of ϵ to be $\varphi_{SW} \equiv \arctan\frac{2(m_L-m_S)}{\Gamma_S-\Gamma_L}$. Imposing unitarity to an arbitrary combination of K^0 and $\overline{K}^0$ wave functions, we obtain the Bell-Steinberger relation [5] connecting CP and CPT violation in the mass matrix to CP and CPT violation in the decay; in fact, neglecting $\mathcal{O}(\epsilon)$ corrections to the coefficient of the CPT-violating parameter, δ, we can write [4]

$$\left[\frac{\Gamma_S+\Gamma_L}{\Gamma_S-\Gamma_L} + i\tan\phi_{\rm SW}\right]\left[\frac{\Re(\epsilon)}{1+|\epsilon|^2} - i\Im(\delta)\right] = \frac{1}{\Gamma_S-\Gamma_L}\sum_f A_L(f)A_S^*(f), \tag{66.2}$$

where $A_{L,S}(f) \equiv A(K_{L,S} \to f)$. We stress that this relation is phase-convention-independent. The advantage of the neutral kaon system is that only a few decay modes give significant contributions to the r.h.s. in Eq. (66.2); in fact, defining for the hadronic modes

$$\alpha_i \equiv \frac{1}{\Gamma_S}\langle\mathcal{A}_L(i)\mathcal{A}_S^*(i)\rangle = \eta_i\ \mathcal{B}(K_S \to i),$$
$$i = \pi^0\pi^0, \pi^+\pi^-(\gamma), 3\pi^0, \pi^0\pi^+\pi^-(\gamma), \tag{66.3}$$

the recent data from CPLEAR, KLOE, KTeV, and NA48 have led to the following determinations (the analysis described in Ref. [4] has been updated by using the recent measurements of K_L branching ratios from KTeV [6, 7], NA48 [8, 9], the results described in the CP violation in K_L decays minireview, and the KLOE result [10])

$$\begin{aligned}\alpha_{\pi^+\pi^-} &= ((1.121\pm0.010) + i(1.061\pm0.010))\times10^{-3}\ ,\\ \alpha_{\pi^0\pi^0} &= ((0.493\pm0.005) + i(0.471\pm0.005))\times10^{-3}\ ,\\ \alpha_{\pi^+\pi^-\pi^0} &= ((0\pm2) + i(0\pm2))\times10^{-6},\\ |\alpha_{\pi^0\pi^0\pi^0}| &< 1.5\times10^{-6}\ \text{ at 95\% CL}\ .\end{aligned} \tag{66.4}$$

The semileptonic contribution to the right-handed side of Eq. (66.2) requires the determination of several observables: we define [2,3]

$$\begin{aligned}\mathcal{A}(K^0 \to \pi^- l^+ \nu) &= \mathcal{A}_0(1-y)\ ,\\ \mathcal{A}(K^0 \to \pi^+ l^- \nu) &= \mathcal{A}_0^*(1+y^*)(x_+ - x_-)^*\ ,\\ \mathcal{A}(\overline{K}^0 \to \pi^+ l^- \nu) &= \mathcal{A}_0^*(1+y^*)\ ,\\ \mathcal{A}(\overline{K}^0 \to \pi^- l^+ \nu) &= \mathcal{A}_0(1-y)(x_+ + x_-)\ ,\end{aligned} \tag{66.5}$$

where x_+ (x_-) describes the violation of the $\Delta S = \Delta Q$ rule in CPT-conserving (violating) decay amplitudes, and y parameterizes CPT violation for $\Delta S = \Delta Q$ transitions. Taking advantage of their tagged $K^0(\overline{K}^0)$ beams, CPLEAR has measured $\Im(x_+)$, $\Re(x_-)$, $\Im(\delta)$, and $\Re(\delta)$ [11]. These determinations have been improved in Ref. [4] by including the information $A_S - A_L = 4[\Re(\delta) + \Re(x_-)]$ (valid at first order in the small parameters), where $A_{L,S}$ are the K_L and K_S semileptonic charge asymmetries, respectively, from the PDG [12] and the new KLOE semileptonic measurement [13]. Here we are also including the T-violating asymmetry measurement from CPLEAR [14] with a finer binning than appearing in the published article.

Table 66.1: Values, errors, and correlation coefficients for $\Re(\delta)$, $\Im(\delta)$, $\Re(x_-)$, $\Im(x_+)$, and $A_S + A_L$ obtained from a combined fit, including KLOE [4, 13] and CPLEAR [14].

	value	Correlations coefficients				
$\Re(\delta)$	$(4.3\pm2.7)\ \times10^{-4}$	1				
$\Im(\delta)$	$(-0.9\pm0.6)\times10^{-2}$	−0.40	1			
$\Re(x_-)$	$(-0.22\pm0.10)\times10^{-2}$	−0.14	−0.30	1		
$\Im(x_+)$	$(0.06\pm0.19)\times10^{-2}$	−0.12	−0.02	0.34	1	
A_S+A_L	$(-0.23\pm0.38)\times10^{-2}$	−0.12	−0.29	0.94	0.18	1

The value $A_S + A_L$ in Table 66.1 can be directly included in the semileptonic contributions to the Bell Steinberger relations in Eq. (66.2)

$$\begin{aligned}\sum_{\pi\ell\nu}&\langle\mathcal{A}_L(\pi\ell\nu)\mathcal{A}_S^*(\pi\ell\nu)\rangle\\ &= 2\Gamma(K_L\to\pi\ell\nu)(\Re(\epsilon) - \Re(y) - i(\Im(x_+)+\Im(\delta)))\\ &= 2\Gamma(K_L\to\pi\ell\nu)((A_S+A_L)/4 - i(\Im(x_+)+\Im(\delta)))\ .\end{aligned} \tag{66.6}$$

Defining

$$\alpha_{\pi\ell\nu} \equiv \frac{1}{\Gamma_S}\sum_{\pi\ell\nu}\langle\mathcal{A}_L(\pi\ell\nu)\mathcal{A}_S^*(\pi\ell\nu)\rangle + 2i\frac{\tau_{K_S}}{\tau_{K_L}}\mathcal{B}(K_L\to\pi\ell\nu)\Im(\delta)\ , \tag{66.7}$$

we find:

$$\alpha_{\pi\ell\nu} = ((-0.1\pm0.2) + i(-0.1\pm0.5))\times10^{-5}\ . \tag{66.8}$$

Table 66.2: Summary of results: values, errors, and correlation coefficients for $\Re(\epsilon)$, $\Im(\delta)$, $\Re(\delta)$, and $\Re(x_-)$.

	value	Correlations coefficients			
$\Re(\epsilon)$	$(161.2\pm0.5)\times10^{-5}$	+1			
$\Im(\delta)$	$(-0.3\pm1.4)\times10^{-5}$	+0.08	1		
$\Re(\delta)$	$(2.6\pm2.5)\times10^{-4}$	+0.00	−0.05	1	
$\Re(x_-)$	$(-2.7\pm1.0)\times10^{-3}$	+0.05	0.13	−0.30	1

The analysis of semileptonic decay asymmetries implicitly assumes Lepton Flavour Universality (LFU) of any effect violating CPT or $\Delta S = \Delta Q$, through the use of a single set of x, y parameters, consistently with the availability of experimental information on A_S for the electron mode only. The explicit LFU assumption in the input BR measurements has been lifted exploiting the measurement of $BR(K_S \to \pi\mu\nu)$ Ref. [15], with no effect on the numerical results.

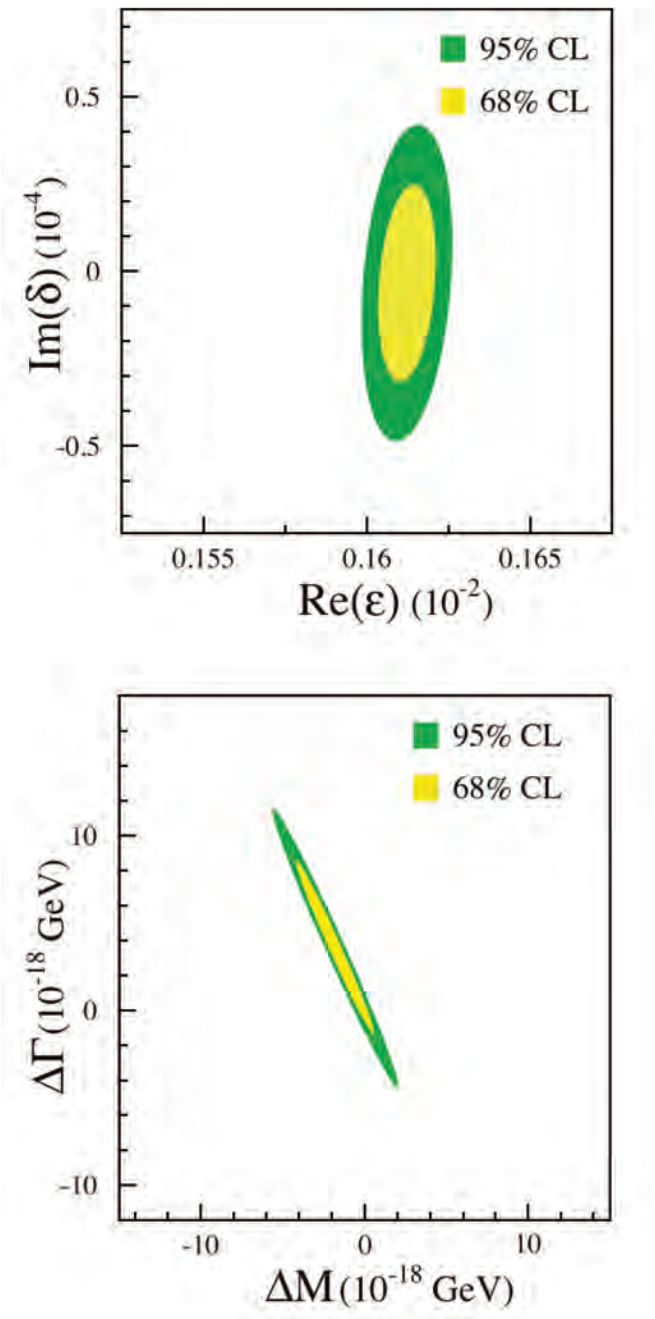

Figure 66.1: Top: allowed region at 68% and 95% C.L. in the $\Re(\epsilon)$, $\Im(\delta)$ plane. Bottom: allowed region at 68% and 95% C.L. in the $\Delta M, \Delta\Gamma$ plane.

Inserting the values of the α parameters into Eq. (66.2), we find

$$\Re(\epsilon) = (161.2 \pm 0.5) \times 10^{-5},$$
$$\Im(\delta) = (-0.3 \pm 1.4) \times 10^{-5}\,. \qquad (66.9)$$

The complete information on Eq. (66.9) is given in Table 66.2.

Now the agreement with CPT conservation, $\Im(\delta) = \Re(\delta) = \Re(x_-) = 0$, is at 18% C.L.

The allowed region in the $\Re(\epsilon) - \Im(\delta)$ plane at 68% CL and 95% C.L. is shown in the top panel of Fig. 66.1.

The process giving the largest contribution to the size of the allowed region is $K_L \to \pi^+\pi^-$, through the uncertainty on ϕ_{+-}.

The limits on $\Im(\delta)$ and $\Re(\delta)$ can be used to constrain the $K^0 - \overline{K}^0$ mass and width difference

$$\delta = \frac{i(m_{K^0} - m_{\overline{K}^0}) + \frac{1}{2}(\Gamma_{K^0} - \Gamma_{\overline{K}^0})}{\Gamma_S - \Gamma_L} \cos\phi_{SW} e^{i\phi_{SW}} [1 + \mathcal{O}(\epsilon)]\,.$$

The allowed region in the $\Delta M = (m_{K^0} - m_{\overline{K}^0}), \Delta\Gamma = (\Gamma_{K^0} - \Gamma_{\overline{K}^0})$ plane is shown in the bottom panel of Fig. 66.1. As a result, we improve on the previous limits (see for instance, P. Bloch in Ref. [12]) and in the limit $\Gamma_{K^0} - \Gamma_{\overline{K}^0} = 0$ we obtain

$$-4.0\times10^{-19}\ \text{GeV} < m_{K^0} - m_{\overline{K}^0} < 4.0\times10^{-19}\ \text{GeV} \quad \text{at 95 \% C.L.}$$

67. V_{ud}, V_{us} the Cabibbo Angle, and CKM Unitarity

Revised August 2021 by E. Blucher (Chicago U.) and W.J. Marciano (BNL).

The Cabibbo-Kobayashi-Maskawa (CKM) [1, 2] three-generation quark mixing matrix written in terms of the Wolfenstein parameters (λ, A, ρ, η) [3] nicely illustrates the orthonormality constraint of unitarity, as well as the central role played by λ.

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} = \begin{pmatrix} 1-\lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\lambda^2/2 & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1 \end{pmatrix} + \mathcal{O}(\lambda^4)\ . \tag{67.1}$$

That cornerstone parameter is a carryover from the two-generation Cabibbo angle, $\lambda = \sin(\theta_{\rm Cabibbo}) = V_{us}$. Its value is an important component in tests of CKM unitarity.

Up until 2003, the precise value of λ was controversial, with kaon decays (specifically $K \to \pi e \nu$) branching fractions suggesting [4] $\lambda \simeq 0.220$, while indirect determinations via V_{ud} obtained from nuclear β-decays combined with unitarity preferred a somewhat larger $\lambda \simeq 0.225 - 0.230$. This difference implied a 2 - 2.5 sigma deviation from the first row unitarity requirement

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 1, \tag{67.2}$$

a possible hint [5, 6] of new physics effects. Below, we describe the current status of V_{ud} and V_{us}, and their implication for the unitarity test in Eq. (67.2). (Since $|V_{ub}|^2 \simeq 1.7\times10^{-5}$ is negligibly small, it is ignored in this discussion.) Eq. (67.2) is currently the most stringent test of unitarity in the CKM matrix. As we shall see, it is again showing signs of a possible 2 to 3 sigma inconsistency.

67.1 V_{ud}

Precise values of V_{ud} have been obtained from superallowed nuclear, neutron, and pion beta decays. Currently, the best determination of V_{ud} comes from analysis of a set of 15 precisely measured superallowed nuclear beta-decays [5,6] ($0^+ \to 0^+$ transitions). Measuring their half-lives, t, and Q values gives the decay rate factors, f, which lead to a precise determination of V_{ud} via [7–12]. Based on several decades of dedicated studies, Hardy and Towner recently updated the average [6]

$$|V_{ud}|^2 = 0.97154(22)(54)_{\rm NS}/(1+\Delta_{\rm R}^{\rm V}), \tag{67.3}$$

where Δ_R^V denotes the so-called inner or universal electroweak radiative corrections (RC) to superallowed nuclear beta decays. Note that an additional uncertainty $(54)_{\rm NS}$ from nuclear structure (NS) [13] has been recently included [6] in that master formula. A dispersion relation (DR) calculational approach [14] to quantum loop corrections, specifically the gamma-W box diagram, gives $\Delta_R^V = 0.02467(22)$. Because of its small uncertainty and more rigorous theoretical footing, we use that value below. A somewhat different approach [15] found $\Delta_R^V = 0.02426(32)$. These recent values are roughly consistent. Both are larger than the 2018 PDG value of 0.02361(38). Implications and possible nuclear physics modifications of those studies are still under scrutiny [13,16]. Nevertheless, currently the 15 most precisely measured superallowed transitions [12] lead to the DR based weighted average of

$$V_{ud} = 0.97373(11)_{\rm exp.,nucl.}(9)_{\rm RC}(27)_{\rm NS}\ \text{(superallowed)}\ , \tag{67.4}$$

which, assuming unitarity, corresponds to the relatively large $\lambda = 0.2277(13)$. This recent determination of V_{ud} has shifted significantly down compared to the 2018 PDG value of 0.97420(21). In addition, NS uncertainties are now the dominant contribution to the overall uncertainty. Taken at face value, along with current V_{us} determinations (see subsection 67.2), the reduced V_{ud} would seem to violate the first row unitarity requirement and thus suggest the presence of "new physics".

Measurements of the neutron lifetime, τ_n, and the ratio of axial-vector/vector couplings, $g_A \equiv G_A/G_V$, via neutron decay asymmetries combined with the inner radiative corrections can also be used to determine V_{ud} via the precise formula:

$$|V_{ud}|^2 = \frac{5024.7\ \text{s}}{\tau_n(1+3g_A^2)(1+\Delta_R^V)}, \tag{67.5}$$

where Δ_R^V represents the same inner electroweak radiative corrections [8,9] as discussed above.

Using the current published world averages [17],

$$\tau_n^{\rm ave} = 879.4(6)\ \text{s}\ \ \text{(1.6 PDG scale factor)}$$
$$g_A^{\rm ave} = 1.2756(13),\ \text{(2.6 PDG scale factor)} \tag{67.6}$$

leads to

$$|V_{ud}| = 0.9737(3)_{\tau_n}(8)_{g_A}(1)_{\rm RC}, \tag{67.7}$$

for an inner radiative correction of 0.02467(22), while for 0.02426(32) it increases to 0.9739(9). Both central values are similar to the superallowed nuclear beta decay result reported above. Reconciliation with CKM unitarity suggests a shorter neutron lifetime near 878.5 s or a smaller g_A. We note that the most precise recent neutron lifetime update reported [18], $\tau_n = 877.75(34)$ s, has an uncertainty about half as big as the average given in Eq. 67.6. It corresponds to $|V_{ud}| = 0.9746(8)$, a value more in keeping with unitarity expectations; but too large an uncertainty from g_A to be meaningful. Future neutron studies [19] are expected to resolve any current inconsistencies and further reduce the uncertainties in g_A and τ_n making them a potentially better way to determine V_{ud} without the nuclear physics uncertainties.

The PIBETA experiment at PSI measured the very small ($\mathcal{O}(10^{-8})$) branching ratio for $\pi^+ \to \pi^o e^+ \nu_e$ with about $\pm 0.6\%$ precision. Its result gives [20]

$$|V_{ud}| = 0.9739(27)\left[\frac{BR(\pi^+ \to e^+\nu_e(\gamma))}{1.2325\times10^{-4}}\right]^{\frac{1}{2}}, \tag{67.8}$$

which is normalized using the very precisely measured $BR(\pi^+ \to e^+\nu_e(\gamma)) = 1.2325(23)\times10^{-4}$ [7], rather than the theoretical branching ratio of $1.2350(2)\times10^{-4}$, which if used, would increase $|V_{ud}|$ to 0.9749(27). Theoretical uncertainties in pion beta decay are very small [21], leaving open more than an order of magnitude improvement of its experimental branching ratio before theory uncertainties become a problem. Although challenging, improved measurements of pion beta decay currently under discussion would allow this decay mode to compete with superallowed beta decays and future neutron decay efforts for the most precise direct $|V_{ud}|$ determination.

67.2 V_{us}

$|V_{us}|$ may be directly obtained from kaon decays, hyperon decays, and tau decays. Early determinations most often used $K\ell3$ decays:

$$\Gamma_{K\ell3} = \frac{G_F^2 M_K^5}{192\pi^3} S_{EW}(1+\delta_K^\ell + \delta_{SU2})C^2\,|V_{us}|^2\,f_+^2(0) I_K^\ell. \tag{67.9}$$

Here, ℓ refers to either e or μ, G_F is the Fermi constant, M_K is the kaon mass, S_{EW} is the short-distance radiative correction, δ_K^ℓ is the mode-dependent long-distance radiative correction, $f_+(0)$ is the calculated form factor at zero momentum transfer for the $\ell\nu$ system, and I_K^ℓ is the phase-space integral, which depends on measured semileptonic form factors. For charged kaon decays, δ_{SU2} is the deviation from one of the ratio of $f_+(0)$ for the charged to neutral kaon decay; it is zero for the neutral kaon. C^2 is 1 (1/2) for neutral (charged) kaon decays. Most early determinations of $|V_{us}|$ were based solely on $K \to \pi e \nu$ decays; $K \to \pi\mu\nu$ decays were not used because of large uncertainties in I_K^μ. The experimental measurements are the semileptonic decay widths (based on the semileptonic branching fractions and lifetime) and form factors (allowing calculation of the phase space integrals). Theory is needed for S_{EW}, δ_K^ℓ, δ_{SU2}, and $f_+(0)$.

Many measurements during the last 20 years have resulted in a shift in $|V_{us}|$. Most importantly, the $K \to \pi e \nu$ branching fractions are significantly different than much earlier PDG averages, probably as a result of inadequate treatment of radiation in older experiments. This effect was first observed by BNL E865 [22] in the charged kaon system and then by KTeV [23,24] in the neutral kaon system; subsequent measurements were made by KLOE [25–28], NA48 [29–31], and ISTRA+ [32]. Current averages (*e.g.*, by the PDG [33] or Flavianet [34]) of the semileptonic branching fractions are based only on recent, high-statistics experiments where the treatment of radiation is clear. In addition to measurements of branching fractions, new measurements of lifetimes [35] and form factors [36–40], have resulted in improved precision for all of the experimental inputs to $|V_{us}|$. Precise measurements of form factors for $K_{\mu 3}$ decay make it possible to use both semileptonic decay modes to extract V_{us}.

Following the analysis of Moulson [41] and the Flavianet group [34, 42], along with recent improvements in the QED radiative corrections [43], one finds [44], after including the isospin violating effect, δ_{SU2} , the values of $|V_{us}|f_+(0)$ in Table 67.1. The average of these measurements, including correlation effects [44] gives

$$f_+(0)|V_{us}| = 0.21635(38)(3) \tag{67.10}$$

where the errors correspond to Kaon experimental parameters and radiative corrections respectively.

Lattice QCD calculations of $f_+(0)$ have been carried out for 2, 2+1, and 2+1+1 quark flavors and range from about 0.96 to 0.97. Here, we illustrate recent FLAG (2020) updated averages [45] for 2+1 and 2+1+1 flavors:

$$\begin{aligned} f_+(0) &= 0.9677(27) \quad N_f = 2+1 \\ f_+(0) &= 0.9698(17) \quad N_f = 2+1+1 \end{aligned} \tag{67.11}$$

One finds from Eq. (67.10) and Eq. (67.11),

$$\begin{aligned} |V_{us}| &= 0.2236(4)_{\rm exp+RC}(6)_{\rm lattice} \ (N_f = 2+1, \ K_{\ell 3} \text{ decays}) \\ &= 0.2231(4)_{\rm exp+RC}(4)_{\rm lattice} \ (N_f = 2+1+1, \ K_{\ell 3} \text{ decays}) \end{aligned} \tag{67.12}$$

Table 67.1: $|V_{us}|f_+(0)$ from $K\ell 3$, based on ref. [44]

Decay Mode	$\lvert V_{us}\rvert f_+(0)$
$K^\pm e3$	0.21714 ± 0.00091
$K^\pm \mu 3$	0.21703 ± 0.00114
$K_L e3$	0.21617 ± 0.00047
$K_L \mu 3$	0.21664 ± 0.00058
$K_S e3$	0.21530 ± 0.00122
$K_S \mu 3$	0.21265 ± 0.00467
Average (including correlation effects [44])	0.21635 ± 0.00038

A value of V_{us} can also be obtained from a comparison of the radiative inclusive decay rates for $K \to \mu\nu(\gamma)$ and $\pi \to \mu\nu(\gamma)$ combined with a lattice gauge theory calculation of f_{K^+}/f_{π^+} via

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.23871(20) \left[\frac{\Gamma(K \to \mu\nu(\gamma))}{\Gamma(\pi \to \mu\nu(\gamma))}\right]^{\frac{1}{2}} \tag{67.13}$$

with the small error coming from electroweak radiative corrections [46–48]; these corrections were confirmed by direct lattice calculation of the kaon and pion leptonic decay rates [47,48]. Employing

$$\frac{\Gamma(K \to \mu\nu(\gamma))}{\Gamma(\pi \to \mu\nu(\gamma))} = 1.3367(28), \tag{67.14}$$

which includes $\Gamma(K \to \mu\nu(\gamma)) = 5.134(11) \times 10^7 s^{-1}$ [41,49], leads to

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27600(37). \tag{67.15}$$

Employing the FLAG [45] lattice QCD averages for the isospin broken decay constants

$$\begin{aligned} \frac{f_{K^+}}{f_{\pi^+}} &= 1.1917(37) \qquad N_f = 2+1 \\ &= 1.1932(21) \quad N_f = 2+1+1. \end{aligned} \tag{67.16}$$

along with the value of $|V_{ud}|$ in Eq. (67.4) leads to

$$\begin{aligned} |V_{us}| &= 0.2255(8) \ (N_f = 2+1, \ K_{\mu 2} \text{ decays}) \\ &= 0.2252(5) \ (N_f = 2+1+1, \ K_{\mu 2} \text{ decays}). \end{aligned} \tag{67.17}$$

Together, weighted averages of the $K\ell 3$ (Eq. (67.12)) and $K\mu 2$ (Eq. (67.17)) values give similar results for $N_f = 2{+}1$ and $2{+}1{+}1$ flavors:

$$\begin{aligned} |V_{us}| &= 0.2244(5) \quad N_f = 2+1 \\ |V_{us}| &= 0.2243(4) \quad N_f = 2+1+1. \end{aligned} \tag{67.18}$$

Note that the differences between $K\ell 3$ and $K\mu 2$ values for V_{us} differ by 2 and 3 sigma, respectively, for $N_f = 2{+}1$ and $2{+}1{+}1$ flavors. One should therefore scale the uncertainties in Eq. (67.18) accordingly. For that reason, we allow for a scale factor of 2.7 for both 2+1 and 2+1+1 flavors and average the two values. That approximate procedure leads to $|V_{us}| = 0.2243(8)$ which we use when we consider the first row test of CKM unitarity.

It should be mentioned that hyperon decay fits suggest [50]

$$|V_{us}| = 0.2250(27) \text{ (Hyperon Decays)} \tag{67.19}$$

modulo SU(3) breaking effects that could shift that value up or down. We note that a representative effort [51] that incorporates SU(3) breaking found $V_{us} = 0.226(5)$. Strangeness changing tau decays, averaging both inclusive and exclusive measurements, give [52]

$$|V_{us}| = 0.2221(13) \text{ (Tau Decays)} \ , \tag{67.20}$$

which differs by about 2 sigma from the kaon determination discussed above, and would, if combined with V_{ud} from super-allowed beta decays, lead to a 4 sigma deviation from unitarity. This discrepancy results mainly from the inclusive tau decay results that rely on Finite Energy Sum Rule techniques and assumptions, as well as experimental uncertainties. Recent investigation of that approach suggests a larger value for V_{us}, which is more in accord with other determinations [53].

Employing the values of V_{ud} and V_{us} with an error scale factor of 2 from Eq. (67.4) and the average obtained after rescaling the errors from Eq. (67.18), respectively, leads to the unitarity consistency check

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9985(6)(4). \tag{67.21}$$

where the first error is the uncertainty from $|V_{ud}|^2$ and the second error is the uncertainty from the average $|V_{us}|^2$ from $N_f = 2{+}1{+}1$. and $N_f = 2+1$. One finds about an overall 2 sigma deviation from unitarity. (The deviation increases to 3 sigma if nuclear structure uncertainties are ignored.) That deviation could be due a problem with $|V_{ud}|$ theory (RC or NS), the lattice determination of $f_+(0)$ or new physics.

67.3 CKM Unitarity Constraints

The current 2 sigma experimental disagreement with unitarity, $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9985(7)$, still provides strong confirmation of Standard Model radiative corrections (which range between 3-4% depending on the nucleus used) at a high significance level [54]. In addition, it implies constraints on "New Physics" effects at both the tree and quantum loop levels. Those effects could be in the form of contributions to nuclear beta decays, K decays and/or muon decays, with the last of these providing normalization via the muon lifetime [55], which is used to obtain the Fermi constant, $G_\mu = 1.1663787(6) \times 10^{-5}\text{GeV}^{-2}$.

In the following examples, we illustrate the implications of CKM unitarity for (1) exotic muon decays [56] (beyond ordinary muon decay $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$) and (2) new heavy quark mixing V_{uD} [57]. Other examples in the literature [58, 59] include Z_χ boson quantum loop effects, supersymmetry, leptoquarks, compositeness etc.

67.3.1 *Exotic Muon Decays*

If additional lepton flavor violating decays such as $\mu^+ \to e^+\bar{\nu}_e\nu_\mu$ (wrong neutrinos) occur, they would cause confusion in searches for neutrino oscillations at, for example, muon storage rings/neutrino factories or other neutrino sources from muon decays. Calling the rate for all such decays Γ(exotic μ decays), they should be subtracted before the extraction of G_μ and normalization of the CKM matrix. Since that is not done and unitarity works, one has (at one-sided 95% CL)

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 1 - BR(\text{exotic } \mu \text{ decays}) \geq 0.9975 \tag{67.22}$$

or

$$BR(\text{exotic } \mu \text{ decays}) \leq 0.0025\ . \tag{67.23}$$

This bound is a factor of 10 better than the direct experimental bound on $\mu^+ \to e^+\bar{\nu}_e\nu_\mu$.

67.3.2 *New Heavy Quark Mixing*

Heavy D quarks naturally occur in fourth quark generation models and some heavy quark "new physics" scenarios such as E_6 grand unification. Their mixing with ordinary quarks gives rise to V_{uD}, which is constrained by unitarity (one sided 95% CL)

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 1 - |V_{uD}|^2 \geq 0.9975$$
$$|V_{uD}| \leq 0.05\ . \tag{67.24}$$

A similar constraint applies to heavy neutrino mixing and the couplings $V_{\mu N}$ and V_{eN}.

68. CP Violation in K_L^0 Decays

Revised August 2021 by C.-J. Lin (LBNL).

The symmetries C (particle-antiparticle interchange) and P (space inversion) hold for strong and electromagnetic interactions. After the discovery of large C and P violation in the weak interactions, it appeared that the product CP was a good symmetry. In 1964 CP violation was observed in K^0 decays at a level given by the parameter $\epsilon \approx 2.3 \times 10^{-3}$.

A unified treatment of CP violation in K, D, B, and B_s mesons is given in "CP Violation in Meson Decays" by D. Kirkby and Y. Nir in this *Review*. A more detailed review including a thorough discussion of the experimental techniques used to determine CP violation parameters is given in a book by K. Kleinknecht [1]. Here we give a concise summary of the formalism needed to define the parameters of CP violation in K_L decays, and a description of our fits for the best values of these parameters.

68.1 Formalism for CP violation in Kaon decay

CP violation has been observed in the semi-leptonic decays $K_L^0 \to \pi^\mp \ell^\pm \nu$, and in the nonleptonic decay $K_L^0 \to 2\pi$. The experimental numbers that have been measured are

$$A_L = \frac{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) - \Gamma(K_L^0 \to \pi^+ \ell^- \nu)}{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) + \Gamma(K_L^0 \to \pi^+ \ell^- \nu)} \tag{68.1a}$$

$$\eta_{+-} = A(K_L^0 \to \pi^+\pi^-)/A(K_S^0 \to \pi^+\pi^-) = |\eta_{+-}|\, e^{i\phi_{+-}} \tag{68.1b}$$

$$\eta_{00} = A(K_L^0 \to \pi^0\pi^0)/A(K_S^0 \to \pi^0\pi^0) = |\eta_{00}|\, e^{i\phi_{00}} \ . \tag{68.1c}$$

CP violation can occur either in the $K^0 - \overline{K}^0$ mixing or in the decay amplitudes. Assuming CPT invariance, the mass eigenstates of the K^0–$\overline{K}^0$ system can be written

$$|K_S\rangle = p|K^0\rangle + q|\overline{K}^0\rangle \ , \quad |K_L\rangle = p|K^0\rangle - q|\overline{K}^0\rangle \ . \tag{68.2}$$

If CP invariance held, we would have $q = p$ so that K_S would be CP-even and K_L CP-odd. (We define $|\overline{K}^0\rangle$ as $CP\ |K^0\rangle$). CP violation in K^0–$\overline{K}^0$ mixing is then given by the parameter $\widetilde{\epsilon}$ where

$$\frac{p}{q} = \frac{(1+\widetilde{\epsilon})}{(1-\widetilde{\epsilon})} \ . \tag{68.3}$$

CP violation can also occur in the decay amplitudes

$$A\Big(K^0 \to \pi\pi(I)\Big) = A_I e^{i\delta_I} \ , \quad A\Big(\overline{K}^0 \to \pi\pi(I)\Big) = A_I^* e^{i\delta_I} \ , \tag{68.4}$$

where I is the isospin of $\pi\pi$, δ_I is the final-state phase shift, and A_I would be real if CP invariance held. The CP-violating observables are usually expressed in terms of ϵ and ϵ' defined by

$$\eta_{+-} = \epsilon + \epsilon' \ , \quad \eta_{00} = \epsilon - 2\epsilon' \ . \tag{68.5a}$$

One can then show [2]

$$\epsilon = \widetilde{\epsilon} + i\,\Big(\mathrm{Im}\ A_0/\mathrm{Re}\ A_0\Big) \ , \tag{68.5b}$$

$$\sqrt{2}\epsilon' = ie^{i(\delta_2-\delta_0)}(\mathrm{Re}\,A_2/\mathrm{Re}\,A_0)\,\Big(\mathrm{Im}\,A_2/\mathrm{Re}\,A_2 - \mathrm{Im}\,A_0/\mathrm{Re}\,A_0\Big) \ , \tag{68.5c}$$

$$A_L = 2\mathrm{Re}\ \epsilon/(1+|\epsilon|^2) \approx 2\mathrm{Re}\ \epsilon \ . \tag{68.5d}$$

In Eq. (68.5a), small corrections [3] of order $\epsilon' \times \mathrm{Re}\ (A_2/A_0)$ are neglected, and Eq. (68.5d) assumes the $\Delta S = \Delta Q$ rule.

The quantities Im A_0, Im A_2, and Im $\widetilde{\epsilon}$ depend on the choice of phase convention, since one can change the phases of K^0 and $\overline{K}^0$ by a transformation of the strange quark state $|s\rangle \to |s\rangle\ e^{i\alpha}$; of course, observables are unchanged. It is possible by a choice of phase convention to set Im A_0 or Im A_2 or Im $\widetilde{\epsilon}$ to zero, but none of these is zero with the usual phase conventions in the Standard Model. The choice Im $A_0 = 0$ is called the Wu-Yang phase convention [4], in which case $\epsilon = \widetilde{\epsilon}$. The value of ϵ' is independent of phase convention, and a nonzero value demonstrates CP violation in the decay amplitudes, referred to as direct CP violation. The possibility that direct CP violation is essentially zero, and that CP violation occurs only in the mixing matrix, was referred to as the superweak theory [5].

By applying CPT invariance and unitarity the phase of ϵ is given approximately by

$$\phi_\epsilon \ \approx\ \tan^{-1}\frac{2(m_{K_L} - m_{K_S})}{\Gamma_{K_S} - \Gamma_{K_L}} \approx 43.52 \pm 0.05^\circ \ , \tag{68.6a}$$

while Eq. (68.5c) gives the phase of ϵ' to be

$$\phi_{\epsilon'} = \delta_2 - \delta_0 + \frac{\pi}{2} \approx 42.3 \pm 1.5^\circ \ , \tag{68.6b}$$

where the numerical value is based on an analysis of π–π scattering using chiral perturbation theory [6]. The approximation in Eq. (68.6a) depends on the assumption that direct CP violation is very small in all K^0 decays. This is expected to be good to a few tenths of a degree, as indicated by the small value of ϵ' and of η_{+-0} and η_{000}, the CP-violation parameters in the decays $K_S \to \pi^+\pi^-\pi^0$ [7], and $K_S \to \pi^0\pi^0\pi^0$ [8]. The relation in Eq. (68.6a) is exact in the superweak theory, so this is sometimes called the superweak-phase $\phi_{\rm SW}$. An important point for the analysis is that $\cos(\phi_{\epsilon'} - \phi_\epsilon) \simeq 1$. The consequence is that only two real quantities need be measured, the magnitude of ϵ and the value of (ϵ'/ϵ), including its sign. The measured quantity $|\eta_{00}/\eta_{+-}|^2$ is very close to unity so that we can write

$$|\eta_{00}/\eta_{+-}|^2 \approx 1 - 6\mathrm{Re}\ (\epsilon'/\epsilon) \approx 1 - 6\epsilon'/\epsilon \ , \tag{68.7a}$$

$$\mathrm{Re}(\epsilon'/\epsilon) \approx \frac{1}{3}(1 - |\eta_{00}/\eta_{+-}|) \ . \tag{68.7b}$$

From the experimental measurements in this edition of the *Review*, and the fits discussed in the next section, one finds

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}, \tag{68.8a}$$

$$\phi_\epsilon = (43.5 \pm 0.5)^\circ, \tag{68.8b}$$

$$\mathrm{Re}(\epsilon'/\epsilon) \approx \epsilon'/\epsilon = (1.66 \pm 0.23) \times 10^{-3}, \tag{68.8c}$$

$$\phi_{+-} = (43.4 \pm 0.5)^\circ, \tag{68.8d}$$

$$\phi_{00} - \phi_{+-} = (0.34 \pm 0.32)^\circ, \tag{68.8e}$$

$$A_L = (3.32 \pm 0.06) \times 10^{-3}. \tag{68.8f}$$

Direct CP violation, as indicated by ϵ'/ϵ, is expected in the Standard Model. However, the numerical value cannot be reliably predicted because of theoretical uncertainties [9]. The value of A_L agrees with Eq. (68.5d). The values of ϕ_{+-} and $\phi_{00} - \phi_{+-}$ are used to set limits on CPT violation [see "Tests of Conservation Laws"].

68.2 Fits for K_L^0 CP-violation parameters

In recent years, K_L^0 CP-violation experiments have improved our knowledge of CP-violation parameters,

and their consistency with the expectations of CPT invariance and unitarity. To determine the best values of the CP-violation parameters in $K_L^0 \to \pi^+\pi^-$ and $\pi^0\pi^0$ decay, we make two types of fits, one for the phases ϕ_{+-} and ϕ_{00} jointly with Δm and τ_S, and the other for the amplitudes $|\eta_{+-}|$ and $|\eta_{00}|$ jointly with the $K_L^0 \to \pi\pi$ branching fractions.

68.2.1 *Fits to ϕ_{+-}, ϕ_{00}, $\Delta\phi$, Δm, and τ_S data*

These are joint fits to the data on ϕ_{+-}, ϕ_{00}, the phase difference $\Delta\phi = \phi_{00} - \phi_{+-}$, the $K_L^0 - K_S^0$ mass difference Δm, and the K_S^0 mean life τ_S, including the effects of correlations.

Measurements of ϕ_{+-} and ϕ_{00} are highly correlated with Δm and τ_S. Some measurements of τ_S are correlated with Δm. The correlations are given in the footnotes of the ϕ_{+-} and ϕ_{00} sections of the K_L^0 Listings, and the τ_S section of the K_S^0 Listings.

In most cases, the correlations are quoted as 100%, with the value and error of ϕ_{+-} or ϕ_{00} given at a fixed value of Δm and τ_S, with additional terms specifying the dependence of the value on Δm and τ_S. These cases lead to diagonal bands in Figs. 68.1

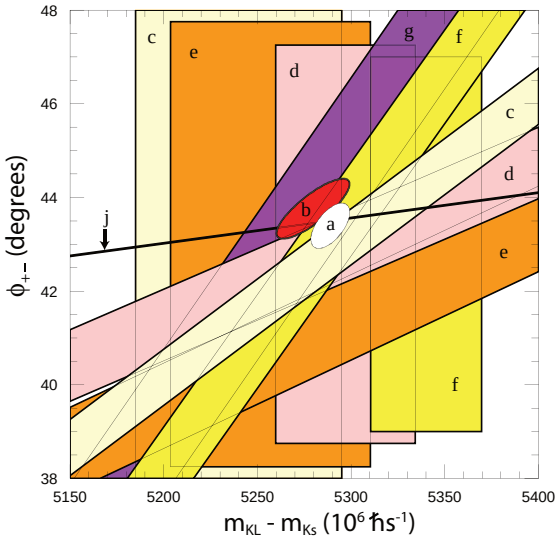

Figure 68.1: ϕ_{+-} vs Δm for experiments which do not assume CPT invariance. Δm measurements appear as vertical bands spanning $\Delta m \pm 1\sigma$, cut near the top and bottom to aid the eye. Most ϕ_{+-} measurements appear as diagonal bands spanning $\phi_{+-} \pm \sigma_\phi$. Data are labeled by letters: "b"–FNAL KTeV, "c"–CERN CPLEAR, "d"–FNAL E773, "e"–FNAL E731, "f"–CERN, "g"–CERN NA31, and are cited in Table 68.1. The narrow band "j" shows ϕ_{SW}. The ellipse "a" shows the $\chi^2 = 1$ contour of the fit result.

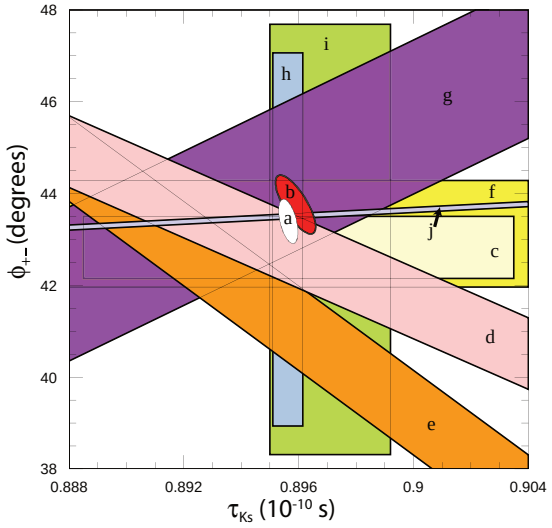

Figure 68.2: ϕ_{+-} vs τ_S. τ_S measurements appear as vertical bands spanning $\tau_S \pm 1\sigma$, some of which are cut near the top and bottom to aid the eye. Most ϕ_{+-} measurements appear as diagonal or horizontal bands spanning $\phi_{+-} \pm \sigma_\phi$. Data are labeled by letters: "b"–FNAL KTeV, "c"–CERN CPLEAR, "d"–FNAL E773, "e"–FNAL E731, "f"–CERN, "g"–CERN NA31, "h"–CERN NA48, "i"–CERN NA31, and are cited in Table 68.1. The narrow band "j" shows ϕ_{SW}. The ellipse "a" shows the fit result's $\chi^2 = 1$ contour.

and 68.2. The KTeV experiment [10] quotes its results as values of Δm, τ_S, ϕ_ϵ, Re(ϵ'/ϵ), and Im(ϵ'/ϵ) with correlations, leading to the ellipses labeled "b." The correlations for the KTeV measurements are given in the Im(ϵ'/ϵ) section of the K^0_L Listings. For small $|\epsilon'/\epsilon|$, $\phi_{+-} \approx \phi_\epsilon + \text{Im}(\epsilon'/\epsilon)$.

Table 68.1: References, Document ID's, and sources corresponding to the letter labels in the figures. The data are given in the ϕ_{+-} and Δm sections of the K_L Listings, and the τ_S section of the K_S Listings.

j	This *Review*	SUPERWEAK 16	

The data on τ_S, Δm, and ϕ_{+-} shown in Figs. 68.1 and 68.2 are combined with data on ϕ_{00} and $\phi_{00} - \phi_{+-}$ in two fits, one without assuming CPT, and the other with this assumption. The results without assuming CPT are shown as ellipses labeled "a." These ellipses are seen to be in good agreement with the superweak phase

$$\phi_{SW} = \tan^{-1}\left(\frac{2\Delta m}{\Delta\Gamma}\right) = \tan^{-1}\left(\frac{2\Delta m \tau_S \tau_L}{\hbar(\tau_L - \tau_S)}\right) . \qquad (68.9)$$

In Figs. 68.1 and 68.2, ϕ_{SW} is shown as narrow bands labeled "j."

Table 68.2 column 2, "Fit w/o CPT," gives the resulting fitted parameters, while Table 68.3 gives the correlation matrix for this fit. The white ellipses labeled "a" in Figure 68.1 and 68.2 are the $\chi^2 = 1$ contours for this fit.

For experiments which have dependencies on unseen fit parameters, that is, parameters other than those shown on the x or y axis of the figure, their band positions are evaluated using the fit results and their band widths include the fitted uncertainty in the unseen parameters. This is also true for the ϕ_{SW} bands.

If CPT invariance and unitarity are assumed, then by Eq. (68.6a), the phase of ϵ is constrained to be approximately equal to

$$\phi_{SW} = (43.50258 \pm 0.00021)^\circ + 54.1(\Delta m - 0.5289)^\circ + 32.0(\tau_S - 0.89564) \qquad (68.10)$$

where we have linearized the Δm and τ_S dependence of Eq. (68.9). The error ± 0.00021 is due to the uncertainty in τ_L. Here Δm has units $10^{10}\,\hbar\,\text{s}^{-1}$ and τ_S has units 10^{-10} s.

If in addition we use the observation that $Re(\epsilon'/\epsilon) \ll 1$ and $cos(\phi_{\epsilon'} - \phi_\epsilon) \simeq 1$, as well as the numerical value of $\phi_{\epsilon'}$ given in Eq. (68.6b), then Eqs. 68.5a, which are sketched in Fig 68.3, lead to the constraint

$$\begin{aligned} \phi_{00} - \phi_{+-} &\approx -3\ \text{Im}\left(\frac{\epsilon'}{\epsilon}\right) \\ &\approx -3\ \text{Re}\left(\frac{\epsilon'}{\epsilon}\right)\tan(\phi_{\epsilon'} - \phi_\epsilon) \\ &\approx 0.006^\circ \pm 0.008^\circ\ , \end{aligned} \qquad (68.11)$$

so that $\phi_{+-} \approx \phi_{00} \approx \phi_\epsilon \approx \phi_{SW}$.

In the fit assuming CPT, we constrain $\phi_\epsilon = \phi_{SW}$ using the linear expression in Eq. (68.10), and constrain $\phi_{00} - \phi_{+-}$ using Eq. (68.11). These constraints are inserted into the Listings with the Document ID of SUPERWEAK 16. Some additional data for which the authors assumed CPT are added to this fit or substitute for other less precise data for which the authors did not make this assumption. See the Listings for details.

The results of this fit are shown in Table 68.2, column 3, "Fit w/CPT," and the correlation matrix is shown in Table 68.4. The Δm precision is improved by the CPT assumption.

68.2.2 *Fits for ϵ'/ϵ, $|\eta_{+-}|$, $|\eta_{00}|$, and $B(K_L \to \pi\pi)$*

We list measurements of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ. Independent information on $|\eta_{+-}|$ and $|\eta_{00}|$ can be obtained from

Table 68.2: Fit results for ϕ_{+-}, Δm, τ_S, ϕ_{00}, $\Delta\phi = \phi_{00} - \phi_{+-}$, and ϕ_ϵ without and with the CPT assumption

ϕ_{00}	0.957	0.958	-0.306	1.000	0.189	0.981
$\Delta\phi$	-0.105	-0.007	0.004	0.189	1.000	-0.006
ϕ_ϵ	0.995	0.977	-0.312	0.981	-0.006	1.000

measurements of the K_L^0 and K_S^0 lifetimes (τ_L, τ_S), and branching ratios (B) to $\pi\pi$, using the relations

$$|\eta_{+-}| = \left[\frac{\mathrm{B}(K_L^0 \to \pi^+\pi^-)}{\tau_L}\,\frac{\tau_S}{\mathrm{B}(K_S^0 \to \pi^+\pi^-)}\right]^{1/2}, \quad (68.12a)$$

$$|\eta_{00}| = \left[\frac{\mathrm{B}(K_L^0 \to \pi^0\pi^0)}{\tau_L}\,\frac{\tau_S}{\mathrm{B}(K_S^0 \to \pi^0\pi^0)}\right]^{1/2}. \quad (68.12b)$$

For historical reasons, the branching ratio fits and the CP-violation fits are done separately, but we want to include the influence of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ measurements on $\mathrm{B}(K_L^0 \to \pi^+\pi^-)$ and $\mathrm{B}(K_L^0 \to \pi^0\pi^0)$ and vice versa. We approximate a global fit to all of these measurements by first performing two independent fits: 1) BRFIT, a fit to the K_L^0 branching ratios, rates, and mean life, and 2) ETAFIT, a fit to the $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{+-}/\eta_{00}|$, and ϵ'/ϵ measurements. The results from fit 1, along with the K_S^0 values from this edition, are used to compute values of $|\eta_{+-}|$ and $|\eta_{00}|$, which are included as measurements in the $|\eta_{00}|$ and $|\eta_{+-}|$ sections with a document ID of BRFIT 16. Thus, the fit values of $|\eta_{+-}|$ and $|\eta_{00}|$ given in this edition include both the direct measurements and the results from the branching ratio fit.

The process is reversed in order to include the direct $|\eta|$ measurements in the branching ratio fit. The results from fit 2 above (before including BRFIT 16 values) are used along with the K_L^0 and K_S^0 mean lives and the $K_S^0 \to \pi\pi$ branching fractions to compute the K_L^0 branching ratio $\Gamma(K_L^0 \to \pi^0\pi^0)/\Gamma(K_L^0 \to \pi^+\pi^-)$. This branching ratio value is included as a measurement in the branching ratio section with a document ID of ETAFIT 16. Thus, the K_L^0 branching ratio fit values in this edition include the results of the direct measurement of $|\eta_{00}/\eta_{+-}|$ and ϵ'/ϵ. Most individual measurements of $|\eta_{+-}|$ and $|\eta_{00}|$ enter our fits directly via the corresponding measurements of $\Gamma(K_L^0 \to \pi^+\pi^-)/\Gamma$(total) and $\Gamma(K_L^0 \to \pi^0\pi^0)/\Gamma$(total), and those that do not have too large errors to have any influence on the fitted values of these branching ratios. A more detailed discussion of these fits is given in the 1990 edition of this *Review* [20].

69. Review of Multibody Charm Analyses

Revised August 2021 by D.M. Asner (BNL) and J. Rademacker (Bristol U.).

69.1 Overview

The study of multibody charm decays is a vibrant field, with many new experimental results with implications reaching beyond charm, vast and fast-increasing datasets, and new developments in theory and experimental technique. This review is structured as follows. Sec. 69.2 summarises key elements of the theory of multibody charm decays. Sec. 69.3 describes model-independent approaches for precision measurements of mixing and *CP* violation and the critical role of charm threshold data in this context. Sec. 69.4 reviews applications of the techniques described, and their results. In Sec. 69.5, we conclude.

69.2 Kinematics & Models

The differential decay rate to a point $\mathbf{s} = (s_1, \ldots, s_n)$ in n dimensional phase space can be expressed as

$$d\Gamma = |\mathcal{M}(\mathbf{s})|^2 \left| \frac{\partial^n \phi}{\partial(s_1 \ldots s_n)} \right| d^n s \qquad (69.1)$$

where $|\partial^n \phi / \partial(s_1 \ldots s_n)|$ represents the density of states at $\mathbf{s}$, and $\mathcal{M}$ the matrix element for the decay at that point in phase space, which is $2, 5, 8, \ldots$ dimensional for D decays to $3, 4, 5, \ldots$ spinless particles. Additional parameters are required to fully describe decays involving particles with non-zero spin in the initial or final state.

For the important case of D decays to three pseudoscalars, the decay kinematics can be represented in a two-dimensional Dalitz plot [1]. This is usually parametrized in terms of $s_{12} \equiv (p_1 + p_2)^2$ and $s_{23} \equiv (p_2 + p_3)^2$, where p_1, p_2, and p_3 are the four-momenta of the final state particles. In terms of these variables, phase-space density is constant across the kinematically allowed region, so that any structure seen in the Dalitz plot is a direct consequence of the dynamics encoded in $|\mathcal{M}|^2$. Note that here, because the three-momenta of the decay products are confined to a plane, no parity violating kinematic observables can be constructed (unless they also violate rotational invariance). This is not the case for decays to four or more particles. These can therefore not be unambiguously described in terms of analogously-defined variables s_{ij}, s_{ijk}, which are parity-even. The use of parity-odd observables in four body decays is discussed below.

In the widely-used isobar approach, the matrix element $\mathcal{M}$ is modeled as a sum of interfering decay amplitudes, each proceeding through resonant two-body decays [2–6]. See Refs. [2,7,8] for a review of resonance phenomenology. In most analyses, each resonance is described by a relativistic Breit-Wigner [9] or Flatté [10] lineshape, and the model includes a non-resonant term with a constant phase and magnitude. This approach has well-known theoretical limitations, such as the violation of unitarity and analyticity, which can break the relationship between magnitude and phase across phase space. This motivates the use of more sophisticated descriptions, especially for broad, overlapping resonances (frequently found in S-wave components) where these limitations are particularly problematic. In charm analyses, these approaches have included the K-matrix approach [11] which respects two-body unitarity; the use of LASS scattering data [12]; dispersive methods [13–16]; multi-meson models using chiral Lagrangians [17–20] and methods based on chiral unitarity [21, 22]; QCD factorisation [23–26]; and quasi model-independent parametrizations which use generic lineshapes, with minimal theory input and many free parameters, for a subset of resonances [27–32]. An important example, with a rich resonance structure, is $D^0 \to K_S\pi^+\pi^-$, which is a key channel in Charge-Parity (*CP*) violation and charm-mixing analyses. The first analysis by CLEO [33] described the Dalitz plot with approximately 5000 signal events with 10 resonant components. This and analyses by Belle [34] and CDF [35] model the Dalitz plot as a sum of Breit Wigner and Flatté line shapes, and a non-resonant component. BaBar [36] and a more recent Belle analysis [37] on the other hand use a K-matrix description for the $\pi\pi$ S-wave based on [38] and input from LASS scattering data for the $K\pi$ S-wave, with no need to add a non-resonant component to describe the data. This approach is also followed in the latest analysis of this channel, published jointly by BaBar and Belle [39]. In total 18 resonant components, including four doubly Cabibbo suppressed ones, are required to describe the Dalitz plot with 1.1M $D^0 \to K_S\pi^+\pi^-$ events. Belle's and BaBar's data have been re-analyzed by [23] in a QCD factorization framework, using line-shape parametrizations for the S [40, 41] and P wave [14] contributions that preserve two-body unitarity and analyticity. The measurements give compatible results for the components they share.

The field of charm amplitude analyses remains very active. Publications since the last update of this review two years ago include Dalitz plot analyses of $D_s^+ \to K^+K^-\pi^+$, $K^+K_S\pi^0$, $K_S^0\pi^+\pi^0$, $\pi^+\pi^-\pi^+$, $D^0 \to K_S^0K^+K^-$ by BES III [31, 32, 42–44]; $D^0 \to K^-\pi^+\eta$ by Belle [45]; a re-analysis of BaBar's $D^0 \to K_SK^+K^-$ data in a factorisation approach [26] and of LHCb's $D^+ \to K^+K^-K^+$ data [46] in a chiral unitarity approach [22]; four-body amplitude analyses of $D_s^+ \to \pi^+\pi^+\pi^-\eta$, $K^-K^+\pi^+\pi^0$, $K_S^0K^-\pi^+\pi^+$ by BES III [31, 47–49] and of $D^0 \to K^+K^-\pi^+\pi^-$ by LHCb [50]; and the amplitude analysis of the charm baryon decay $\Xi_c^0 \to \Xi^0K^+K^-$ by Belle [51]. Noteworthy is the increasing sophistication of recent amplitude analyses, most of which go substantially beyond the isobar model with Breit Wigner and Flatté lineshapes. However, with the notable exceptions of [15, 16, 22, 46, 52], they remain within the isobar framework which describes the decay as a series of two-body processes, and ignores long-range hadronic effects such as re-scattering and does not respect three (or four)-body unitarity and analyticity.

Several groups work on improved models. Dispersive techniques, which respect three-body unitarity and analyticity, have been applied to regions of the $D^+ \to K^-\pi^+\pi^+$ and $D^+ \to K_S\pi^0\pi^+$ Dalitz plots below the $\eta' K$ threshold [15,16], where they provide a good description of the data with fewer fit parameters than the isobar approach. Ref. [52] uses a unitary coupled channel approach to describe $D^+ \to K^-\pi^+\pi^+$, which has no restrictions on the kinematic range, but requires additional parameters to describe the Dalitz plot above the $\eta' K$ threshold. Using an effective chiral Lagrangian, the authors of Ref. [19] provide a description of the annihilation contribution to the decay amplitude which respects three-body unitarity. The approach provides a good description of LHCb $D^+ \to K^+K^-K^+$ data, with fewer parameters than an equivalent isobar model [46]. The same channel has more recently been re-analysed by the authors of [22], who argue that the internal emission diagram should dominate and use a chiral unitarity-based approach to achieve a reasonable description of the data with two free parameters.

Limitations in the theoretical description of interfering resonances are the leading source of systematic uncertainty in many analyses. This is set to become increasingly problematic given the statistical precision achievable with the vast, clean charm samples available at the B factories, LHCb, and their upgrades, and BES III. In some cases, the model uncertainty can be removed through model-independent methods, often relying on input from the charm threshold, as discussed below. The authors of [53] expand the scope and applicability of the quasi model-independent approach in amplitude fits. At the same time, increasingly sophisticated models are being developed, and applied to data. The authors of [20] and [54] provide valuable frameworks for sophisticated amplitude analyses.

69.3 Model Independent Methods and the Charm Threshold

The precision measurement of mixing or *CP* violation parameters such γ/ϕ_3 from multibody charm decays requires as input the phase-differences between the D^0 and $\overline{D}^0$ amplitudes across phase space, as well as their magnitudes, for each final state of interest. While the magnitudes are fairly easily measured, the phase information requires either amplitude models with reliable phase motion, or model-independent approaches.

Model-independent measurements of the relevant phase differences rely on interference effects in the decays of well-defined coherent superpositions of D^0 and $\overline{D}^0$. These are accessible at the charm threshold, where CLEO–c and BES III operate [55–63]. Charm mixing also results in a (time-dependent) $D^0 - \overline{D}^0$ su-

perposition, that can be used to measure the relevant phase information as input to γ/ϕ_3 measurements. This method is particularly powerful in doubly Cabibbo-suppressed decays such as $D^0 \to K^+\pi^-\pi^+\pi^-$, and when used in combination with threshold data [64,65]. Under some circumstances, with large data sets, the relevant strong phases and γ/ϕ_3 can be extracted simultaneously without external input, for example in simultaneous analysis of the $B^0 \to DK^+\pi^-$ Dalitz plot and that of the subsequent $D \to K^0_S\pi^+\pi^-$ decay [66]. However, the global effort to achieve a measurement of γ/ϕ_3 to sub-degree precision will continue to rely critically on input from the charm threshold and BES III's increasing datasets [67]. A particularly noteworthy recent development is the substantial improvement not only in the precision on γ but also on charm mixing parameters achieved through a combined fit of charm mixing, charm threshold, $B \to DK$ and related data [68].

The model-independent phase information of the charm decay is provided either integrated over the entire phase space of the decay, or in sub-regions/bins. The results can be expressed in terms of one complex parameter $\mathcal{Z} = Re^{-i\delta} = c + is$ per pair of *CP*-conjugate bins, with magnitude $R \leq 1$. Larger R values lead to higher sensitivity to γ/ϕ_3. Amplitude models can be used to optimise the binning for sensitivity to γ/ϕ_3, without introducing a model-dependent bias in the result; novel unbinned approaches are expected to increase the precision on γ in future analyses [69].

CLEO–c data have been analyzed to provide binned $\mathcal{Z}$ for the self-conjugate decays $D^0 \to K_S\pi^+\pi^-$, $K_SK^+K^-$, $\pi^+\pi^-\pi^+\pi^-$, and $K_S\pi^-\pi^+\pi^0$ and phase space-integrated values for $D^0, \overline{D}^0 \to K_SK^+\pi^-$, $K^+\pi^-\pi^0$ and $K^+\pi^-\pi^+\pi^+$ [70–75]. BES III significantly improved the precision for the $K_S\pi^+\pi^-$, $K_SK^+K^-$, $K^+\pi^-\pi^0$ and $K^+\pi^-\pi^+\pi^-$ final states [76–79]. Critically, BES III was able to perform this measurement in four separate bins of $K^+\pi^-\pi^+\pi^-$ phase space. Studies based on recent $D^0 \to K^\pm\pi^\mp\pi^\pm\pi^\mp$ amplitude models [30] indicate that such a binned analysis could lead to the most precise individual γ measurement [80], especially when combined with LHCb charm mixing data [65, 75, 81]. For self-conjugate decays such as $D^0 \to \pi^+\pi^-\pi^0$, analysed with a single pair of bins, $\mathcal{Z}$ is real-valued, and usually expressed in terms of the *CP*-even fraction $F_+ \equiv \frac{1}{2}(\mathrm{Re}(\mathcal{Z}) + 1)$, defined such that a *CP*-even eigenstate has $F_+ = 1$, while a *CP*-odd eigenstate has $F_+ = 0$ [61]. Recent analyses of CLEO–c data reveal that $D^0 \to \pi^+\pi^-\pi^0$ is compatible with being completely *CP*-even with $F_+ = 0.973 \pm 0.017$, while $D^0 \to K^+K^-\pi^0$ has $F_+ = 0.732 \pm 0.055$, $D^0 \to \pi^+\pi^-\pi^+\pi^-$ has $F_+ = 0.769 \pm 0.023$ and $D^0 \to K_S\pi^+\pi^-\pi^0$ has 0.238 ± 0.020 [62, 72, 73].

It is interesting to compare these values with those obtained from amplitude models as a cross-check of the models' phase-motion. $F_+^{4\pi\ \mathrm{model}} = 0.729 \pm 0.020$ calculated from Ref. [29]'s $D^0 \to \pi^+\pi^-\pi^+\pi^-$ model compares well to the measured value given above, as does $\left|\mathcal{Z}^{K3\pi\ \mathrm{model}}\right| = 0.459 \pm 0.025$ [30] to $\mathcal{Z}^{K3\pi\ \mathrm{meas}} = 0.44^{+0.10}_{-0.09}\ \exp(-i(161^{\circ\,+28^\circ}_{\ -18^\circ}))$ [75, 81]. Only for self-conjugate decays or multiple bins does the model provide relevant phase information. The latest bin wise comparisons between model and data for $D^0 \to K_S\pi^+\pi^-$, $K_SK^+K^-$, $\pi^+\pi^-\pi^+\pi^-$, and $K^\pm\pi^\mp\pi^\pm\pi^\mp$ can be found in [72, 76–79] and generally show good agreement, which is a welcome surprise given the preceding discussion on the theoretical shortcomings of such amplitude models.

69.4 Applications of multibody charm analyses

Amplitude analyses provide sensitivity to both relative magnitudes and phases of the interfering decay amplitudes. It is especially this sensitivity to phases that makes amplitude analyses such a uniquely powerful tool for studying a wide range of phenomena. Here we concentrate on their use for *CP* violation and mixing measurements in charm, and charm inputs to *CP* violation analyses in B meson decays (properties of light-meson resonances determined in D amplitude analyses are reported in the light-unflavored-meson section of this *Review*).

69.4.1 *Time-integrated searches for CP violation in charm*

Comparing the results of amplitude fits for *CP*-conjugate decay modes provides a measure of *CP* violation. Recent *CP* violation searches using this method include amplitude analyses of $D^0 \to K^0_S K^\pm\pi^\mp$ and $D^0 \to K^+K^-\pi^+\pi^-$ by LHCb [82, 83], and $D^0 \to K^+K^-\pi^+\pi^-$, $D^0 \to \pi^+\pi^-\pi^+\pi^-$ [29, 84] using CLEO data.

A widely-used amplitude model-independent technique to search for local *CP* violation is based on performing a χ^2 comparison of *CP*-conjugate phase-space distributions. This method was pioneered by BaBar [85] and developed further in [86–88], with results reported by BaBar [85, 89] and LHCb in $D^\pm \to K^+K^-\pi^\pm$ [90, 91], CDF in $D^0 \to K_S\pi^+\pi^-$ [35], and LHCb in $D^+ \to \pi^-\pi^+\pi^+$, $D^0 \to K^+K^-\pi^+\pi^-$, $D^0 \to \pi^+\pi^-\pi^+\pi^-$, and $\Xi_c^+ \to pK^-\pi^+$ [88, 92, 93]. Unbinned methods can increase sensitivity [94] and have been applied by LHCb to $D^+ \to \pi^-\pi^+\pi^+$, $D^0 \to \pi^+\pi^-\pi^0$, $D^0 \to \pi^+\pi^-\pi^+\pi$, and $\Xi_c^+ \to pK^-\pi^+$ [92, 93, 95, 96].

An alternative model-independent approach is based on observables in four body decays that are odd under motion reversal ("naïve T") [97–105], which is equivalent to P for scalar particles [105]. One such observable is $C_T = \vec{p}_2 \cdot (\vec{p}_3 \times \vec{p}_4) = (1/m_D)\epsilon_{\alpha\beta\gamma\delta}\, p_1^\alpha p_2^\beta p_3^\gamma p_4^\delta$, where $\vec{p}_i$ are the decay products' three momenta in the decay's rest frame, and p_i are their four-momenta. Identical particles (as in $D^0 \to K^+\underline{\pi}^-\pi^+\underline{\pi}^-$) are ordered by momentum magnitude. Comparing the P violating asymmetry $A_T \equiv \frac{\Gamma(C_T>0)-\Gamma(C_T<0)}{\Gamma(C_T>0)+\Gamma(C_T<0)}$ with its C-conjugate provides sensitivity to *CP* violation. Searches for *CP* violation in this manner have been carried out by BaBar, Belle, FOCUS and LHCb in $D^0 \to K^+K^-\pi^+\pi^-$ [106–109], $D^+ \to K^+K_S\pi^+\pi^-$, $D_s^+ \to K^+K_S\pi^+\pi^-$ [110], $D^0 \to K_S\pi^+\pi^-\pi^0$ [111], and $D^0 \to \pi^+\pi^-\pi^+\pi^-$ [96]. The authors of [109] use additional P-odd variables and [108,111]/[96] increase sensitivity by resolving four-body phase space in a binned/unbinned approach.

The results of all measurements described in this section are compatible with *CP* conservation in charm. Given the discovery of *CP* violation in $D^0 \to K^+K^-$, $D^0 \to \pi^+\pi^-$ decays [112], and the vast data samples about to be collected, one might expect this to change in the foreseeable future.

69.4.2 *CP violation in decays of Beauty to Charm*

Neutral D mesons originating from $B^- \to DK^-$ (here denoted as D_{B^-}) are a superposition of D^0 and $\overline{D}^0$ with a relative phase that depends on the CKM unitarity triangle parameter γ/ϕ_3,

$$D_{B^-} \propto D^0 + r_B e^{i(\delta_B - \gamma)}\overline{D}^0,$$

where δ_B is a *CP* conserving strong phase, and $r_B \sim 0.1$. In the corresponding *CP*-conjugate expression, γ/ϕ_3 changes sign. An amplitude analysis of the subsequent decay of the $D_{B^\pm}$ to a state accessible to both D^0 and $\overline{D}^0$ allows the measurement of γ/ϕ_3 [56, 113–116]. The method generalizes to similar B hadron decays, such as $B^0 \to DK^{*0}$. Measurements based on this technique have been reported by BaBar [117, 118], Belle [34, 119] and LHCb [120–129]. The most precise individual result with an uncertainty of $\sim 5^\circ$ comes from an amplitude model-independent study of $D_{B^-} \to K_S\pi^+\pi^-$ and $D_{B^-} \to K_SK^+K^-$ [130], using input from the charm threshold [70, 77] as described above. Combining measurements in multiple decay modes from LHCb, CLEO–c and BES III in an amplitude-model independent approach leads to a current uncertainty on γ/ϕ_3 of 4° [68, 131].

The interference between mixing and decay in $B^0 \to D^0h^0$ with $h^0 = \pi^0, \eta, \omega$ provides sensitivity to β, which can be extracted from the Dalitz plot of the subsequent $D^0 \to K_S\pi^+\pi^-$ decay [39, 132–135]. The combined BaBar/Belle analysis based on this technique resolved the ambiguity in β present in other measurements, such as $B^0 \to J/\psi K_S$, in favour of the solution compatible with other unitarity triangle constraints [39].

Further details on *CP* violation in beauty and charm can be found in [55, 136].

69.4.3 *Charm Mixing and CP violation*

Time-dependent amplitude analyses in decays to final states that are accessible to both D^0 and $\overline{D}^0$ have unique sensitivity to mixing parameters. A Dalitz plot analysis of a self-conjugate

final state, such as $K_S\pi^+\pi^-$ and $K_SK^+K^-$, allows the measurement of the phase difference between the relevant D^0 and $\overline{D}^0$ decay amplitudes, and thus a direct measurement of x and y, the normalized mass and width difference of the $D^0 - \overline{D}^0$ system's mass eigenstates. This is in contrast to decays like $D^0 \to K\pi$ [137] which only provide access to the decay-specific parameters x'^2, y'. The phase differences between D^0 and $\overline{D}^0$ amplitudes across the Dalitz plot affect these measurements in the same way as measurements of γ/ϕ_3 in $B^+ \to DK^+$, and can be taken into account in an amplitude model-independent way using the same charm threshold results [70,77]. This approach recently resulted the first observation of the mass difference of the neutral charm mass eigenstates by LHCb [138], using a model-independent analysis of $D^0 \to K_S\pi^+\pi^-$. The "bin flip" technique applied in this measurements exploits that *CP*-conjugate regions of the $D^0 \to K_S\pi^+\pi^-$ Dalitz plot have near-identical experimental efficiencies [139]. This measurement is also sensitive to *CP* violation in mixing and in the interference between mixing and decay, which is discussed further in [55,136]. The most precise values for charm mixing parameters result from a combination of charm data from LHCb and the charm threshold with input from γ-sensitive decays of the type $B^+ \to D^0K^+$ [68]. The substantial impact of the latter is noteworthy, as it improves the precision on y by a factor of two compared to the previous world average.

69.5 Summary

Multibody charm decays offer a rich phenomenology, including unique sensitivity to *CP* violation and charm mixing. This is a highly dynamic field with many new results (some of which we presented here) and rapidly increasing, high quality datasets. These datasets constitute a huge opportunity, but also a challenge to improve the theoretical descriptions of soft hadronic effects in multibody decays. For some measurements, model-independent methods, many relying on input from the charm threshold, provide a way of removing model-induced uncertainties. At the same time, substantial progress in the theoretical description of multibody decays is being made.

70. D^0-$\overline{D}^0$ Mixing

Revised September 2021 by D.M. Asner (BNL) and A.J. Schwartz (U. of Cincinnati).

The formalism for D^0-$\overline{D}^0$ mixing is closely related to that for CP violation; for further details on the latter, see the note "CP Violation in the Quark Sector" in this *Review*. The time evolution of the D^0–$\overline{D}^0$ system is described by the Schrödinger equation

$$i\frac{\partial}{\partial t}\begin{pmatrix}D^0(t)\\ \overline{D}^0(t)\end{pmatrix} = \left(\mathbf{M}-\frac{i}{2}\mathbf{\Gamma}\right)\begin{pmatrix}D^0(t)\\ \overline{D}^0(t)\end{pmatrix}, \tag{70.1}$$

where the $\mathbf{M}$ and $\mathbf{\Gamma}$ matrices are Hermitian, and CPT invariance requires that $M_{11} = M_{22} \equiv M$ and $\Gamma_{11} = \Gamma_{22} \equiv \Gamma$. The off-diagonal elements of $\mathbf{M}$ and $\mathbf{\Gamma}$ are referred to as the dispersive and absorptive parts, respectively, of the mixing. The mass eigenstates D_1 and D_2 of the Hamiltonian $\mathbf{M}$ - $i\mathbf{\Gamma}/2$ are defined as

$$|D_{1,2}\rangle \;\equiv\; p|D^0\rangle \pm q|\overline{D}^0\rangle\,, \tag{70.2}$$

where normalization imposes $|p|^2 + |q|^2 = 1$. If $p = \pm q$, then the mass eigenstates are CP eigenstates and CP is conserved. Our phase convention is $CP|D^0\rangle = -|\overline{D}^0\rangle$, which implies that, in the absence of CP violation, D_2 is CP-even and D_1 is CP-odd.

The eigenvalues of $\mathbf{M}$ - $i\mathbf{\Gamma}/2$ are

$$\omega_{1,2} \;=\; \left(M-\frac{i}{2}\Gamma\right) \pm \frac{q}{p}\left(M_{12}-\frac{i}{2}\Gamma_{12}\right) \;\equiv\; m_{1,2}-\frac{i}{2}\Gamma_{1,2}\,, \tag{70.3}$$

where $m_{1,2}$ and $\Gamma_{1,2}$ are real and correspond to the masses and decay widths, respectively, of the $D_{1,2}$ mass eigenstates. As the trace $\Gamma_{11} + \Gamma_{22} = 2\Gamma$ is unchanged by diagonalizing $\mathbf{\Gamma}$, Γ must equal $(\Gamma_1 + \Gamma_2)/2$, the mean decay width. Solving for the eigenstates of the eigenvalues yields

$$\left(\frac{q}{p}\right)^2 = \frac{M_{12}^* - \frac{i}{2}\Gamma_{12}^*}{M_{12}-\frac{i}{2}\Gamma_{12}}\,. \tag{70.4}$$

If CP is conserved, then $(q/p)^2 = 1$ and M_{12} and Γ_{12} must be real. In this case, the difference in eigenvalues is $\Delta m \equiv m_2 - m_1 = 2M_{12}$ and $\Delta\Gamma \equiv \Gamma_2 - \Gamma_1 = 2\Gamma_{12}$. The signs of Δm and $\Delta\Gamma$ are difficult to predict from theory and thus must be determined experimentally.

We define dimensionless mixing parameters x and y as

$$x \equiv \frac{\Delta m}{\Gamma} \tag{70.5}$$

$$y \equiv \frac{\Delta\Gamma}{2\Gamma}\,. \tag{70.6}$$

These parameters are measured in several ways. The most precise values are obtained by measuring the time dependence of D^0 decays. For all methods, the initial flavor of the D^0 or $\overline{D}^0$ when produced must be determined. The most common method used for this is to reconstruct $D^{*+} \to D^0\pi^+$ or $D^{*-} \to \overline{D}^0\pi^-$ decays; the charge of the accompanying pion (which has low momentum in the lab frame and is often referred to as the "soft" pion) determines the flavor of the neutral D. BaBar and LHCb have also identified the flavor of the neutral D by reconstructing the semileptonic decays $B^+ \to \overline{D}^0\ell^+\nu$, $B^0 \to D^{*-}\ell^+\nu$, $B^- \to D^0\ell^-\nu$, and $\overline{B}^0 \to D^{*+}\ell^-\nu$; in this case the charge of the accompanying lepton determines the D flavor. Both experiments have used both tags together to select "double-tagged" $B \to D^{*\pm}\ell^{\mp}\nu$, $D^{*\pm} \to (D^0, \overline{D}^0)\pi^{\pm}$ decays, which have especially high purity. At e^+e^- collider experiments such as Belle, BaBar, and BESIII, the D flavor can also be determined by fully reconstructing a flavor-specific D decay on the "opposite side" of an event, i.e., recoiling against the signal-side D decay.

At BESIII, where $D\overline{D}$ pairs are produced near their threshold via $e^+e^- \to \psi(3770) \to D^0\overline{D}^0$, there is relatively little background and the purity of opposite-side tagging is equivalent to that achieved using $D^{*\pm}$ decays. However, BESIII operates at a symmetric e^+e^- collider, and the $D\overline{D}$ pairs are produced almost at rest in the lab frame. As a consequence, the D's do not travel any appreciable distance before decaying, and time-dependent analyses are not possible. To overcome this, measurements of mixing at BESIII utilize the quantum coherence of the initial $\psi(3770) \to D^0\overline{D}^0$ state and time-integrated measurements [1–5].

70.1 Time-Dependent Analyses

Our notation is as follows: Cabibbo-favored (CF) decay amplitudes are denoted $\overline{A}_f \equiv \langle f|H|\overline{D}^0\rangle$ and $A_{\overline{f}} \equiv \langle \overline{f}|H|D^0\rangle$; i.e, the final state is $f = K^+\ell^-\nu$, $K^+\pi^-$, $K^+\pi^-\pi^0$, etc. Doubly-Cabibbo-suppressed (DCS) decay amplitudes are denoted $A_f \equiv \langle f|H|D^0\rangle$ and $\overline{A}_{\overline{f}} \equiv \langle \overline{f}|H|\overline{D}^0\rangle$.

Starting from a pure $|D^0\rangle$ or $|\overline{D}^0\rangle$ state at $t = 0$, the time-dependent decay rates to "wrong-sign" final states can be written

$$r(t) \equiv \left|\langle f|H|D^0(t)\rangle\right|^2 = \left|\overline{A}_f\right|^2\left|\frac{q}{p}\right|^2\left|g_+(t)\,\lambda_f^{-1} + g_-(t)\right|^2 \tag{70.7}$$

$$\overline{r}(t) \;\equiv\; \left|\langle \overline{f}|H|\overline{D}^0(t)\rangle\right|^2 = \left|A_{\overline{f}}\right|^2\left|\frac{p}{q}\right|^2\left|g_+(t)\,\lambda_{\overline{f}} \;+\; g_-(t)\right|^2, \tag{70.8}$$

where

$$\lambda_f \;\equiv\; \frac{q}{p}\frac{\overline{A}_f}{A_f}\,, \quad \lambda_{\overline{f}} \;\equiv\; \frac{q}{p}\frac{\overline{A}_{\overline{f}}}{A_{\overline{f}}}\,, \tag{70.9}$$

and

$$g_\pm(t) \;=\; \frac{1}{2}\left(e^{-i\omega_1 t} \pm e^{-i\omega_2 t}\right). \tag{70.10}$$

A change in convention for the relative phase of D^0 and $\overline{D}^0$ would cancel between q/p and $\overline{A}_f/A_f$ or $\overline{A}_{\overline{f}}/A_{\overline{f}}$, leaving λ_f and $\lambda_{\overline{f}}$ unchanged. For multibody final states, these equations apply separately to each point in phase-space. Integrating over regions of phase-space can lead to enhanced sensitivity to CP violation; see the discussion below on multibody decays and the note "Review of Multibody Charm Analyses" in this *Review*. As the mixing parameters x and y are very small, $r(t)$ and $\overline{r}(t)$ are usually expanded to second order in x and y.

70.2 Semileptonic decays

Consider the final state $f = K^+\ell^-\bar{\nu}_\ell$, where $A_f = \overline{A}_{\overline{f}} = 0$ is an excellent approximation in the Standard Model. The final state f is accessible from a D^0 only via mixing,[1] and the decay rate is

$$r(t) = \left|\overline{A}_f\right|^2\left|\frac{q}{p}\right|^2|g_-(t)|^2 \;\approx\; \left|\overline{A}_f\right|^2\left|\frac{q}{p}\right|^2\left(\frac{x^2+y^2}{4}\right)(\Gamma t)^2\,e^{-\Gamma t}\,. \tag{70.11}$$

For $\overline{r}(t)$, q/p is replaced by p/q. In the Standard Model, CP violation in charm mixing is small and $|q/p| \approx 1$. In the limit of CP conservation, $r(t) = \overline{r}(t)$, and the time-integrated mixed decay rate relative to the time-integrated unmixed decay rate for semileptonic decays is

$$\frac{\displaystyle\int_0^\infty r(t)\,dt}{\displaystyle\int_0^\infty \left|\overline{A}_f\right|^2 e^{-\Gamma t}\,dt} \;=\; \frac{x^2+y^2}{2} \;\equiv\; R_M\,. \tag{70.12}$$

Table 70.1 summarizes results for R_M from semileptonic decays. The world average from the Heavy Flavor Averaging Group (HFLAV) [6] is $R_M = (1.30 \pm 2.69) \times 10^{-4}$.

[1] There exists a doubly Cabibbo-suppressed amplitude in which the c and $\bar{u}$ quarks exchange a W, and then the resulting d quark (from c) decays semileptonically. We neglect this second-order process.

Table 70.1: Results for $R_M = (x^2+y^2)/2$ in D^0 semileptonic decays. The HFLAV average assumes statistical and systematic uncertainties are uncorrelated. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded and thus are not included in the HFLAV average.

Year	Experiment	Final state(s)	R_M ($\times 10^{-3}$)	90% C.L. ($\times 10^{-3}$)
2008	Belle (492 fb^{-1}) [7]	$K^{(*)+}e^-\overline{\nu}_e$	$0.13\pm0.22\pm0.20$	< 0.61
2007	BaBar (344 fb^{-1}) [8]	$K^{(*)+}e^-\overline{\nu}_e$	$0.04\,^{+0.70}_{-0.60}$	$(-1.3, 1.2)$

70.3 Wrong-sign decays to hadronic non-CP eigenstates

Consider the final state $f = K^+\pi^-$, i.e., $A_{\overline{f}}$ and $\overline{A}_f$ are CF, A_f and $\overline{A}_{\overline{f}}$ are DCS. Because CF and DCS decays proceed via tree-level amplitudes, and such amplitudes involve only the first two quark generations, direct CP violation is negligible[2]. The ratios of decay amplitudes can be written

$$\frac{A_f}{\overline{A}_f} = -\sqrt{R_D^+}\,e^{-i\delta_f} \qquad \frac{\overline{A}_{\overline{f}}}{A_{\overline{f}}} = -\sqrt{R_D^-}\,e^{-i\delta_f}\,, \quad (70.13)$$

where δ_f is the strong phase difference between the DCS and CF amplitudes. The minus sign originates from the weak phase difference between the amplitudes, specifically, the relative minus sign between V_{us} and V_{cd} (which produces a relative minus sign between $V_{cs}^*V_{ud}$ and $V_{us}^*V_{cd}$). The parameters R_D^+ and R_D^- are the ratios of the DCS decay rate to the CF decay rate. From the relevant CKM matrix elements, one estimates R_D^+, $R_D^- \sim \tan^4\theta_c$, where θ_c is the Cabibbo angle.

With the parameterization of Eq. (70.13), Eq. (70.9) becomes

$$\lambda_f^{-1} = \frac{p}{q}\frac{A_f}{\overline{A}_f} = -\sqrt{R_D^+}\left|\frac{p}{q}\right| e^{-i(\delta_f+\phi)} \quad (70.14)$$

$$\lambda_{\overline{f}} = \frac{q}{p}\frac{\overline{A}_{\overline{f}}}{A_{\overline{f}}} = -\sqrt{R_D^-}\left|\frac{q}{p}\right| e^{-i(\delta_f-\phi)}\,, \quad (70.15)$$

where $\phi = \mathrm{Arg}(q/p)$. The weak phase ϕ is independent of the final state f and is often referred to as "universal." For convenience, we define the mean decay rate $R_D \equiv (R_D^+ + R_D^-)/2$, and the decay rate asymmetry $A_D \equiv (R_D^+ - R_D^-)/(R_D^+ + R_D^-)$.

[2] For two quark generations, the weak phases can be defined to eliminate all weak-phase differences.

With these definitions, we expand the decay rates in Eqs. (70.7) and (70.8) to second order in the small mixing parameters x and y to obtain [26, 27]:

$$r(t) = \left|\overline{A}_f\right|^2 e^{-\Gamma t}\,[\,R_D(1+A_D) + \sqrt{R_D(1+A_D)}\left|\frac{q}{p}\right| y'_+(\Gamma t) + \left|\frac{q}{p}\right|^2 \frac{(x'^2_+ + y'^2_+)}{4}(\Gamma t)^2\Big] \quad (70.16)$$

and

$$\overline{r}(t) = \left|A_{\overline{f}}\right|^2 e^{-\Gamma t}\,[\,R_D(1-A_D) + \sqrt{R_D(1-A_D)}\left|\frac{p}{q}\right| y'_-(\Gamma t) + \left|\frac{p}{q}\right|^2 \frac{(x'^2_- + y'^2_-)}{4}(\Gamma t)^2\Big]\,, \quad (70.17)$$

where

$$x'_\pm = x\cos(\delta_f \pm \phi) + y\sin(\delta_f \pm \phi) \quad (70.18)$$

$$y'_\pm = y\cos(\delta_f \pm \phi) - x\sin(\delta_f \pm \phi)\,. \quad (70.19)$$

Defining the "strong-phase-rotated" mixing parameters

$$x' \equiv x\cos\delta_f + y\sin\delta_f \quad (70.20)$$

$$y' \equiv y\cos\delta_f - x\sin\delta_f \quad (70.21)$$

gives

$$x'_\pm = x'\cos\phi \pm y'\sin\phi \quad (70.22)$$

$$y'_\pm = y'\cos\phi \mp x'\sin\phi\,, \quad (70.23)$$

i.e., $x'_\pm$ and $y'_\pm$ are obtained from x', y' via an additional "weak-phase rotation." To summarize, parameters (x', y') are the mixing parameters (x, y) rotated by the strong phase δ_f, and parameters

$(x'_\pm, y'_\pm)$ are the parameters (x', y') rotated by the weak phase $+\phi$ for D^0 decays and $-\phi$ for $\overline{D}^0$ decays. Note that $x'^2_+ + y'^2_+ = x'^2_- + y'^2_- = x'^2 + y'^2 = x^2 + y^2$. In Eqs. (70.16) and (70.17), a fourth term $R_D(1 \pm A_D)(x^2_\pm - y^2_\pm)(\Gamma t)^2/4$ has been dropped, as it is negligible relative to the other terms for the range of decay times measured by experiments.

Comparing Eqs. (70.16) and (70.17), one sees that $r(t) \neq \bar{r}(t)$ and CP is violated if either $A_D \neq 0$, $|q/p| \neq 1$, or $\phi \neq 0$. These three inequalities correspond, respectively, to the three types of CP violation: in the decay amplitudes ($R^+_D \neq R^-_D$); in the mixing; and due to interference between a mixed decay amplitude (i.e., mixing is followed by decay) and an unmixed decay amplitude. Whereas CP violation in the decay amplitudes is parameterized by A_D, CP violation in mixing is parameterized by $A_M \equiv (|q/p| - |p/q|)/(|q/p| + |p/q|)$.

In the limit of CP conservation, $A_D = 0$, $|q/p| = 1$, and $\phi = 0$. In this case

$$r(t) = \bar{r}(t) = \left|A_{\overline{f}}\right|^2 e^{-\Gamma t}\left[R_D + \sqrt{R_D}\, y'(\Gamma t) + \frac{x'^2 + y'^2}{4}(\Gamma t)^2\right], \tag{70.24}$$

and the total number of $D^0 \to f$ decays divided by the total number of $D^0 \to \bar{f}$ decays is

$$R = \frac{\displaystyle\int_0^\infty r(t)\, dt}{\displaystyle\int_0^\infty \left|A_{\overline{f}}\right|^2 e^{-\Gamma t}\, dt} = R_D + \sqrt{R_D}\, y' + \frac{x'^2 + y'^2}{2}. \tag{70.25}$$

The ratio R is more straightforward to measure than $r(t)$ or $\bar{r}(t)$, as there is no decay-time dependence. In Table 70.2 we report measurements of R, R_D, and A_D in $D^0 \to K^+\pi^-$ decays normalized to $D^0 \to K^-\pi^+$ decays, and results from HFLAV [18] obtained from a global fit to all relevant data that allows for both mixing and CP violation (see Section 70.7). The experiments typically perform a single fit for parameters R_D, x'^2, and y'; results for x'^2 and y' are listed in Table 70.3. Allowing for CP violation, the experiments measure parameters (R^+_D, x'^2_+, y'_+) and (R^-_D, x'^2_-, y'_-) [or equivalently (R_D, A_D) instead of (R^+_D, R^-_D)] by separately fitting the $D^0 \to K^+\pi^-$ and $\overline{D}^0 \to K^-\pi^+$ event samples.

Extraction of the mixing parameters x and y from measurements of x' and y' requires knowledge of the strong phase difference $\delta_{K\pi}$. This can be determined from the decay rates of $D_\pm \to K^+\pi^-$, where D_+ (D_-) denotes the CP-even (CP-odd) eigenstate. Since $|D_\pm\rangle = (|D^0\rangle \mp |\overline{D}^0\rangle)/\sqrt{2}$,

$$\sqrt{2}\, A(D_\pm \to K^+\pi^-) = A(D^0 \to K^+\pi^-) \mp A\left(\overline{D}^0 \to K^+\pi^-\right). \tag{70.26}$$

Squaring this amplitude and using Eq. (70.13) yields the relation

$$\cos\delta_{K\pi} = \frac{|A(D_+ \to K^+\pi^-)|^2 - |A(D_- \to K^+\pi^-)|^2}{2\,|A(D^0 \to K^+\pi^-)|\,|A(\overline{D}^0 \to K^+\pi^-)|}. \tag{70.27}$$

Measuring the right-hand side is possible if one can identify pure D_+, D_-, D^0, and $\overline{D}^0$ initial states. This is accomplished at CLEOc and BESIII utilizing the processes $e^+e^- \to \psi(3770) \to \overline{D}^0 D^0 \to (f_{CP})(K^+\pi^-)$, or $\psi(3770) \to \overline{D}^0 D^0 \to (f_{\overline{D}^0})(K^+\pi^-)$, where f_{CP} denotes a CP-specific final state, and $f_{\overline{D}^0}$ denotes a $\overline{D}^0$-flavor-specific final state. In the first case, quantum coherence and CP symmetry ensures that the $K^+\pi^-$ state originates from a neutral D with CP opposite that of f_{CP}. In the second case, at the time when the $\overline{D}^0$ decays, the opposite side is D^0. However, it can potentially mix to $\overline{D}^0$ before decaying to $K^+\pi^-$, and this introduces some dependence on the mixing parameters x and y. This dependence is seen explicitly in the observable

$$A^{CP}_{K\pi} \equiv \frac{|A(D_- \to K^-\pi^+)|^2 - |A(D_+ \to K^-\pi^+)|^2}{|A(D_- \to K^-\pi^+)|^2 + |A(D_+ \to K^-\pi^+)|^2}. \tag{70.28}$$

To lowest order in the mixing parameters [28],

$$A^{CP}_{K\pi} = \frac{2\sqrt{R_D}\cos\delta_{K\pi} + y}{1 + R}, \tag{70.29}$$

where R is defined in Eq. (70.25). Such measurements are discussed in Section 70.5.

70.3.1 *Wrong-sign decays to multibody final states*

For multibody final states, Eqs. (70.13)-(70.25) apply to each point in phase-space. Although x and y do not vary across phase-space, knowledge of the resonant substructure is needed to determine the strong phase difference δ from point to point to extract x and y. Alternatively, experimental knowledge of the strong phase difference between D^0 and $\overline{D}^0$ decay amplitudes across phase space [39] allow one to determine x and y independent of a decay model of resonant substructure. This phase information can be measured at the charm threshold, where CLEO-c and BESIII took data.

A time-dependent analysis at BaBar [40,41] of $D^0 \to K^+\pi^-\pi^0$ decays, relative to CF $\overline{D}^0 \to K^+\pi^-\pi^0$ decays, determined the strong phase variation across the Dalitz plot and reported $x'' = (2.61\,^{+0.57}_{-0.68} \pm 0.39)\%$ and $y'' = (-0.06\,^{+0.55}_{-0.64} \pm 0.34)\%$. These mixing parameters are defined as

$$x'' = x\cos\delta_{K\pi\pi^0} + y\sin\delta_{K\pi\pi^0} \tag{70.30}$$

$$y'' = y\cos\delta_{K\pi\pi^0} - x\sin\delta_{K\pi\pi^0}, \tag{70.31}$$

in analogy with x', y', and $\delta_{K\pi}$ of Eqs. (70.20) and (70.21). Here, $\delta_{K\pi\pi^0}$ is the strong phase difference between the amplitudes $A(D^0 \to K^+\pi^-\pi^0)$ and $A(\overline{D}^0 \to K^+\pi^-\pi^0)$ at a "reference point" of the Dalitz plot. For this analysis, the reference point chosen is $m_{\pi^-\pi^0} = m_{\rho^-}$. The strong phase difference $\delta_{K\pi\pi^0}$ can be determined in a manner similar to that for $\delta_{K\pi}$: by using Eq. (70.27) and quantum-correlated measurements of the branching fractions $B(D_+ \to K^+\rho^-)$, $B(D_- \to K^+\rho^-)$, $B(D^0 \to K^+\rho^-)$, and $B(\overline{D}^0 \to K^+\rho^-)$ in $e^+e^- \to \psi(3770)$ events.

For the decay modes D^0 and $\overline{D}^0 \to K^+\pi^-\pi^+\pi^-$, Belle measured $R = (0.324 \pm 0.008 \pm 0.007)\%$ [42]. Subsequently, a phase-space-integrated analysis from LHCb [43] measured the product of a "coherence factor" $R_D^{K3\pi}$ and the strong-phase-rotated mixing parameter $y''_{K3\pi}$. This measurement resulted in an observation of charm mixing with 8.2σ significance.

Both the sign and magnitude of x and y without strong phases entering or sign ambiguity can be determined by measuring the time-dependent resonant substructure of multibody D^0 decays to self-conjugate final states [37, 38]. For such decays, e.g., $D^0 \to K^0_S\pi^+\pi^-$, the DCS and CF decay amplitudes populate the same Dalitz plot, which allows for direct measurement of the strong phase difference. Belle [35, 37], BaBar [36], and CLEO [44] have measured the overall phase difference between $D^0 \to K^*(892)^-\pi^+$ and $D^0 \to K^*(892)^+\pi^-$ to be $[173.9 \pm 0.7$ (stat. only)$]^\circ$, $[177.6 \pm 1.1$ (stat. only)$]^\circ$, and $[189 \pm 10 \pm 3\,^{+15}_{-5}]^\circ$, respectively. These results are close to the 180° expected from Cabibbo factors, i.e., the relative minus sign between $V^*_{cs}V_{ud}$ and $V^*_{us}V_{cd}$; thus they indicate a small strong phase. Three LHCb measurements [31–33] of x, y using $D^0 \to K^0_S\pi^+\pi^-$ decays are decay-model independent, as the model of resonances in the intermediate state is replaced by strong-phase measurements from CLEO-c [29] and BESIII [45]. Table 70.4 summarizes results from time-dependent analyses of self-conjugate multibody final states. World average values for the measurements listed are given later, as a result of the HFLAV global fit.

With regard to resonant substructure in $D^0 \to K^0_S\pi^+\pi^-$ decays, Belle [35, 37] measured the relative strong phase (statistical errors only) and the ratio R (central values only) of the DCS fit fraction relative to the CF fit fraction for five excited K states: $K^*(892)^+\pi^-$, $K^*_0(1430)^+\pi^-$, $K^*_2(1430)^+\pi^-$, $K^*(1410)^+\pi^-$, and $K^*(1680)^+\pi^-$. Similarly, BaBar [36, 46, 47] reported central values of R for $K^*(892)^+\pi^-$, $K^*_0(1430)^+\pi^-$, and $K^*_2(1430)^+\pi^-$.

Table 70.3: Results for x'^2 and y', as measured using $D^0 \to K^\pm\pi^\mp$ decays. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded and thus are not included in the HFLAV global fit. The measurements with a dagger (†) are not included in the HFLAV global fit due to much poorer precision. All confidence limits and intervals correspond to 95% C.L. The Belle 2006 results restrict x'^2 to the physical region. The BaBar confidence intervals are obtained from the fit, whereas Belle uses a Feldman-Cousins method, and CDF uses a Bayesian method.

‡This result allows for all types of CP violation and is superseded by Ref. [35], which assumes no direct CP violation in CF or DCS decays.

The systematic uncertainties on R are not evaluated. Large differences in R are observed among these final states, which indicates significant hadronic effects.

70.4 Decays to CP Eigenstates

When the final state f is a CP eigenstate, there is no distinction between f and $\overline{f}$. Thus $A_f = A_{\overline{f}}$ and $\overline{A}_{\overline{f}} = \overline{A}_f$. We denote final states with CP eigenvalues ±1 by $f_\pm$. Decays to CP eigenstates proceed mainly via singly Cabibbo-suppressed amplitudes. Such amplitudes can contain internal loops and thus involve the third quark generation; in this manner a weak phase would appear in the decay amplitude, leading to direct CP violation. However, such internal loop amplitudes are suppressed, and the presence of a weak phase is often neglected.

The mixing parameter y may be measured by comparing the rate for D^0 decays to CP eigenstates such as K^+K^- with the rate to flavor eigenstates such as $K^-\pi^+$ [27]. If decays to K^+K^- have a shorter effective lifetime than those to $K^-\pi^+$, then $\Gamma_+ > \Gamma_-$, or, since CP violation is very small, $\Gamma_2 > \Gamma_1$ and y is positive. For small mixing ($x, y \ll 1$), the decay rates for $D^0 \to f_\pm$ and

Table 70.5: Results for y_{CP} and A_Γ from D^0 decays to CP eigenstates. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded.

‡This result for y_{CP} is not superseded, but it is not included in the HFLAV average due to having some correlations with the result of Ref. [51] but much worse precision.

$\overline{D}^0 \to f_\pm$ have an approximately exponential time dependence:

$$r_\pm(t) \propto \exp(-\Gamma_\pm\, t) \tag{70.32}$$

$$\overline{r}_\pm(t) \propto \exp(-\overline{\Gamma}_\pm\, t)\,, \tag{70.33}$$

where the effective decay widths are given by

$$\Gamma_\pm = \Gamma\left(1 \pm \left|\frac{q}{p}\right|(y\cos\phi - x\sin\phi)\right) \tag{70.34}$$

$$\overline{\Gamma}_\pm = \Gamma\left(1 \pm \left|\frac{p}{q}\right|(y\cos\phi + x\sin\phi)\right)\,. \tag{70.35}$$

Thus, the effective decay rate to a CP eigenstate combining equal numbers of D^0 and $\overline{D}^0$ decays (e.g., an untagged sample with no production asymmetry) is

$$r_\pm(t) \;+\; \overline{r}_\pm(t) \;\propto\; e^{-(1\pm y_{CP})\Gamma t}\,, \tag{70.36}$$

where

$$y_{CP} = \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) y\cos\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) x\sin\phi \tag{70.37}$$

$$\approx y\cos\phi - A_M\, x\sin\phi\,. \tag{70.38}$$

If CP is conserved, $y_{CP} = y$. Most measurements of y_{CP} have used $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays, which are CP-even, measured relative to $D^0 \to K^-\pi^+$. Belle measured y_{CP} also using $D^0 \to K^0_S\,\omega$ decays [49], which are CP-odd, and $D^0 \to K^0_S\,K^+K^-$ decays [58], which are dominated by the CP-odd final state $K^0_S\,\phi$. Table 70.5 summarizes the current status of measurements.

In addition to y_{CP}, Belle [53], BaBar [57], CDF [56], and LHCb [48,64] have reported measurements of the decay-rate asymmetry for CP-even final states:

$$A_\Gamma \equiv \frac{\Gamma_+ - \overline{\Gamma}_+}{\Gamma_+ + \overline{\Gamma}_+} \;=\; \frac{(1/\tau_+) - (1/\overline{\tau}_+)}{(1/\tau_+) + (1/\overline{\tau}_+)} \;=\; \frac{\overline{\tau}_+ - \tau_+}{\overline{\tau}_+ + \tau_+} \tag{70.39}$$

$$\approx \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) y\cos\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) x\sin\phi \tag{70.40}$$

$$\approx A_M\, y\cos\phi - x\sin\phi\,. \tag{70.41}$$

If CP is conserved, $A_\Gamma = 0$.

There is a contribution to Eq. (70.41) from direct CP violation, i.e., $|\overline{A}_f/A_f| \neq 1$ [79,80]. For $f = K^+K^-$ and $\pi^+\pi^-$, this contribution can be estimated from measurements of $A_{CP}(K^+K^-)$ and $A_{CP}(\pi^+\pi^-)$ (see below) and is much smaller than the current uncertainty on A_M; thus we neglect it here. We note that, when averaging A_Γ measurements over K^+K^- and $\pi^+\pi^-$ final states, the contribution from direct CP violation cancels, as it has the same magnitude but opposite signs for K^+K^- and $\pi^+\pi^-$ due to U-spin symmetry [80].

Table 70.6: Results for the difference in time-integrated CP asymmetries ΔA_{CP} between $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been either superseded or combined with subsequent results and thus are not included in the HFLAV global fit.

χ^2/d.o.f.	$98.68/52 = 1.90$	$66.27/53 = 1.25$	$63.64/51 = 1.25$	

The asymmetry A_Γ is an asymmetry in the full decay widths. An asymmetry in partial widths is referred to as A_{CP} and is final-state dependent:

$$A_{CP} \equiv \frac{\Gamma(D^0 \to f) - \Gamma(\overline{D}^0 \to \overline{f})}{\Gamma(D^0 \to f) + \Gamma(\overline{D}^0 \to \overline{f})}. \qquad (70.42)$$

Unlike A_Γ, which is measured by fitting decay time distributions, A_{CP} is measured by fitting for signal yields and (aside from acceptance effects) does not require measuring decay times. For neutral D decays, A_{CP} receives contributions from both direct (in the decay amplitudes) and indirect (due to mixing) processes: $A_{CP}(D^0 \to f) = A_{CP}^f + A_{CP}^{\rm indirect}$. The latter indirect contribution depends on the mixing parameters x and y:

$$\begin{aligned} A_{CP}^{\rm indirect} &= \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) x \sin\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) y \cos\phi \\ &= -A_\Gamma . \end{aligned} \qquad (70.43)$$

Numerous measurements of A_{CP} for decays to CP eigenstates are listed in this *Review* [81]. Table 70.6 summarizes the current status of measurements of the *difference* in A_{CP} for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays: $\Delta A_{CP} \equiv A_{CP}(K^+K^-) - A_{CP}(\pi^+\pi^-)$. Within the Standard Model, $A_{CP}^{KK} \approx -A_{CP}^{\pi\pi}$ [82], and ΔA_{CP} essentially doubles any direct CP violation present. The difference is also advantageous experimentally, as several systematic uncertainties cancel. As $A_{CP}^{\rm indirect}$ is independent of final state, it subtracts out of ΔA_{CP}. However, at hadron experiments such as LHCb, there are differences in efficiencies between K^+K^- and $\pi^+\pi^-$ such that $\langle t \rangle_{KK} \neq \langle t \rangle_{\pi\pi}$, i.e., the mean decay times slightly differ. This difference retains a small contribution to ΔA_{CP} from $A_{CP}^{\rm indirect}$ [79]. The most recent ΔA_{CP} result from LHCb [70], based on 8.9 fb^{-1} of data, differs from zero with a statistical significance of 5.3σ. Thus, this measurement constitutes the first observation of CP violation in charm decays. These CP asymmetries are included in HFLAV's global fit for charm mixing parameters discussed below; the fit shows that the CP violation observed is due to the direct contributions A_{CP}^{KK} and $A_{CP}^{\pi\pi}$.

70.5 Quantum-correlated $D^0\overline{D}^0$ Analyses

Measurements of R_D, $\cos\delta_{K\pi}$, $\sin\delta_{K\pi}$, x, and y can be obtained from a combined fit to time-integrated yields of single-tagged (ST) and double-tagged (DT) $D^0\overline{D}^0$ events produced at the $\psi(3770)$ resonance [83,84]. Single-tagged events are those in which either the D^0 or $\overline{D}^0$ decay is reconstructed (identified), and the other neutral D decays generically. Double-tagged events are those in which both the D^0 and $\overline{D}^0$ decay are identified. Due to quantum correlations, the decay of a D^0, $\overline{D}^0$, D_+, or D_- projects the other neutral D into a state $\overline{D}^0$, D^0, D_-, and D_+, respectively. The CP-specific D_- and D_+ decays (or, neglecting CP violation, D_1 and D_2 decays) include interference between D^0 and $\overline{D}^0$ amplitudes, and this provides sensitivity to R_D and $\cos\delta_{K\pi}$. The flavor-specific D^0 and $\overline{D}^0$ decays include interference between D_1 and D_2 amplitudes, and this provides sensitivity to x and y. For details of this method, see Refs. [1–5].

BESIII has reported results using 2.92 fb^{-1} of $e^+e^- \to \psi(3770)$ data, where the quantum-correlated $D^0\overline{D}^0$ pairs are produced in a $C=-1$ state. They measure $y_{CP} = (-2.0 \pm 1.3 \pm 0.7)\%$ [55] from DT yields using a CP-eigenstate tag for one D and a semileptonic tag for the other; and they measure $A_{K\pi}^{CP} = (12.7 \pm 1.3 \pm 0.7)\%$ [28] from DT yields using a CP tag for one D and a $K^\pm\pi^\mp$ tag for the other. For y_{CP}, the CP eigenstates used are K^-K^+ (f_+), $\pi^+\pi^-$ (f_+), $K_S^0\,\pi^0\pi^0$ (f_+), $K_S^0\,\pi^0$ (f_-), $K_S^0\,\eta$ (f_-), and $K_S^0\,\omega$ (f_-). For $A_{K\pi}^{CP}$, additional CP eigenstates included are $\pi^0\pi^0$ (f_+) and $\rho^0\pi^0$ (f_+). Using external inputs for R_D and y from HFLAV [85], and R from the PDG [86], BESIII uses Eq. (70.29)

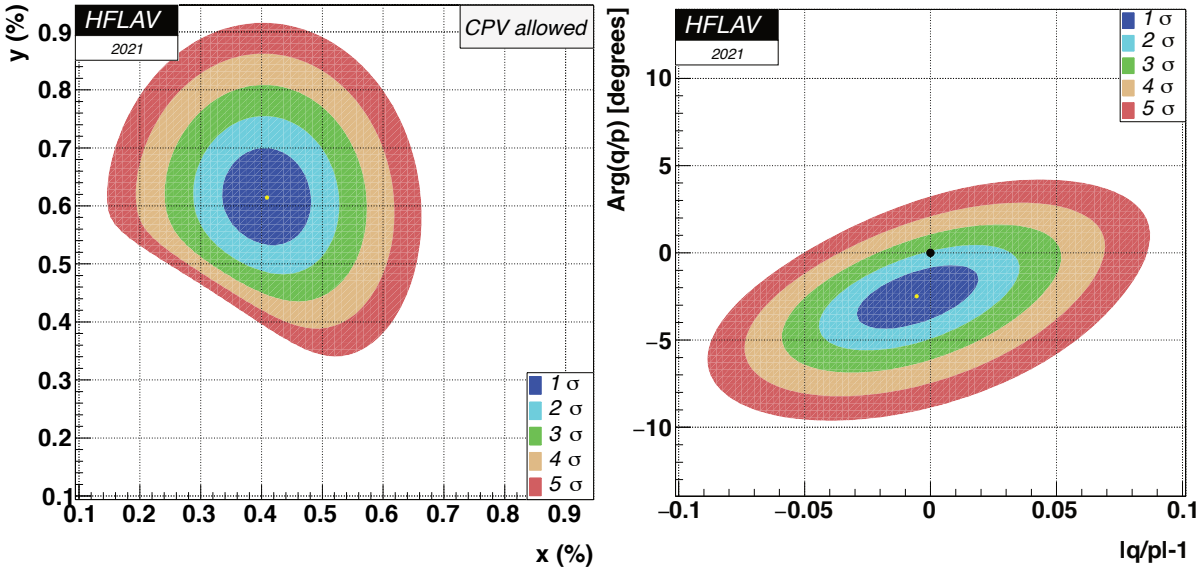

Figure 70.1: Two-dimensional 1σ-5σ contours for (x, y) (left) and for $(|q/p|,\mathrm{Arg}(q/p))$ (right) as obtained by HFLAV [18], from measurements of $D^0 \to K^{(*)+}\ell\nu$, h^+h^-, $K^+\pi^-$, $K^+\pi^-\pi^0$, $K^+\pi^-\pi^+\pi^-$, $K^0_S\pi^+\pi^-$, $K^0_S K^+K^-$, and $\pi^+\pi^-\pi^0$ decays, and double-tagged branching fractions measured at the $\psi(3770)$ resonance. In the right plot, the black dot denotes the no-CPV point $(0, 0)$.

to determine $\cos\delta_{K\pi} = 1.02 \pm 0.11 \pm 0.06 \pm 0.01$ [28], where the third uncertainty is due to the external inputs.

CLEO-c has reported results using 0.82 fb^{-1} of $e^+e^- \to \psi(3770)$ data [87–89]. The values for y, R_M, $\cos\delta_{K\pi}$, and $\sin\delta_{K\pi}$ are obtained from a combined fit to the ST (hadronic only) and DT yields. The DT yields include events in which one D is reconstructed in a hadronic mode and the other D is partially reconstructed in either $D \to K^\mp e^\pm\nu$ or $D \to K^\mp\mu^\pm\nu$. The CLEO-c analysis obtains $\cos\delta_{K\pi} = 0.81\,^{+0.22\,+0.07}_{-0.18\,-0.05}$ and $\sin\delta_{K\pi} = -0.01 \pm 0.41 \pm 0.04$. These fits allow $\cos\delta_{K\pi}$ and $\sin\delta_{K\pi}$ (and also x^2) to be unphysical. Constraining $\cos\delta_{K\pi}$ and $\sin\delta_{K\pi}$ to the physical range $[-1, +1]$ (i.e., interpreting $\delta_{K\pi}$ as an angle) and also using external inputs for x, y and y_{CP} from HFLAV [90], CLEO-c obtains $\delta_{K\pi} = (18\,^{+11}_{-17})^\circ$ [89].

70.6 Summary of Experimental Results

The first evidence for D^0-$\overline{D}^0$ mixing was obtained in 2007 by Belle [67] and BaBar [17]. These results were confirmed by CDF [91] and, much later, by LHCb [20]. There are now numerous measurements of D^0-$\overline{D}^0$ mixing with various levels of sensitivity. For $D^0 \to K^+\pi^-$ decays, LHCb [19, 20], CDF [16], and Belle [15] each exclude the no-mixing hypothesis by more than five standard deviations. LHCb [43] reported the observation of charm mixing in $D^0 \to K^+\pi^-\pi^+\pi^-$ decays with 8.2σ significance. However, the strong phase difference for this decay is not known, and thus the mixing parameters x and y cannot be extracted. The most precise measurements of x and y are obtained from a time-dependent Dalitz plot analysis of $D^0 \to K^0_S\pi^+\pi^-$ decays. This method was originally used at CLEO [92] and subsequently exploited at Belle [35, 37] and BaBar [36] with much higher statistics. BaBar has applied this method also to $D^0 \to K^0_S K^+K^-$ decays [36]. It has recently been used by LHCb with very high statistics [31] to obtain the most precise values of x and y to date. This measurement resulted in the first observation ($> 5\sigma$ significance) of dispersive mixing, i.e., $x \neq 0$.

The experimental data demonstrate that D^0 and $\overline{D}^0$ mesons mix. This mixing is presumably dominated by long-distance amplitudes, which are difficult to calculate. Under the assumption that the observed mixing is due entirely to non-Standard Model processes, significant constraints on New Physics models can be obtained [93]. A significant limitation to interpreting charm mixing in terms of New Physics is the theoretical uncertainty on Standard Model predictions [94, 95]. We note that the HFLAV global fit results for x and y (see below) indicate that charm mixing is at the upper end of the range of Standard Model predictions.

The current situation would benefit from better knowledge of the strong phase difference $\delta_{K\pi}$ than that currently available from CLEO-c [89] and BESIII [28]. Such knowledge would allow one to extract x and y directly from $D^0 \to K^+\pi^-$ measurements of x'^2 and y'. Similarly, knowledge of the strong phase difference $\delta_{K\pi\pi\pi}$ would allow one to extract x and y from measurements of x''^2 and y'' obtained using $D^0 \to K^+\pi^-\pi^+\pi^-$ decays.

With regard to CP violation, by combining four separate measurements from two data sets totalling 8.9 fb^{-1} of data, LHCb observed CP violation in D decays for the first time [70]. The amount of CP violation measured is small, only $\sim$0.15%. A theory calculation indicates that this value is consistent with Standard Model expectations [96]; however, new physics contributions cannot be excluded.

70.7 HFLAV Global Fit for Charm Mixing Parameters

The Heavy Flavor Averaging Group (HFLAV) performs a global fit to all relevant mixing measurements to obtain world average values for 10 fitted parameters: x, y, $\delta_{K\pi}$, $\delta_{K\pi\pi^0}$, $R_D(K^+\pi^-)$, $A_D(K^+\pi^-)$, $|q/p|$, $\mathrm{Arg}(q/p) \equiv \phi$, and the direct CP-violating asymmetries A^{KK}_{CP} and $A^{\pi\pi}_{CP}$. Correlations among observables are taken into account by using the error matrices provided by the experiments. Measurements of $D^0 \to K^{(*)+}\ell^-\overline{\nu}$, K^+K^-, $\pi^+\pi^-$, $K^+\pi^-$, $K^+\pi^-\pi^0$, $K^+\pi^-\pi^+\pi^-$, $K^0_S\pi^+\pi^-$, $K^0_S K^+K^-$, and $\pi^+\pi^-\pi^0$ decays are used, as well as CLEO-c fitted values of R_D, x^2, y, $\cos\delta$, and $\sin\delta$ obtained from quantum-correlated branching fractions measured in $e^+e^- \to \psi(3770) \to D^0\overline{D}^0$ reactions. There are three observables input to the fit that are

themselves world average values calculated by HFLAV: R_M from $D^0 \to K^{(*)+}\ell^-\overline{\nu}$ decays (Table 70.1), and y_{CP} and A_Γ from $D^0 \to f_{CP}$ decays (Table 70.5). A measurement by LHCb of R_M using $D^0 \to K^+\pi^-\pi^+\pi^-$ decays is input separately. Details of the fitting procedure are given in Ref. [6].

The results of the fit as of July, 2021 are listed in Table 70.7. Three separate fits are performed: *(a)* assuming no CP violation; *(b)* assuming no CP violation in doubly Cabibbo-suppressed decays; and *(c)* allowing for all CP violation. The second fit *(b)* corresponds to the theory expectation [97, 98]; in this case four fitted parameters are reduced to three using the relationship $\tan\phi = (x/y)\cdot(1-|q/p|^2)/(1+|q/p|^2)$ [97–99]. Alternatively, one can fit for the three parameters $x_{12} \equiv 2|M_{12}|/\Gamma$, $y_{12} \equiv |\Gamma_{12}|/\Gamma$, and $\phi_{12} \equiv \mathrm{Arg}(M_{12}/\Gamma_{12})$, from which x, y, $|q/p|$, and ϕ can be derived.

Confidence contours in the two dimensions (x, y) and $(|q/p|, \phi)$ resulting from the fit are plotted in Fig. 70.1. These contours are obtained by allowing, for any point in the two-dimensional plane, all other fitted parameters to take their preferred values. The 1σ–5σ boundaries drawn are the loci of points in which the χ^2 has risen above the minimum by 2.30, 6.18, 11.83, 19.33, and 28.67 units. The fit excludes the no-mixing point $x=y=0$ at more than 11.5σ. The fit is consistent with CP conservation ($|q/p| = 1$, $\phi = 0$) at the 1.6σ level. The χ^2 of the fit is 63.6 for $61-10 = 51$ degrees of freedom, which is satisfactory.

One-dimensional likelihood functions for parameters are obtained by allowing, for any value of the parameter, all other fitted parameters to take their preferred values. The resulting likelihood functions give central values, 68.3% C.L. intervals, and 95% C.L. intervals as listed in Table 70.7. The parameter ranges $x \leq 0$ and $y \leq 0$ are excluded at 8.2σ and more than 11.4σ significance, respectively.

From the results of the HFLAV averaging and global fit, we conclude the following: (1) Since CP violation is small and y_{CP} is positive, the CP-even state is shorter-lived, as in the $K^0\overline{K}^0$ system. (2) Since x is positive, the CP-even state is heavier, unlike in the $K^0\overline{K}^0$ system. (3) The strong phase difference $\delta_{K\pi}$ is consistent with the $SU(3)$ expectation of zero, and large values are unlikely (the 95% C.L. interval is $-13^\circ < \delta_{K\pi} < 22^\circ$). (4) While direct CP violation has been observed in D decays, there is no evidence for indirect CP violation, i.e., $|q/p| \neq 1$ or $\phi \neq 0$. Observing such CP violation at the current level of sensitivity would indicate new physics.

70.8 Future Data

Current results are based primarily upon CLEO-c (0.82 fb^{-1} of $e^+e^- \to \psi(3770)$ data), Belle and BaBar ($\sim$1.4 ab^{-1} of $e^+e^- \to \Upsilon(4S)$ data), CDF (9.6 fb^{-1} of $p\overline{p}$ collision data at $\sqrt{s} = 1.96$ TeV), and LHCb Runs 1 and 2 (3.0 fb^{-1}+5.9 fb^{-1} of pp collision data at $\sqrt{s} = 7$, 8, 13 TeV).

BESIII has accumulated 2.9 fb^{-1} of $e^+e^- \to \psi(3770)$ data and plans to collect up to 20 fb^{-1} in the next few years. These data should provide strong phase measurements that enable improved model-independent determinations of mixing parameters from Belle II and LHCb. In 2019, Belle II began accumulating 50 ab^{-1} of $e^+e^- \to \Upsilon(4S)$ data [100], which is expected to take approximately ten years to collect. At LHCb, Run 2 was completed in 2018, Run 3 is planned for 2022-24, and Run 4 is planned for 2027-30 [101]. The goal for Runs 3+4 is to accumulate an additional 50 fb^{-1} of pp data at $\sqrt{s} \approx 14$ TeV [102]. These data, along with the large e^+e^- dataset from Belle II, should provide more precise measurements of D^0-$\overline{D}^0$ mixing and significantly greater sensitivity to direct and indirect CP violation in D^0 decays.

71. D_s^+ Branching Fractions

Revised September 2021 by J.L. Rosner (Chicago U.) and C.G. Wohl (LBNL).

Figure 71.1 shows a partial breakdown of the D_s^+ branching fractions. The rest of this note is about how the figure was constructed. The values shown make heavy use of CLEO measurements of inclusive branching fractions [1]. For references to other data cited in the following, see the Listings. An addendum updates branching fractions to two-body final states reported by the BESIII Collaboration in 2020 [2], and the conclusion stresses modes still to be identified.

71.1 Modes with leptons

The bottom (18.0±1.0)% of Fig. 71.1 shows the fractions for the modes that include leptons. The measured $K^0e^+\nu_e$ and $K^{*0}e^+\nu_e$ fractions have been doubled to take account of the corresponding $\mu^+\nu_\mu$ fractions. The sum of the exclusive $Xe^+\nu_e$ fractions is (6.0± 0.3)%, consistent with an inclusive semileptonic measurement of (6.5 ± 0.4)%. There seems to be little missing here.

71.2 Inclusive hadronic $K\overline{K}$ fractions

The Cabibbo-favored $c \to s$ decay in D_s^+ decay produces a final state with both an s and an $\bar{s}$; and thus modes with a $K\overline{K}$ pair or with an η, ω, η', or ϕ predominate (as may already be seen in Fig. 71.1 in the semileptonic fractions). We consider the $K\overline{K}$ modes first. A complete picture of the exclusive $K\overline{K}$ charge modes is not yet possible, because branching fractions for many of those modes have not yet been measured. However, CLEO has measured the inclusive K^+, K^-, K_S^0, K^+K^-, $K^+K_S^0$, $K^-K_S^0$, and $2K_S^0$ fractions (these include modes with leptons) [1]. And each of these inclusive fractions with a K_S^0 is equal to the corresponding fraction with a K_L^0: $f(K^+K_L^0) = f(K^+K_S^0)$, $f(2K_L^0) = f(2K_S^0)$, *etc.* Therefore, of all-inclusive fractions pairing a K^+, K_S^0, or K_L^0 with a K^-, K_S^0, or K_L^0, we know all but $f(K_S^0K_L^0)$.

We can get that fraction. The total K_S^0 fraction is

$$f(K_S^0) = f(K^+K_S^0) + f(K^-K_S^0) + 2f(2K_S^0) + f(K_S^0K_L^0) + f(\text{single } K_S^0) \ ,$$

where $f(\text{single } K_S^0)$ is the sum of the branching fractions for modes such as $K_S^0\pi^+2\pi^0$ with a K_S^0 and no second K. The $K_S^0\pi^+2\pi^0$ mode is in fact the only unmeasured single-K_S^0 mode (throughout, we shall assume that fractions for modes with a K or $K\overline{K}$ and more than three pions are negligible), and we shall take its fraction to be the same as for the $K_S^0 2\pi^+\pi^-$ mode, (0.30 ± 0.11)%. Any reasonable deviation from this value would be too small to matter much in the following. Adding the several small single-K_S^0 branching fractions, including those from semileptonic modes, we get $f(\text{single } K_S^0) = (1.7 \pm 0.2)$%. Using this, we have:

$$\begin{aligned} f(K_S^0K_L^0) &= f(K_S^0) - f(K^+K_S^0) - f(K^-K_S^0) \\ &\quad - 2f(2K_S^0) - f(\text{single } K_S^0) \\ &= (19.0 \pm 1.1) - (5.8 \pm 0.5) - (1.9 \pm 0.4) \\ &\quad - 2 \times (1.7 \pm 0.3) - (1.7 \pm 0.2) \\ &= (6.2 \pm 1.4)\% \ . \end{aligned}$$

Here and below we treat the errors as uncorrelated, although often they are not. However, our main aim is to get numbers for Fig. 71.1; errors are secondary.

There is a check on our result: The ϕ inclusive branching fraction is (15.7 ± 1.0)%, of which 34%, or (5.34 ± 0.34)% of D_s^+ decays, produces a $K_S^0K_L^0$. Our $f(K_S^0K_L^0) = (6.2 \pm 1.4)$% has to be at least this large—and it is, within the sizable error.

We now have all the inclusive $K\overline{K}$ fractions. We use $f(K^+\overline{K}^0) = 2\,f(K^+K_S^0)$, and likewise for $f(K^-K^0)$. For K^+K^- and $K_S^0K_L^0$, we subtract off the contributions from $\phi\ell^+\nu$ decay to get the purely hadronic $K\overline{K}$ inclusive fractions:

$$\begin{aligned} f(K^+K^-, \text{hadronic}) &= (15.8 \pm 0.7) - (2.1 \pm 0.3) \\ &= (13.7 \pm 0.8)\% \\ f(K^+\overline{K}^0, \text{hadronic}) &= (11.6 \pm 1.0)\% \\ f(K^-K^0, \text{hadronic}) &= (3.8 \pm 0.8)\% \\ f(2K_S^0 + 2K_L^0, \text{hadronic}) &= (3.4 \pm 0.6)\% \\ f(K_S^0K_L^0, \text{hadronic}) &= (6.2 \pm 1.4) - (1.5 \pm 0.2) \\ &= (4.7 \pm 1.4)\% \ . \end{aligned}$$

The fractions are shown in Fig. 71.1. They total (37.2 ± 2.2)% of

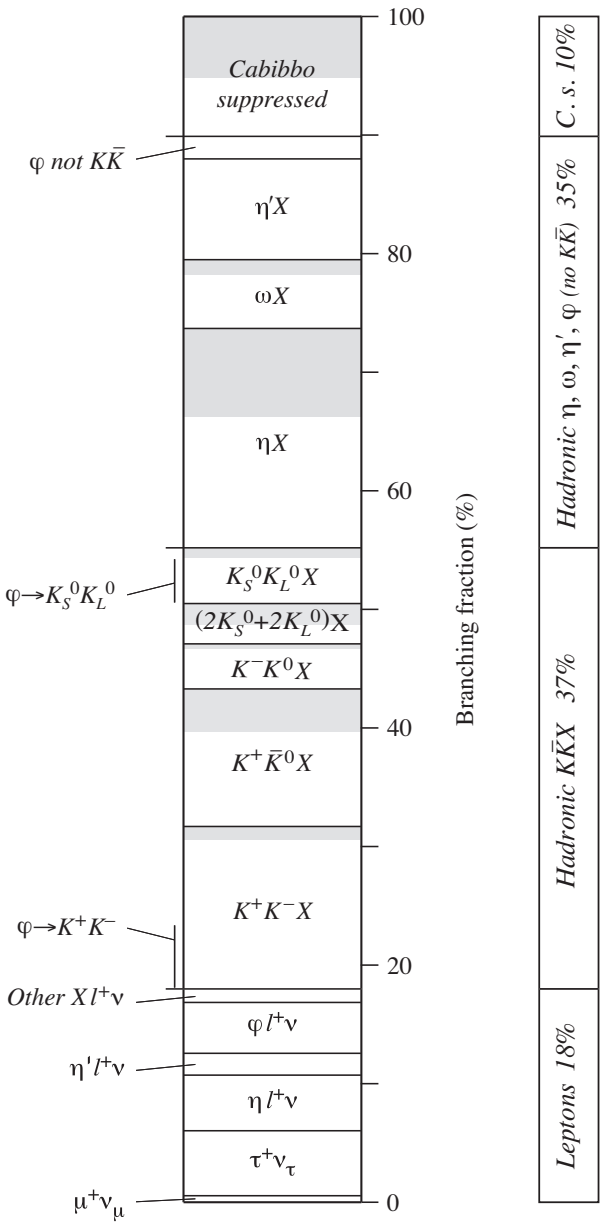

Figure 71.1: A partial breakdown of D_s^+ branching fractions. The hadronic bins in the left column show inclusive fractions. Shading within a bin shows how much of the inclusive fraction is not yet accounted for by adding up all the relevant exclusive fractions. The inclusive hadronic ϕ fraction is spread over three bins, in proportion to its decay fractions into K^+K^-, $K_S^0K_L^0$, and no-$K\bar{K}$ modes.

D_s^+ decays.

We can add more information to the figure by summing up measured branching fractions for exclusive modes within each bin:

K^+K^- *modes*—The sum of measured $K^+K^-\pi^+$, $K^+K^-\pi^+\pi^0$, and $K^+K^-2\pi^+\pi^-$ branching fractions is $(12.6 \pm 0.6)\%$. That leaves $(1.1 \pm 1.0)\%$ for the $K^+K^-\pi^+2\pi^0$ mode, which is the only other K^+K^- mode with three or fewer pions. In Fig. 71.1, this unmeasured part of the K^+K^- bin is shaded.

$K^+\overline{K}^0$ *modes*—Two times the sum of the measured $K^+K_S^0$, $K^+K_S^0\pi^0$, and $K^+K_S^0\pi^+\pi^-$ branching fractions is $(8.0 \pm 0.5)\%$. This leaves $(3.6 \pm 1.1)\%$ for the unmeasured $K^+\overline{K}^0$ modes (there are three such modes with three or fewer pions). This is shaded in the figure.

K^-K^0 *modes*—Twice the $K^-K_S^0 2\pi^+$ fraction is $(3.4 \pm 0.2)\%$, which leaves about $(0.4 \pm 0.8)\%$ for $K^-K^0 2\pi^+\pi^0$, the only other K^-K^0 mode with three or fewer pions.

$2K_S^0$+$2K_L^0$ *modes*—The $2K_S^0\pi^+$ and $2K_S^0 2\pi^+\pi^-$ fractions sum to $(0.86 \pm 0.07)\%$; this times two (for the corresponding $2K_L^0$ modes) is $(1.72 \pm 0.14)\%$. This leaves about $(1.7 \pm 0.7)\%$ for other $2K_S^0 + 2K_L^0$ modes.

$K_S^0K_L^0$ *modes*—Most of the $K_S^0K_L^0$ fraction is accounted for by ϕ decays (see below).

71.3 Inclusive hadronic η, ω, η', and ϕ fractions

These are easier. We start with the inclusive branching fractions, and then, to avoid double counting, subtract: (1) fractions for modes with leptons; (2) η mesons that are included in the inclusive η' fraction; and (3) K^+K^- and $K_S^0K_L^0$ from ϕ decays:

$$\begin{aligned} f(\eta \text{ hadronic}) &= f(\eta \text{ inclusive}) - 0.65\, f(\eta' \text{ inclusive}) \\ &\quad - f(\eta\ell^+\nu) = (18.5 \pm 3.0)\% \\ f(\omega \text{ hadronic}) &= f(\omega \text{ inclusive}) - 0.026\, f(\eta' \text{ inclusive}) \\ &= (5.8 \pm 1.4)\% \\ f(\eta' \text{ hadronic}) &= f(\eta' \text{ inclusive}) - f(\eta'\ell^+\nu) \\ &= (8.5 \pm 1.5)\% \\ f(\phi \text{ hadronic}, \not\to K\overline{K}) &= 0.17 \left[f(\phi \text{ inclusive}) - f(\phi\ell^+\nu) \right] \\ &= (1.9 \pm 0.2)\% \ . \end{aligned}$$

The factors 0.65, 0.026, and 0.17 are the $\eta' \to \eta$, $\eta' \to \omega$, and $\phi \not\to K\overline{K}$ branching fractions. Figure 71.1 shows the results; the sum is $(34.7 \pm 3.6)\%$, which is about equal to the hadronic $K\overline{K}$ total.

Note that the bin marked ϕ near the top of Fig. 71.1 includes neither the $\phi\ell^+\nu$ decays nor the 83% of other ϕ decays that produce a $K\overline{K}$ pair. There is twice as much ϕ in the $K_S^0K_L^0$ bin, and nearly three times as much in the K^+K^- bin. These contributions are indicated in those bins.

Again, we can show how much of each bin is accounted for by measured exclusive branching fractions: η *modes*—The sum of $\eta\pi^+$, $\eta\pi^+\pi^0$ (nearly all $\eta\rho^+$), and ηK^+ branching fractions is $(11.1 \pm 1.2)\%$, which leaves a good part of the inclusive hadronic η fraction, $(18.5 \pm 3.0)\%$, to be accounted for. This is shaded in the figure. ω *modes*—The sum of $\omega\pi^+$, $\omega\pi^+\pi^0$, and $\omega 2\pi^+\pi^-$ fractions is $(4.6 \pm 0.9)\%$, which is nearly as large as the inclusive hadronic ω fraction, $(5.8 \pm 1.4)\%$. η' *modes*—The sum of $\eta'\pi^+$, $\eta'\rho^+$, and $\eta' K^+$ fractions is $(9.9 \pm 1.5)\%$, which is larger than but not in serious disagreement with the inclusive hadronic η' fraction, $(8.5 \pm 1.5)\%$.

71.4 Cabibbo-suppressed modes

The sum of the fractions for modes with a $K\bar{K}$, η, ω, η', or leptons is $(89.9 \pm 4.4)\%$. The remaining $(10.1 \pm 4.4)\%$ is to Cabibbo-suppressed modes, mainly single-K+ pions and multiple-pion modes (see below). However, it should be noted that some small parts of the modes already discussed are Cabibbo-suppressed. For example, the $(1.1 \pm 0.2)\%$ of D_s^+ decays to $K^0\ell\nu$ or $K^{*0}\ell\nu$ is already in the $X\ell\nu$ bin in Fig. 71.1. And the inclusive measurements of η, ω, and η' fractions do not distinguish between (and therefore include both) Cabibbo-allowed and -suppressed modes. We shall not try to make a separation here.

K^0 + *pions*—Above, we found that $f(\text{single } K_S^0) = (1.7 \pm 0.2)\%$. Subtracting semileptonic fractions with a K_S^0 leaves $(1.3 \pm 0.2)\%$. The hadronic single-K^0 fraction is twice this, about $(2.6 \pm 0.4)\%$. The sum of measured $K^0\pi^+$, $K^0\pi^+\pi^0$, and $K^0 2\pi^+\pi^-$ fractions is $(1.8 \pm 0.3)\%$, about two-thirds as much.

K^+ + *pions*—The $K^+\pi^0$ and $K^+\pi^+\pi^-$ fractions sum to $(0.72 \pm 0.05)\%$. The total K^+ fraction wanted here is probably in the 1-to-2% range.

Multi-pions—The $2\pi^+\pi^-$, $\pi^+2\pi^0$, and $3\pi^+2\pi^-$ fractions total $(2.5 \pm 0.2)\%$. Modes not measured might double this.

The sum of the actually measured fractions is, including the semileptonics, $(4.9 \pm 0.3)\%$. The error on our Cabibbo-suppressed total, $(10.1 \pm 4.4)\%$ is too large to know how much we might be missing.

71.5 Addendum: Improved precision in some measurements

The Table compares measurements of branching fractions to pairs of two pseudoscalar mesons used in our 2019 update of the 2018 PDG review with values available in 2021 [2]. They have not changed much but are much better known.

Final state	2019 PDG avg or fit (%)	New BESIII entry in 2021 PDG (%)	2021 PDG avg or fit (%)
$K^+\eta'$	0.18±0.06	0.268±0.025	0.265±0.025
$K^+\eta$	0.177±0.035	0.162±0.012	0.160±0.011
$\eta\pi^+$	1.70±0.09	1.741±0.063	1.68±0.10
$K^+K_S^0$	1.50±0.05	1.502±0.055	1.46±0.04
$K_S^0\pi^+$	0.122±0.006	0.1109±0.005	0.110±0.005
$K^+\pi^0$	0.063±0.021	0.0748±0.0057	0.074±0.0057

Other recent BESIII additions include the measurements $\mathcal{B}(D_s \to \omega\pi^+, \omega K^+) = (1.77 \pm 0.32 \pm 0.13,\ 0.87 \pm 0.24 \pm 0.08) \times 10^{-3}$ [3] and $\mathcal{B}(D_s \to K_{S,L}K^+) = (1.425 \pm 0.038 \pm 0.031,\ 1.485 \pm 0.039 \pm 0.046)\%$ [4].

71.6 Concluding remarks

The shaded bands in the figure imply that about eight percent of the total D_s decay rate is into ηX, with X still to be accounted for. Unidentified Cabibbo-suppressed modes and the modes $K^+\overline{K}^0X$ and $(2K_S^0 + 2K_L^0)X$ respectively correspond to $\sim (5, 3, 2)\%$ of the total. However, one can consider the vast majority of D_s decays to be represented by exclusive final states.

72. Leptonic Decays of Charged Pseudoscalar Mesons

Revised Sept. 2021 by J.L. Rosner (Chicago U.); written with S.L. Stone (Syracuse U.) and R. Van de Water (FNAL)

72.1 Introduction

This review updates one in Ref. [1]. Extensive use is made of results of the Flavor Lattice Averaging group (FLAG 21), Ref. [2], which have not changed much since the previous compilation [3].

Charged mesons formed from a quark and antiquark can decay to a lepton-neutrino pair when these objects annihilate via a virtual W boson. Figure 72.1 illustrates this process for the purely leptonic decay of a D^+ meson.

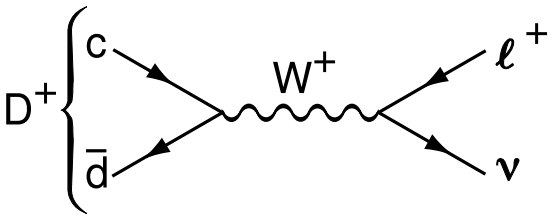

Figure 72.1: The annihilation process for pure D^+ leptonic decays in the standard model.

Similar quark-antiquark annihilations via a virtual W^+ to the $\ell^+\nu$ final states occur for the π^+, K^+, D_s^+, and B^+ mesons. (Whenever pseudoscalar-meson charges are specified in this article, use of the charge-conjugate particles and corresponding decays are also implied.) Let P be any of these pseudoscalar mesons. To lowest order, the decay width is

$$\Gamma^{(0)}(P \to \ell\nu) = \frac{G_F^2}{8\pi} f_P^2 \; m_\ell^2 M_P \left(1 - \frac{m_\ell^2}{M_P^2}\right)^2 |V_{q_1 q_2}|^2 \; . \quad (72.1)$$

Here M_P is the P mass, m_ℓ is the ℓ mass, $V_{q_1 q_2}$ is the Cabibbo-Kobayashi-Maskawa (CKM) matrix element between the quarks $q_1\bar{q}_2$ in P, and G_F is the Fermi coupling constant. The decay constant f_P is proportional to the matrix element of the axial current between the one-P-meson state and the vacuum:

$$\langle 0|\bar{q}_1 \gamma_\mu \gamma_5 q_2|P(p)\rangle = ip_\mu f_P \, , \quad (72.2)$$

and can be thought of as proportional to the "wave function overlap" of the quark and antiquark. In this article, we use the convention in which $f_\pi \approx 130$ MeV. For brevity, we will often denote the purely leptonic decay width in Eq. (72.1) by $\Gamma^{(0)}$.

The decay of $P^\pm$ starts with a spin-0 meson, and ends up with a left-handed neutrino or right-handed antineutrino. By angular momentum conservation, the $\ell^\pm$ must then also be left-handed or right-handed, respectively. In the $m_\ell = 0$ limit, the decay is forbidden, and can only occur as a result of the finite ℓ mass. This helicity suppression is the origin of the m_ℓ^2 factor in the decay width.

Experimentally, it is difficult to isolate events in which there are *only* a lepton and neutrino in the final state from those with a lepton, neutrino, and soft photon. Thus, radiative contributions must be removed from the experimental measurements *a posteriori* to obtain $\Gamma^{(0)}$. The radiative contributions can be broken into three pieces: the short-distance contribution to leptonic and semileptonic decays mediated by a $W^\pm$ boson that accounts for electroweak corrections not included in the definition of G_F, the long-distance internal bremsstrahlung (IB) contribution, and the contribution from photon emission that depends upon the hadron's structure. The universal electroweak correction was calculated at $\mathcal{O}(\alpha)$ by Sirlin [4], and increases the purely leptonic decay rate by ~ 1.8–2.2% depending on the decaying meson. The $\mathcal{O}(\alpha)$ IB contribution was calculated by Kinoshita [5], and again is universal for all leptonic decays at this order. Numerically, the universal long-distance contribution lowers the purely leptonic decay rate by ~ 0.4–2.4%, where the correction is smallest for pions and largest for $D_{(s)}$ mesons. The structure-dependent contributions have been estimated within various effective theories to increase the purely leptonic rate by one to a few percent [6–11].

In this review, we treat the radiative corrections differently for the light, charm, and bottom meson systems for several reasons. First, the experimental uncertainties on the decay widths vary substantially Thus, while the inclusion of radiative corrections is essential for the pion, kaon, and D-meson decay widths, which have been measured to (sub)-percent precision, radiative corrections can be neglected (for now) for $B \to \tau\nu$ decay. Second, the photons are treated differently on the experimental side for the different decay processes. For pions and kaons, the experimental measurements of $\Gamma_{P\ell 2[\gamma]}$ are fully inclusive, while for D mesons, the experiments impose cuts on the energy of any neutral cluster deposited in the calorimeter, which reduce the soft-photon background substantially. Some experiments also remove the QED bremsstrahlung in the leading-logarithmic approximation using the PHOTOS Monte-Carlo generator [12]. Third, the theoretical knowledge of the structure-dependent corrections varies for each meson system.

Once radiative corrections have been accounted for, measurements of purely leptonic decay branching fractions and lifetimes allow an experimental determination of the product $|V_{q_1 q_2}|\, f_P$. If the decay constant f_P is known to sufficient precision from theory, one can obtain the corresponding CKM element within the standard model. If, on the other hand, one takes the value of $|V_{q_1 q_2}|$ assuming CKM unitarity, one can infer an "experimental measurement" of the decay constant that can then be compared with theory.

The importance of measuring $\Gamma(P \to \ell\nu)$ depends on the particle being considered. Leptonic decays of charged pseudoscalar mesons occur at tree level within the standard model. Thus one does not expect large new-physics contributions to measurements of $\Gamma(P \to \ell\nu)$ for the lighter mesons $P = \pi^+, K^+$, and these processes, in principle, provide clean standard-model determinations of $|V_{ud}|$ and $|V_{us}|$. The situation is different for leptonic decays of charm and bottom mesons. The presence of new heavy particles such as charged Higgs bosons or leptoquarks could lead to observable effects in $\Gamma(P \to \ell\nu)$ for $P = D_{(s)}^+, B^+$ [13–17]. Thus, the determination of $|V_{ub}|$ from $B^+ \to \tau\nu$ decay, in particular, should be considered a probe of new physics. More generally, the ratio of leptonic decays to $\tau\nu$ over $\mu\nu$ final states probes lepton universality [13, 18].

The determinations of CKM elements from leptonic decays of charged pseudoscalar mesons provide complementary information to those from other decay processes. The decay $P \to \ell\nu$ proceeds in the standard model via the axial-vector current $\bar{q}_1 \gamma_\mu \gamma_5 q_2$, whereas semileptonic pseudoscalar meson decays $P_1 \to P_2 \ell\nu$ proceed via the vector current $\bar{q}_1 \gamma_\mu q_2$. Thus the comparison of determinations of $|V_{q_1 q_2}|$ from leptonic and semileptonic decays tests the $V - A$ structure of the standard-model electroweak charged-current interaction. More generally, a small right-handed admixture to the standard-model weak current would lead to discrepancies between $|V_{q_1 q_2}|$ obtained from leptonic pseudoscalar-meson decays, exclusive semileptonic pseudoscalar-meson decays, exclusive semileptonic baryon decays, and inclusive semileptonic decays [19, 20].

Both measurements of the decay rates $\Gamma(P \to \ell\nu)$ and theoretical calculations of the decay constants f_P for $P = \pi^+, K^+, D_{(s)}^+$ from numerical lattice-QCD calculations are now quite precise. As a result, the elements of the first row of the CKM matrix $|V_{ud}|$ and $|V_{us}|$ can be obtained to sub-percent precision from $\pi^+ \to \ell\nu$ and $K^+ \to \ell\nu$, where the limiting error is from continuum theory radiative ccorrections. The elements of the second row of the CKM matrix $|V_{cd(s)}|$ can be obtained from leptonic decays of charmed pseudoscalar mesons to few-percent precision, where here the limiting error is from experiment. These enable stringent tests of the unitarity of the first and second rows of the CKM matrix.

This review is organized as follows. Because the experimental and theoretical issues associated with measurements of pions and kaons, charmed mesons, and bottom mesons differ, we discuss each one separately. We begin with the pion and kaon system in Sec. 72.2. First, in Sec. 72.2.1, we review current measurements of the experimental decay rates. We provide tables of

branching-ratio measurements and determinations of the product $|V_{ud(s)}|f_{\pi^+(K^+)}$, as well as average values for these quantities including correlations and other effects needed to combine results. Then, in Sec. 72.2.2, we summarize the status of theoretical calculations of the decay constants. We provide tables of recent lattice-QCD results for f_{π^+}, f_{K^+}, and their ratio from calculations including dynamical u, d, s, and (in some cases c) quarks, along with averages including correlations and strong SU(2)-isospin breaking corrections as needed. We next discuss the charmed meson system in Sec. 72.3, again reviewing current experimental rate measurements in Sec. 72.3.1 and theoretical decay-constant calculations in Sec. 72.3.2. Last, we discuss the bottom meson system in Sec. 72.4, following the same organization as the two previous sections. For almost all of the decay constants presented in Secs. 72.2.2, 72.3.2, and 72.4.2, we take as our preferred values the four-flavor averages from the FLAG 21 review [2], which incorporate all lattice-QCD results that appeared before 30 April 2021.

After having established the status of both experimental measurements and theoretical calculations of leptonic charged pseudoscalar-meson decays, we discuss some implications for phenomenology in Sec. 72.5. For each process discussed in Secs. 72.2–72.4, we combine the average $\mathcal{B}(P \to \ell\nu)$ with the decay constant f_P to infer the associated CKM matrix element. We then compare these results with determinations of the same CKM elements from other processes. We also use the CKM elements obtained from leptonic decays to test the unitarity of the first and second rows of the CKM matrix. Further, as in previous reviews, we combine the experimental $\mathcal{B}(P \to \ell\nu)$s with the associated CKM elements obtained from CKM unitarity to infer "experimental" values for the decay constants. The comparison of these values with theory provides a test of lattice and other QCD approaches, assuming that new-physics contributions to these processes are not significant.

72.2 Pions and kaons

72.2.1 *Experimental rate measurements*

Experimental rate measurements of pion and kaon leptonic decays are fully radiation inclusive. Following Refs. [21, 22], and references therein, we combine the $\mathcal{O}(\alpha)$ radiative corrections to the purely leptonic rate as follows:

$$\Gamma(P \to \ell\nu[\gamma]) = \Gamma^{(0)}(P \to \ell\nu)\left[1 + \frac{\alpha}{\pi}C_P\right], \tag{72.3}$$

where $P = \pi, K$. The full expressions for C_π and C_K are given in Eq. (114) of Ref. [8]. In addition to the universal short- [4] and long-distance [5] corrections, C_π and C_K include hadronic-structure dependent contributions [6] through $\mathcal{O}(\alpha p^4)$ in chiral perturbation theory (χPT), where p is the pion or kaon momentum. The inclusion of radiative corrections to the purely leptonic rates is numerically important given the level of precision achieved on the experimental measurements of the $\pi^\pm \to \mu^\pm\nu$ and $K^\pm \to \mu^\pm\nu$ decay widths.

We evaluate $\delta_P \equiv (\alpha/\pi)C_P$ using experimentally-measured meson and lepton masses and coupling constants from the Particle Data Group [23], and taking the low-energy constants (LECs) that parametrize the hadronic contributions from Refs. [8, 24, 25]. Because the finite non-logarithmic parts of the LECs were estimated within the large-N_C approximation assuming that contributions from the lowest-lying resonances dominate, we conservatively assign a 100% uncertainty to the LECs, which leads to a ± 0.9 error in $C_{\pi,K}$.[1] We obtain the following correction factors to the individual charged pion and kaon decay widths:

$$\delta_\pi = 0.0176(21) \quad \text{and} \quad \delta_K = 0.0107(21)\,. \tag{72.4}$$

The error on the ratio of kaon-to-pion leptonic decay widths is under better theoretical control because the hadronic contributions from low-energy constants estimated within the large-N_c framework cancel at lowest order in the chiral expansion. For the ratio, we use the correction factor

$$\delta_{K/\pi} = -0.0069(17)\,, \tag{72.5}$$

where we take the estimated error due to higher-order corrections in the chiral expansion from Ref. [27].

There have been no new measurements of the pion leptonic decay rate since the review of Ref. [28]. The sum of branching fractions for $\pi^- \to \mu^-\bar\nu$ and $\pi^- \to \mu^-\bar\nu\gamma$ is 99.98770(4)% [23]. Together with the lifetime 26.033(5) ns [23] this implies $\Gamma(\pi^- \to \mu^-\bar\nu[\gamma]) = 3.8408(7) \times 10^7\ \text{s}^{-1}$. We then subtract the estimated radiative correction factor δ_π in Eq. (72.4) to obtain the purely leptonic rate $\Gamma^{(0)}(\pi^- \to \mu^-\bar\nu)$. Using this rate and the masses from the 2014 PDG review [23] in Eq. (72.1) gives

$$f_{\pi^+}|V_{ud}| = (127.13 \pm 0.02 \pm 0.13)\ \text{MeV}\,, \tag{72.6}$$

where the errors are from the experimental rate measurement and the radiative correction factor, respectively.

The uncertainty on $f_{\pi^-}|V_{ud}|$ is dominated by that from theoretical estimate of the hadronic structure-dependent radiative corrections. The first direct lattice-QCD calculation of the radiative corrections to the pion and kaon leptonic decay rates was performed by the RM123-Soton Collaboration [11]. The results for both $\delta_\pi = 0.0153(19)$ and $\delta_K = 0.0088(9)$, which are given in the Gasser-Rusetsky-Scimemi scheme for separating strong and electromagnetic effects [29], are compatible with our chiral-perturbation-theory estimates above and have smaller quoted uncertainties, especially for δ_K. While independent confirmation of these results is needed, they demonstrate a promising approach for reducing the theoretical uncertainties on the pion and kaon leptonic decay rates in the future.

The world average for the $K \to \mu\nu$ decay rate is obtained from a global fit of several kaon-decay branching ratios and lifetime measurements, and was last updated by the FlaviaNet Working Group on Kaon Decays in 2014 [40]. Thus, the radiation-inclusive branching ratio $\mathcal{B}(K^+ \to \mu^+\nu[\gamma]) = 63.58(11)\%$ and lifetime $\tau_{K^\pm} = 12.384(15)$ ns are unchanged from our previous review. These measurements imply $\Gamma(K^+ \to \mu^+\nu[\gamma]) = 5.134(11) \times 10^7\ \text{s}^{-1}$. As before, we subtract δ_K in Eq. (72.4) from the radiation-inclusive decay width to obtain $\Gamma^{(0)}(K^+ \to \mu^+\nu)$. We then use Eq. (72.1) to obtain

$$f_{K^+}|V_{us}| = (35.09 \pm 0.04 \pm 0.04)\ \text{MeV}\,, \tag{72.7}$$

where the errors are from the experimental rate measurement and the radiative correction factor, respectively.

Short-distance radiative corrections cancel in the ratio of pion-to-kaon decay rates [41]:

$$\frac{\Gamma_{K_{\ell 2[\gamma]}}}{\Gamma_{\pi_{\ell 2[\gamma]}}} = \frac{|V_{us}^2|f_{K^-}^2}{|V_{ud}|^2 f_{\pi^-}^2}\,\frac{m_K(1-m_\ell^2/m_K^2)^2}{m_\pi(1-m_\ell^2/m_\pi^2)^2}(1+\delta_{K/\pi})\,, \tag{72.8}$$

where $\delta_{K/\pi}$ is given in Eq. (72.5). The left-hand side of Eq. (72.8) is 1.3367(28), which implies

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27599 \pm 0.00029 \pm 0.00024\,, \tag{72.9}$$

where the first uncertainty is from the branching fractions and the second is from $\delta_{K/\pi}$. Here, the estimated error on the hadronic structure-dependent radiative corrections is commensurate with the experimental error.

In summary, the main experimental results pertaining to charged pion and kaon leptonic decays are

$$|V_{ud}|f_{\pi^+} = (127.13 \pm 0.02 \pm 0.13)\ \text{MeV}\,, \tag{72.10}$$

$$|V_{us}|f_{K^+} = (35.09 \pm 0.04 \pm 0.04)\ \text{MeV}\,, \tag{72.11}$$

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27599 \pm 0.00029 \pm 0.00024\,, \tag{72.12}$$

where the errors are from the experimental uncertainties in the branching fractions and the theoretical uncertainties in the radiative correction factors δ_P, respectively. All of these values are the same as in our earlier reviews [1, 28, 42].

[1] This uncertainty on $C_{\pi,K}$ is smaller than the error estimated by Marciano and Sirlin in Ref. [26], which predates the calculations of the hadronic-structure contributions in Refs. [6, 8, 24, 25]. The hadronic LECs incorporate the large short-distance electroweak logarithm discussed in Ref. [26], and their dependence on the chiral renormalization scale cancels the scale-dependence induced by chiral loops, thereby removing the dominant scale uncertainty of the Marciano–Sirlin analysis [26].

Table 72.1: Recent published lattice-QCD results for f_{π^+}, f_{K^+}, and their ratio. The upper and lower panels show $(2+1+1)$-flavor and $(2+1)$-flavor determinations, respectively. When two errors are shown, they are statistical and systematic, respectively. Results for f_π and f_K in the isospin symetric limit $m_u = m_d$ are noted with a ‡; they are corrected for isospin breaking via Eq. (72.13) before computing the averages. The 2+1+1 FLAG 21 averages are dominated by the Fermilab/MILC values.

72.2.2 *Theoretical decay-constant calculations*

Table 72.1 presents recent published results for the charged pion and kaon decay constants and their ratio from numerical lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. The uncertainties on both the individual decay constants and their ratio are at the sub-percent level. The SU(3)-breaking ratio f_{K^+}/f_{π^+} can be obtained with especially small errors because statistical errors associated with the Monte Carlo calculations are correlated between the numerator and denominator, as are some systematics. The results in Table 72.1 were obtained using several independent sets of gauge-field configurations, and a variety of lattice fermion actions that are sensitive to different systematic uncertainties.[2] Thus, the good agreement between them indicates that the lattice-QCD uncertainties are controlled and the associated error estimates are reliable.[3]

Table 72.1 also shows the three- and four-flavor averages for the pion and kaon decay constants and their ratio from the FLAG 21 review [2] in the lines labeled "FLAG 21 average." There is no four-flavor average for the pion decay constant in Table 72.1 because all of the four-flavor calculations use the quantity $f_{\pi^+} = 130.41(20)$ MeV [23] as an input to fix the absolute lattice scale needed to convert from lattice-spacing units to GeV [10, 32, 33].

All of the results in Table 72.1 were obtained using isospin-symmetric gauge-field configurations, *i.e.*, the dynamical up and down quarks have the same mass. Fortunately, however, the dominant effect of strong-isospin breaking is easily included in lattice-QCD calculations as follows. Because the up-down mass difference $\Delta m_{ud} \equiv (m_u - m_d) \sim -2.5$ MeV [3, 48] is much less than typical hadronic scales, the strong-isospin breaking corrections to physical observables can systematically expanded in the small parameter $\delta m_{ud} \equiv \Delta m_{ud}/\Lambda_{\rm QCD}$. The leading strong-isospin-breaking corrections to pseudoscalar-meson decay constants arise from the light *valence* quarks in the initial- and final-state hadrons. (See, *e.g.,* the discussion in Ref. [49], for a detailed discussion of isospin-breaking effects in pion and kaon observables.) Thus, to include the effect of nondegenerate up- and down-quark masses, most recent lattice-QCD calculations of f_{π^+} and f_{K^+} evaluate the masses of the valence quarks in the pion at the physical m_u and m_d, and the mass of the valence light quark in the kaon at the physical m_u. This procedure yields a correction to the kaon decay constant below 0.5%. Consequently, strong-isospin breaking corrections from the light sea-quark masses — which are suppressed by an additional power of δm_{ud} — can be neglected given present uncertainties.

Some earlier lattice-QCD calculations, however, only provide the decay constants and their ratio in the $SU(2)$ isospin-symmetric limit [36, 38, 39]. The Flavour Lattice Averaging Group corrects these results for strong-isospin breaking using chiral perturbation theory before including them in the averages. The leading strong-isospin-breaking corrections to the pion and kaon decay constants in χPT can be parametrized as [27, 50]

$$f_{\pi^+} = f_\pi\,, \qquad f_{K^+} = f_K\sqrt{1+\delta_{\rm SU(2)}}\,, \tag{72.13}$$

where f_π and f_K denote the values of the decay constants in the isospin-symmetric limit. The pion decay constant does not receive corrections linear in $m_u - m_d$ because of the G-parity symmetry of the pion triplet, so at first order the δm_{ud} expansion, strong-isospin breaking corrections are characterized by a single parameter, $\delta_{\rm SU(2)}$. Next-to-leading order χPT yields numerical values for $\delta_{\rm SU(2)}$ of approximately -0.004. Recent direct lattice-QCD calculations of $\delta_{\rm SU(2)}$ give larger values of around -0.005 to -0.008 [11, 31–33, 49, 51], but further studies are needed. Thus, to be conservative, FLAG includes an uncertainty of 100% on the χPT estimate for $\delta_{\rm SU(2)}$ when correcting those decay-constant values that are quoted in the isospin-symmetric limit.

The errors on the decay-constant results in Table 72.1 obtained from $(2+1)$-flavor lattice-QCD calculations do not include an estimate of the systematic uncertainty from the omission of charm sea quarks in the calculation. Consequently, when the uncertainty on the $(2+1+1)$-flavor FLAG average is comparable to or better than that on the $(2+1)$-flavor FLAG average, we simply use the four-flavor average as our preferred value. This is not possible, however, for the pion decay constant. To account for this, we first estimate the systematic uncertainty on pseudoscalar-meson decay constants associated with the omission of charm sea quarks. We then add this estimate in quadrature to the quoted error on the $(2+1)$-flavor FLAG average for f_{π^+} to obtain our preferred value.

The error introduced by omitting charm sea quarks can be roughly estimated by expanding the charm-quark determinant in powers of $1/m_c$ [58]; the resulting leading contribution is of order $\alpha_s\left(\Lambda_{\rm QCD}/2m_c\right)^2$ [59]. Taking the $\overline{\rm MS}$ values $\overline{m}_c(\overline{m}_c) =$

[2]See the PDG mini-review on "Lattice Quantum Chromodynamics" [43, 44] for a general review of numerical lattice-QCD calculations. Details on the different methods used in modern lattice-QCD calculations are provided in Appendix A of the FLAG "Review[s] of lattice results concerning low energy particle physics" [2, 3, 45, 46].

[3]See the review by Kronfeld [47] for a summary of the large body of evidence validating the methods employed in modern lattice-QCD calculations.

Table 72.2: Experimental results for $\mathcal{B}(D^+ \to \mu^+\nu[\gamma])$, $\mathcal{B}(D^+ \to \tau^+\nu[\gamma])$, and $|V_{cd}|f_{D^+}$. The systematic errors on the inferred values of $|V_{cd}|f_{D^+}$ include those from the D^+ lifetime and mass. The error from radiative corrections is only included in the entries labeled "our average." In the second CLEO line the τ^+ decays to $\mu^+\nu_\mu\bar{\nu}_\tau$.

Experiment	Mode	$\mathcal{B}$	$\lvert V_{cd}\rvert f_{D^+}$ (MeV)
CLEO-c [52,53]	$\mu^+\nu$	$(3.93 \pm 0.35 \pm 0.09) \times 10^{-4}$	$46.70 \pm 2.10 \pm 0.55$
CLEO-c [52,53]	$\mu^+\nu{+}\tau^+\nu$	$(3.82 \pm 0.32 \pm 0.09) \times 10^{-4}$	$46.00 \pm 1.91 \pm 0.56$
BESIII [54]	$\mu^+\nu$	$(3.71 \pm 0.19 \pm 0.06) \times 10^{-4}$	$45.33 \pm 1.17 \pm 0.38$
Our average	Lines 2+3	$(3.74 \pm 0.17) \times 10^{-4}$	45.50 ± 1.22
CLEO-c [55,56]	$\tau^+\nu$ $(\pi^+\overline{\nu})$	$< 1.2 \times 10^{-3}$	
BESIII [57]	$\tau^+\nu$ $(\pi^+\overline{\nu})$	$(1.20 \pm 0.24 \pm 0.12) \times 10^{-3}$	49.95 ± 2.48
Our average	$\mu^+\nu + \tau^+\nu$		46.17 ± 1.16

1.275 GeV, $\overline{\Lambda}_{\rm QCD} \sim 340$ MeV from FLAG [45], and $\overline{\alpha}(\overline{m}_c) \sim 0.4$, leads to an estimate of about 0.7% for the contribution to the decay constants from charm sea quarks. We can compare this power-counting estimate of charm sea-quark contributions with the observed differences between the (2+1)- and (2+1+1)-flavor lattice-QCD averages for kaon, $D_{(s)}$-meson, and $B_{(s)}$-decay constants in Tables 72.1, 72.4, and 72.6. Looking at Table 72.1, the three- and four-flavor averages for f_{K^+} agree to much better than our simple power-counting estimate. Inspection of Tables 72.4 and 72.6 shows, however, that charm sea-quark effects of this size are still allowed for both $D_{(s)}$-meson and $B_{(s)}$-meson decay constants.

Our final preferred theoretical values for the charged pion and kaon decay constants are

$$f_{\pi^+} = 130.2(1.2)\,\text{MeV}\,, \quad f_{K^+} = 155.7(3)\,\text{MeV}\,, \quad \frac{f_{K^+}}{f_{\pi^+}} = 1.193(2)\,, \tag{72.14}$$

where f_{K^+} and f_{K^+}/f_{π^+} are simply the four-flavor FLAG 2021 averages [2], and f_{π^+} is the three-flavor flavor FLAG 2021 average with the error increased by the estimated 0.7% charm sea-quark contribution.

72.3 Charmed mesons

72.3.1 *Experimental rate measurements*

Measurements have been made of the branching fractions for D^+ and D_s^+ mesons decaying to both $\mu^+\nu$ and $\tau^+\nu$ final states. The CLEO-c and BESIII experiments have made measurements of D^+ decays using e^+e^- collisions at the $\psi(3770)$ resonant energy where D^-D^+ pairs are copiously produced. They fully reconstruct one of the D mesons; for concreteness, we will take this to be the D^-. Counting the number of these events provides the normalization for the branching fraction measurement. The experimental analyses then proceed by identifying a candidate μ^+ and forming the missing-mass squared, $MM^2 = (E_{\rm CM} - E_{D^-})^2 - \left(\overrightarrow{p}_{\rm CM} - \overrightarrow{p}_{D^-} - \overrightarrow{p}_{\mu^+}\right)^2$, where $E_{\rm CM}$ and $p_{\rm CM}$ are the center-of-mass energy (which is known) and momentum (which equals zero in e^+e^- collisions). A peak at zero MM^2 implies the existence of a missing neutrino, and hence the $\mu^+\nu$ decay of the D^+. CLEO-c does not explicitly identify the muon, so their data consists of a combination of $\mu^+\nu$ and $\tau^+\nu$, $\tau^+ \to \pi^+\nu$ events. This permits them to do two fits: in one they fit for the individual components, and in the other they fix the ratio of $\tau^+\nu/\mu^+\nu$ events to be that given by the standard-model expectation. Thus, the former measurement should be used for new-physics searches, and the latter for standard-model predictions. Our average uses the fixed-ratio value.

Table 72.2 shows the available measurements of $D^+ \to \mu^+\nu$, an upper limit on $D^+ \to \tau^+\nu$ from CLEO-c, and the first measurement of this decay from BESIII. Here there is no change since the previous review [1].

To extract the values of $|V_{cd}|f_{D^+}$ via Eq. (72.1), we use values of $m_{D^+} = 1.86961$ GeV and the well-measured D^+ lifetime of 1.040(7) ps [42], and apply radiative corrections as described below. For calculating the average $\mu^+\nu$ number, we use the CLEO-c result from $\mu^+\nu + \tau^+\nu$.

To obtain the purely leptonic rates $\Gamma^{(0)}(D^+ \to \mu^+(\tau^+)\nu)$, we subtract the radiative contributions as in Sec. 72.2.1, but use numerical values for the corrections appropriate for D mesons. First, we reduce both the $\mu^+\nu$ and $\tau^+\nu$ branching fractions in Table 72.2 by 1.8%, which is the universal short-distance electroweak contribution of Sirlin [4] evaluated using the D-meson mass for the factorization scale. We do not adjust the experimental rates by the universal long-distance correction [5]. This is because QED bremsstrahlung contributions have already been subtracted at leading-log order from the measurements in Table 72.2 using Monte-Carlo estimates computed with PHOTOS [12]. The $\mu^+\nu$ rates should also be reduced by the 1% estimate of the structure-dependent contributions from Dobrescu and Kronfeld [17]. This correction accounts for tree-level radiative processes in which the D meson decays into a real photon and an off-shell vector meson, which subsequently decays weakly to a charged lepton and neutrino. It is estimated using Eq. (12) of Burdman *et al.* [7] with the CLEO-c cut on the photon energy from Ref. [70], which is typical of all the measurements. We do not need to apply the structure-dependent correction to the $\mu^+\nu$ branching fractions in Table 72.2, however, because the experiments have already included it in their quoted results. Therefore, in summary, we reduce both the $D^+ \to \mu^+\nu$ and the $D^+ \to \tau^+\nu$ rates by 1.8% to account for radiative corrections. It is worth noting, however, that the universal long-distance electromagnetic contribution estimated for point-like charged mesons by Kinoshita [5], which we are not including because IB contributions are already subtracted from the measurements via PHOTOS, would *increase* both rates by about 2.5%.

We now discuss the D_s^+ decay process. Since our previous review [1] there have been several results from BESIII. Measurements of D_s^+ leptonic decay branching fractions by several groups are listed in Table 72.3. We exclude older values obtained by normalizing to D_s^+ decay modes that are not well-defined. Many measurements, for example, used the $\phi\pi^+$ mode. This decay is a subset of the $D_s^+ \to K^+K^-\pi^+$ channel which has interferences from other modes populating the K^+K^- mass region near the ϕ, the most prominent of which is the $f_0(980)$. Thus, the extraction of the effective $\phi\pi^+$ rate is sensitive to the mass resolution of the experiment and the cuts used to define the ϕ mass region [71].[4]

To find D_s decays in the $\mu^+\nu$ signal channels, the experiments rely on fully reconstructing all of the final state particles except for the neutrino and use a missing-mass technique to infer the existence of the neutrino. CLEO and BESIII use $e^+e^- \to D_sD_s^*$ collisions at 4170 MeV, while BaBar and Belle use $e^+e^- \to DKn\pi D_s^*$ collisions at energies near the $\Upsilon(4S)$. CLEO and BESIII do a similar analysis as was done for the D^+ above. BaBar and Belle do a similar MM^2 calculation by using the reconstructed hadrons, the photon from the D_s^{*+} decay and a detected μ^+. To get the normalization they do a MM^2 fit without the μ^+ and use the signal at the D_s^+ mass squared to determine the total D_s^+ yield.

When selecting the $\tau^+ \to \pi^+\bar{\nu}$ and $\tau^+ \to \rho^+\bar{\nu}$ decay modes, CLEO uses both the calculation of the missing-mass and the fact that there should be no extra energy in the event beyond that

[4] We have not included the BaBar result for $\mathcal{B}(D_s^+ \to \mu^+\nu)$ reported in Ref. [72] because this measurement determined the ratio of the leptonic decay rate to the hadronic decay rate $\Gamma(D_s^+ \to \ell^+\nu)/\Gamma(D_s^+ \to \phi\pi^+)$.

Table 72.3: Experimental results for $\mathcal{B}(D_s^+ \to \mu^+\nu[\gamma])$, $\mathcal{B}(D_s^+ \to \tau^+\nu[\gamma])$, and $|V_{cs}|f_{D_s^+}$. The systematic errors on the inferred values of $|V_{cs}|f_{D_s^+}$ include those from the D_s^+ lifetime and mass. The entries labeled "our average" take into account correlations between systematic errors common to the experiments, and also include errors from radiative corrections.

Experiment	Mode	$\mathcal{B}(\%)$	$\lvert V_{cs}\rvert f_{D_s^+}$ (MeV)
CLEO-c [55,56]	$\mu^+\nu$	$0.565 \pm 0.045 \pm 0.017$	$247.6 \pm 9.9 \pm 4.1$

Our average	$\tau^+\nu$	5.33 ± 0.13	244.0 ± 3.1
Our average	$\mu^+\nu + \tau^+\nu$		243.5 ± 2.7

*We do not use a previous unpublished BaBar result from a subsample of data that uses a different technique for obtaining the branching fraction normalization [60].

deposited by the measured tagged D_s^- and the τ^+ decay products. The $\tau^+ \to e^+\nu\bar{\nu}$ mode, however, uses only extra energy. BaBar and Belle also use the extra energy to discriminate signal from background in their $\tau^+\nu$ measurements. BESIII uses $\tau^+ \to \pi^+\overline{\nu}$ decays, where they calculate the MM^2 and discriminate against μ^+ from $D_s^+ \to \mu^+\nu$ decays, and more recently $\tau^+ \to e^+\nu\overline{\nu}$ and $\tau^+ \to \pi^+\pi^0\overline{\nu}$ decays.

When extracting $|V_{cs}|f_{D_s^+}$ via Eq. (72.1), we first apply the -1.8% universal electroweak correction [4] to all of the $\mu^+\nu$ and $\tau^+\nu$ branching fractions in Table 72.3; this is the same as for D^+ mesons. We also decrease the BaBar and Belle $\mu^+\nu$ branching fractions by the 1% structure-dependent correction [17]. This correction was already included in CLEO and BESIII results for the $\mu^+\nu$ branching fractions in Table 72.3. We use the masses and lifetimes $m_{D_s^+} = 1.96834(7)$ GeV, $m_{\tau^+} = 1.77686(12)$ GeV, and $\tau_{D_s^+} = 0.504(4)$ ps [42]. The inferred values for $f_{D_s^+}|V_{cs}|$ are in good agreement for the $\mu^+\nu$ and $\tau^+\nu$ decay modes.

It is clear from the discussion of radiative corrections in this section that they are less well understood theoretically for D^+ and D_s^+ meson decays than for pions and kaons. We therefore assign a 1.4% systematic uncertainty to the purely leptonic decay rates, which is half the size of the applied radiative corrections. This translates to a 0.7% error on the products of the decay constant times CKM matrix element. Putting everything together, the main experimental results pertaining to charmed meson leptonic decays are (see the bottom lines of Tables 72.2 and 72.3):

$$|V_{cd}|f_{D^+} = \ 46.17 \ \pm 1.11 \pm 0.32 = 46.17 \pm 1.16 \text{ MeV}, \quad (72.15)$$

$$|V_{cs}|f_{D_s^+} = 243.5 \ \pm 2.1 \pm 1.7 = 243.5 \pm 2.7 \text{ MeV}, \quad (72.16)$$

where the errors are from the measured branching fractions and the applied radiative corrections, respectively.

72.3.2 *Theoretical decay-constant calculations*

Table 72.4 presents recent theoretical calculations of charmed heavy-light meson decay constants and their ratio in the isospin-symmetric limit $m_u = m_d$. (As in Sec. 72.2.2, we denote the physical D^+-meson decay constant by f_{D^+}, and use f_D for the isospin-symmetric value.) The upper two panels show results from lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. Although there are fewer available results than for the pion and kaon sector, both f_D and f_{D_s} have been obtained using multiple sets of gauge-field configurations with different lattice fermion actions, providing independent confirmation. For comparison, the bottom panel of Table 72.4 shows QCD-model calculations of the D- and D_s-meson decay constants for which uncertainty estimates are provided. The lattice and non-lattice results agree, but numerical lattice-QCD calculations have now reached significantly greater precision than other approaches. There are no new results quoted from FLAG 21 [2] compared with those in our previous review [1] quoted from FLAG 19 [3].

The lattice-QCD decay-constant results in Table 72.4 were all obtained using isospin-symmetric gauge-field configurations. As discussed in Sec. 72.2.2, however, the leading strong-isospin breaking corrections to heavy-light pseudoscalar-meson decay constants can be accounted for by using the physical down (or up) quark in the D (or B) meson. Strong-isospin breaking corrections to heavy-strange meson decay constants are roughly an order-of-magnitude smaller because there are no light valence quarks involved. Recently, the Fermilab Lattice and MILC Collaborations used this approach to calculate directly the dominant strong-isospin breaking corrections to both f_D and f_B, finding [31]

$$\begin{aligned} f_{D^+} - f_D &= 0.58(1)_{\text{stat}}(7)_{\text{syst}}(1)_{\text{EM scheme}} \text{ MeV}, \\ f_{B^+} - f_B &= -0.53(5)_{\text{stat}}(7)_{\text{syst}}(0)_{\text{EM scheme}} \text{ MeV}. \end{aligned} \quad (72.17)$$

These results agree with independent estimates of the strong-isospin-breaking corrections to heavy-light meson decay constants from Borelized sum rules [85]. Combined with the determinations of f_D and f_B from the same work, Eq. (72.17) implies that the corrections to the SU(3)-flavor breaking ratios are

$$\frac{f_{D_s}}{f_{D^+}} = \frac{f_{D_s}}{f_D}\Big(1 - 0.0027(3)\Big), \qquad \frac{f_{B_s}}{f_{B^+}} = \frac{f_{B_s}}{f_B}\Big(1 + 0.0028(5)\Big). \quad (72.18)$$

These estimated strong-isospin-breaking corrections to f_D and f_{D_s}/f_D above are commensurate with the uncertainties on the

Table 72.4: Recent theoretical determinations of f_D, f_{D_s}, and their ratio in the isospin-symmetric limit. The upper panels show results from lattice-QCD calculations with $(2+1+1)$ and $(2+1)$ dynamical quark flavors, respectively. Statistical and systematic errors are quoted separately. The bottom panel shows estimates from QCD sum rules (QCD SR) and the light-front quark model (LFQM). These are not used to obtain our preferred decay-constant values. The 2+1+1 averages are dominated by the Fermilab/MILC values.

*Ref. [31] provides values for f_D and f_{D_s} in the isopsin-symmetric limit, but not for their ratio. Here we infer the central value from those of the individual decay constants, and take the statistical and systematic errors to be the same as for the physical ratio f_{D_s}/f_{D^+}.

†Slight difference from preliminary value quoted in 2019 FLAG review.

‡Obtained using $m_c^{\overline{\rm MS}}$; results using $m_c^{\rm pole}$ are also given in the paper.

(2+1+1)-flavor FLAG averages in Table 72.4. Consequently, it is important to account for isospin-breaking effects before combining the theoretical decay constants with the corresponding experimental decay rates.

To obtain the charged D^+-meson decay constant, we apply the correction in Eq. (72.17) to the (2+1+1)-flavor 2021 FLAG average for the D-meson decay constant in the isospin-symmetric limit. Similarly we use Eq. (72.18) to correct the (2+1+1)-flavor 2021 FLAG average for f_{D_s}/f_D. We take the four-flavor FLAG 2021 average for f_{D_s} directly. Our final preferred theoretical values for the charmed pseudoscalar-meson decay constants are

$$\begin{aligned} f_{D^+} &= 212.0(7)\ \text{MeV}\,, \\ f_{D_s} &= 249.9(5)\ \text{MeV}\,, \\ \frac{f_{D_s}}{f_{D^+}} &= 1.1783(16)\,. \end{aligned} \tag{72.19}$$

Table 72.5: Experimental results for $\mathcal{B}(B^- \to \tau^- \overline{\nu})$ and $|V_{ub}|f_{B^+}$. To extract the values of $|V_{ub}|f_{B^+}$ via Eq. (72.1), we use the PDG 2018 value of the B^+ lifetime of 1.638±0.004 ps, and the τ^+ and B^+ masses of 1.77686 and 5.27933 GeV, respectively.

72.4 Bottom mesons

72.4.1 *Experimental rate measurements*

The Belle and BaBar collaborations have found evidence for $B^- \to \tau^- \overline{\nu}$ decay in $e^+e^- \to B^-B^+$ collisions at the $\Upsilon(4S)$ energy. The analysis relies on reconstructing a hadronic or semileptonic B decay tag, finding a τ candidate in the remaining track and photon candidates, and examining the extra energy in the event which should be close to zero for a real τ^- decay to $e^-\nu\overline{\nu}$ or $\mu^-\nu\overline{\nu}$ opposite a B^+ tag. While the BaBar results have remained unchanged, Belle reanalyzed both samples of their data. The branching fraction using hadronic tags changed from $1.79^{+0.56}_{-0.49}{}^{+0.46}_{-0.51} \times 10^{-4}$ (2006) [86] to $0.72^{+0.27}_{-0.25} \pm 0.11 \times 10^{-4}$ (2012) [87], while the corresponding change using semileptonic tags was from $1.54^{+0.38}_{-0.37}{}^{+0.29}_{-0.31}$ to $1.25 \pm 0.28 \pm 0.27$. These changes demonstrate the difficulty of the analysis. The results are listed in Table 72.5. These are unchanged since the previous review [1].

Because there are large backgrounds under the signals for these measurements, as well as substantial systematic errors, the significances of the individual results are still below the 5σ discovery threshold. Belle quotes 4.6σ for their combined hadronic and semileptonic tags, while BaBar quotes 3.3σ and 2.3σ, for hadronic and semileptonic tags. Greater precision is necessary to determine if any effects beyond the standard model are present.

We do not correct the measured branching ratios in Table 72.5 for radiative corrections because the experimental uncertainties are so large. The relative radiative corrections are expected to be bigger, however, for $B \to \mu\nu$ leptonic decays because the corrections are no longer helicity suppressed [9], and may be a significant fraction of the purely leptonic rate. More theoretical work is needed to understand radiative corrections to leptonic B decays in anticipation of future measurements with greater precision, and of new decay channels.

72.4.2 *Theoretical decay-constant calculations*

Table 72.6 presents recent theoretical calculations of bottom heavy-light meson decay constants and their ratio in the isospin-symmetric limit $m_u = m_d$. The upper two panels show results from lattice-QCD calculations with three $(N_f = 2+1)$ or four flavors $(N_f = 2+1+1)$ of dynamical quarks. For all decay constants, calculations using different gauge-field configurations, light-quark actions, and b-quark actions provide independent confirmation. For comparison, the bottom panel of Table 72.6 shows QCD-model calculations of the B- and B_s-meson decay constants for which uncertainty estimates are provided. These are consistent with the lattice values, but with much larger uncertainties. This table, based on the FLAG 21 averages [2], reflects the latest update of the FLAG 19 averages [3].

The lattice-QCD decay-constant results in Table 72.6 were all obtained using isospin-symmetric gauge-field configurations. Some calculations, however, account for the dominant effect of strong-isospin-breaking by using the correct value for the va-

Table 72.6: Recent theoretical determinations of f_B, f_{B_s}, and their ratio in the isospin-symmetric limit. The upper panels show results from lattice-QCD calculations with $(2+1+1)$ and $(2+1)$ dynamical quark flavors, respectively. When available, statistical and systematic errors are quoted separately. The bottom panel shows estimates from the relativistic potential model (RPM), QCD sum rules, and the light-front quark model, which are not used to obtain our preferred decay-constant values. The 2+1+1 FLAG 21 averages are dominated by the Fermilab/MILC values.

*Average of new HPQCD 17 and previous HPQCD 13 results allowing for correlations between the two sets of results.
†Obtained with static b quarks (*i.e.*, $m_b \to \infty$).
‡Ref. [95] does not provide results in the isospin-symmetric limit, so we show f_{B^+} and f_{B_s}/f_{B^+} for this work.
§Obtained using $m_b^{\overline{\rm MS}}$; results using $m_b^{\rm pole}$ are also given in the paper.

lence light-quark mass in the B meson (m_u for f_{B^+} and m_d for f_{B^0}). Early estimates of the strong-isospin-breaking correction obtained $f_{B^+} - f_B \sim -2$ MeV [93, 95], which would be significant given the present lattice-QCD uncertainties. It turns out, however, that these calculations inadvertently introduced a spurious sea-quark contribution, and therefore overestimated the size of the effect. A more recent calculation by the Fermilab/MILC Collaboration finds very little evidence for isospin violation ($f_{B^+} - f_B \sim -0.5$ MeV) [31], which is more than two times smaller than the total uncertainties on present lattice-QCD calculations. For this reason, we quote isospin averages in the current review. Our preferred theoretical values for the bottom pseudoscalar-meson decay constants are

$$\begin{aligned} f_B &= 190.0(1.3)\ \text{MeV}\,, \\ f_{B_s} &= 230.0(1.3)\ \text{MeV}\,, \\ \frac{f_{B_s}}{f_B} &= 1.209(5)\,, \end{aligned} \tag{72.20}$$

which are simply the $N_f = 2+1+1$ FLAG 2021 averages [2]. Because the uncertainties on the three-flavor results in Table 72.6 are substantially larger than those on the four-flavor results, including them in the average leaves the central values unchanged, and decreases the errors only slightly.

72.5 Phenomenological implications

72.5.1 $|V_{ud}|$, $|V_{us}|$, *and status of first-row unitarity*

Using the average values for $f_{\pi^+}|V_{ud}|$, $f_{K^+}|V_{us}|$, and their ratio from Eqs. (72.10)–(72.12) and for f_{π^+}, f_{K^+}, and their ratio from Eq. (72.14), we obtain the following determinations of the CKM matrix elements $|V_{ud}|$, $|V_{us}|$, and their ratio from leptonic decays within the standard model:

$$\begin{aligned} &|V_{ud}| = 0.9764(2)(90)(10)\,, \quad |V_{us}| = 0.2254(3)(4)(3), \\ &\frac{|V_{us}|}{|V_{ud}|} = 0.2313(2)(4)(2)\,, \end{aligned} \tag{72.21}$$

where the errors are from the experimental branching fraction(s), the pseudoscalar decay constant(s), and radiative corrections, respectively. These results enable a test of the unitarity of the first row of the CKM matrix from leptonic decays alone (the contribution from $|V_{ub}|$ is negligible). Using the values of $|V_{ud}|$ and $|V_{us}|$ from Eq. (72.21), we find

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = 0.004(18)\,, \tag{72.22}$$

which is consistent with three-generation unitarity at the few-percent level.

The determinations of $|V_{ud}|$ and $|V_{us}|$ from leptonic decays in Eq. (72.21) can be compared to those obtained from other processes. The result above for $|V_{ud}|$ agrees with the determination from superallowed β-decay (a previous value of $|V_{ud}| = 0.97420(21)$ [101] has been updated to $|V_{ud}| = 0.97373(31)$ [102]) but has a considerably larger error, primarily due to the uncertainty in the theoretical determination of f_{π^+}.

The CKM element $|V_{us}|$ can be determined from semileptonic $K^+ \to \pi^0 \ell^+ \nu$ decay. Here experimental measurements provide a value for the product $f_+^{K\pi}(0)|V_{us}|$, where $f_+^{K\pi}(0)$ is the form factor at zero four-momentum transfer between the initial state kaon and the final state pion. We quote a recent analysis by Seng *et al.* [103] which finds $|V_{us}|f_+^{K\pi}(0) = 0.21635(38)(3)$, with the first error denoting experiment and the second reflecting uncertainty in higher order corrections. This is not far from the value 0.2165(4) quoted in our 2020 review [40].[5] Choosing the 2021 2+1+1-flavor FLAG average for $f_+(0)^{K\pi} = 0.9698(17)$ [2] based on the calculations of ETM [107] and Fermilab/MILC [108] gives $|V_{us}| = 0.22309(40)_{\rm exp}(39)_{\rm LQCD}(3)_{\rm HO}$ from semileptonic decay. The determinations of $|V_{us}|$ from leptonic and semileptonic kaon decays are both quite precise, with comparable errors, from but the central values differ by 2.9σ.

Finally, the combination of the ratio $|V_{us}|/|V_{ud}|$ from leptonic decays [Eq. (72.21)] with $|V_{ud}|$ from β decay implies an alternative determination of $|V_{us}| = 0.2253(5)$ which agrees with the value

[5] This was an update of the 2010 Flavianet review [41] that included new measurements of the K_S lifetime [104, 105], $\mathrm{Re}(\epsilon'/\epsilon)$ [105], and $\mathcal{B}(K^\pm \to \pi^\pm\pi^+\pi^-)$ [106]. The latter measurement was the primary source of the reduced error on $\mathcal{B}$(semileptonic), via the constraint that the sum of all branching ratios must equal unity.

from leptonic kaon decay, but disagrees with the semileptonic-decay result at the 2.9σ level.

Given the roughly 3σ tension between $|V_{us}|$ from leptonic and semileptonic kaon decays, it is important to scrutinize the uncertainties on the theoretical and experimental inputs to $|V_{us}|$ and other elements of the first row of the CKM matrix. Seng *et al.* have introduced a new approach for calculating radiative corrections to neutron and nuclear beta decays using dispersion relations [109–112]. These calculations imply a value of $|V_{ud}| = 0.97395(23)$, consistent with the updated analysis of Ref. [102].

An independent calculation of the radiative corrections by Czarnecki and Marciano using QCD sum rules yields similar results [113]. Using this value of $|V_{ud}|$ with the determination of $|V_{us}|$ from leptonic kaon decays in Eq. (72.21), we obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = -0.0007(5)$, again consistent with first-row unitarity.

Last, we combine the experimental measurement of $f_{\pi^+}|V_{ud}|$ in Eq. (72.10) with $|V_{ud}|$ from superallowed β-decay [102] to infer an "experimental" value for the pion decay constant:

$$f_{\pi^-}^{\text{"exp"}} = 130.56(2)(3)(13)\ \text{MeV}\,, \tag{72.23}$$

where the uncertainties are from the errors on Γ, $|V_{ud}|$, and higher-order corrections, respectively. Many recent (2+1+1)-flavor lattice-QCD calculations use this quantity to set the overall physical scale in their simulations, *e.g.*, Refs. [10, 31–33]. Conversely, comparing $f_{\pi^-}^{\text{"exp"}}$ with the 2021 FLAG (2+1)-flavor average $f_{\pi^+} = 130.2(8)$ MeV, which only includes lattice-QCD results that employ other observables to set the scale [34–39], provides a test of lattice-QCD methods. The values are in good agreement within present uncertainties. We do not quote an "experimental" value for the kaon decay constant because the value of $|V_{us}|$ is less clear given the $\sim 3\sigma$ tension between the values of $|V_{us}|$ obtained from leptonic and semileptonic kaon decays.

72.5.2 $|V_{cd}|$, $|V_{cs}|$, *and status of second-row unitarity*

Using the average values for $|V_{cd}|f_{D^+}$ and $|V_{cs}|f_{D_s^+}$ from Eqs. (72.15) and (72.16), and for f_{D^+} and $f_{D_s^+}$ from Eq. (72.19), we obtain the following determinations of the CKM matrix elements $|V_{cd}|$ and $|V_{cs}|$ from leptonic decays within the standard model:

$$|V_{cd}| = 0.2178(53)(15)(7) \quad \text{and} \quad |V_{cs}| = 0.9744(84)(16)(20)\,, \tag{72.24}$$

where the errors are from the measured branching fractions, radiative corrections, and decay constants, respectively. These results enable a test of the unitarity of the second row of the CKM matrix. Taking $V_{cb} = 41.0(1.4) \times 10^{-3}$ [1], we obtain

$$|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 - 1 = -0.001(22)\,, \tag{72.25}$$

in agreement with three-generation unitarity.

The uncertainty on $|V_{cd}|$ in Eq. (72.24) is limited by the measurement error on the $D^+ \to \mu^+\nu$ decay rate. For $|V_{cs}|$, however, the experimental and radiative-correction errors are commensurate. The value of $|V_{cs}|$ from leptonic D_s decays decreased substantially from the value of 1.007(17) in an earlier version of this review [28, 114], and is now below unity as expected in the three-generation CKM framework. This change is due to our more consistent treatment of the radiative corrections, which lower the purely leptonic decay rates for $D_s^+ \to \mu^+\nu$ and $D_s^+ \to \tau^+\nu$. We emphasize, however, that we have taken a generous uncertainty on these estimates, and that more theoretical work is needed to really pin down the sizes of the radiative corrections to $D_{(s)}$-meson leptonic decays.

The CKM matrix elements $|V_{cd}|$ and $|V_{cs}|$ can also be obtained from semileptonic $D^+ \to \pi^0\ell^+\nu$ and $D_s^+ \to K^0\ell^+\nu$ decays, respectively. Here experimental measurements determine the product of the form factor times the CKM element, and theory provides the value for the form factor at zero four-momentum transfer between the initial $D_{(s)}$ meson and the final pion or kaon.

The latest experimental averages from the Heavy Flavor Averaging Group (HFLAV) are $f_+^{D\pi}(0)\,|V_{cd}| = 0.1426(19)$ and $f_+^{D_sK}(0)|V_{cs}| = 0.7226(34)$ [115]. There are not enough published lattice-QCD calculations of the zero-momentum $D_{(s)}$-meson semileptonic form factors with $N_f \geq 3$ to permit an average by the FLAG Collaboration. Taking the most precise three-flavor form-factor results $f_+^{D\pi}(0) = 0.666(29)$ and $f_+^{D_sK}(0) = 0.747(19)$ from the HPQCD Collaboration [116,117] gives for the CKM matrix elements $|V_{cd}| = 0.2141(97)$ and $|V_{cs}| = 0.967(25)$, in agreement with those from leptonic decays in Eq. (72.24). A newer, four-flavor calculation of the form factors by the ETM Collaboration [118], however, yields a smaller value of $f_+^{D\pi}(0) = 0.612(35)$ by 1.2σ and a larger $f_+^{D_sK}(0) = 0.765(31)$ by 0.5σ. These imply $|V_{cd}| = 0.233(14)$ and $|V_{cs}| = 0.945(39)$, which are about 1σ above and below the values from leptonic decays in Eq. (72.24), respectively. Independent lattice-QCD calculations of the $D^+ \to \pi^0\ell^+\nu$ and $D_s^+ \to K^0\ell^+\nu$ form factors now in progress [119,120] will help to clarify the picture. In a lattice QCD study of the decay $D \to K\ell\nu$, the HPQCD Collaboration [121] reports $|V_{cs}| = 0.9663(80)$.

We can combine the experimental measurements of $f_{D^+}|V_{cd}|$ and $f_{D_s^+}|V_{cs}|$ from Tables 72.2 and 72.3 with $|V_{cd}| = 0.2245(8)$ and $|V_{cs}| = 0.97370(14)$ from the PDG 2020 global unitarity-triangle analysis [1] to infer "experimental" values for the decay constants within the standard model. We take the CKM elements from the global fit because they are based on many input quantities, thereby reducing the sensitivity to any one outlying measurement or calculation. We obtain for the decay constants

$$\begin{aligned} f_{D^+}^{\text{"exp"}} &= 208.9(5.0)(3.8)(1.5)\ \text{MeV}\,, \\ f_{D_s^+}^{\text{"exp"}} &= 246.7(2.1)(2.8)(1.7)\ \text{MeV}\,, \\ (f_{D_s^+}/f_{D^+})^{\text{"exp"}} &= 1.181(30)(25)(12)\,. \end{aligned} \tag{72.26}$$

where the uncertainties are from the errors on $\Gamma^{(0)}$, CKM matrix elements, and radiative corrections, respectively. The "experimental" values f_{D^+} $(f_{D_s^+}/f_{D^+})$ are consistent within 1σ with the (2+1+1)-flavor lattice-QCD averages in Eq. (72.19). The CKM matrix element $|V_{cd}|$ is approximately equal to $|V_{us}|$, as first shown by Wolfenstein [122, 123]. Thus, resolving the inconsistencies between determinations of $|V_{us}|$ from leptonic and semileptonic decays discussed in Sec. 72.5.1 may benefit from the constraints observed here.

Last, we can test lepton-flavor universality in charm meson decays by checking the following relationship derived from Eq. (72.1):

$$\frac{\Gamma(D_s^+ \to \tau^+\nu)}{\Gamma(D_s^+ \to \mu^+\nu)} = \frac{m_\tau^2\left(1 - m_\tau^2/M_{D_s}^2\right)^2}{m_\mu^2\left(1 - m_\mu^2/M_{D_s}^2\right)^2} = 9.75\,, \tag{72.27}$$

where the uncertainties from the masses are negligible to the number of digits quoted. The measured ratio of $\tau^+\nu$ to $\mu^+\nu$ rates is 9.82 ± 0.40, consistent with this standard-model expectation.

72.5.3 $|V_{ub}|$ *and other applications*

Using the average value for $|V_{ub}|f_{B^+}$ from Table 72.5, and for f_{B^+} from Eq. (72.20), we obtain the following determination of the CKM matrix element $|V_{ub}|$ from leptonic decays within the standard model:

$$|V_{ub}| = 4.05(37)(3) \times 10^{-3}\,, \tag{72.28}$$

where the errors are from experiment and theory, respectively. One should bear in mind when interpreting Eq. (72.28) that none of the experimental measurements that enter the average for $|V_{ub}|f_{B^+}$ have individually reached the 5σ discovery level (see Sec. 72.4.1). Further, decays involving the third generation of quarks and leptons may be particularly sensitive to new physics associated with electroweak symmetry breaking due to their larger masses [13, 15], so Eq. (72.28) is more likely to be influenced by new physics than the determinations of the elements of the first and second rows of the CKM matrix in the previous sections.

The CKM element $|V_{ub}|$ can also be obtained from semileptonic B-meson decays. For more than a decade, there has remained a persistent 2-3σ tension between the determinations of $|V_{ub}|$ from exclusive $B \to \pi\ell\nu$ decay and from inclusive $B \to X_u\ell\nu$ decay,

where X_u denotes all hadronic states populated by the $bb \to u$ weak transition [23, 115, 124–127]. The currently most precise determination of $|V_{ub}|^{\rm excl} = 3.73(14) \times 10^{-3}$ is obtained from a joint z-fit by FLAG [2] of the vector and scalar form factors $f_+^{B\pi}(q^2)$ and $f_0^{B\pi}(q^2)$ calculated in (2+1)-flavor lattice QCD [128–130] and experimental measurements of the differential decay rate from BaBar [131,132] and Belle [133,134]. On the other hand, the PDG 2018 inclusive determination obtained using the theoretical frameworks in Refs. [135–137] is $|V_{ub}|^{\rm incl} = 4.49(28) \times 10^{-3}$ [42, 138]. The value of $|V_{ub}|$ from leptonic $B \to \tau\nu$ decay in Eq. (72.28) splits the difference between the inclusive and exclusive determinations, and is compatible (within large uncertainties) with both.

Given the large uncertainties on the experimental measurements of $\mathcal{B}(B^- \to \tau^- \overline{\nu})$, and the more than 2σ disagreement between $|V_{ub}|$ obtained from inclusive and exclusive semileptonic B decays, we do not present an "experimental" value of the decay constant f_{B^+}.

72.6 Concluding remarks

The increasing precision of measurements of leptonic decays of charged pseudoscalar mesons has begun to require control over radiative corrections at a level superior to that presented here. Improvements will be called for both in theory and in experiment (for example, by BESIII and Belle II).

Unitarity of the CKM matrix is in reasonable shape. However, there is a lingering $\sim 3\sigma$ tension between the values of V_{us} determined by semileptonic and leptonic kaon decays. It will be interesting to follow experimental and theoretical developments on this quantity.

73. Production and Decay of *b*-flavored Hadrons

Revised September 2021 by P. Eerola (Helsinki U.), M. Kreps (Warwick U.) and Y. Kwon (Yonsei U., Seoul).

The b quark belongs to the third generation of quarks and is the weak–doublet partner of the t quark. The existence of the third–generation quark doublet was proposed in 1973 by Kobayashi and Maskawa [1] in their model of the quark mixing matrix ("CKM" matrix), and confirmed four years later by the first observation of a $b\bar{b}$ meson [2]. In the KM model, CP violation is explained within the Standard Model (SM) by an irreducible phase of the 3×3 unitary matrix. The regular pattern of the three lepton and quark families is one of the most intriguing puzzles in particle physics. The existence of families gives rise to many of the free parameters in the SM, including the fermion masses, and the elements of the CKM matrix.

Since the b quark is the lighter element of the third–generation quark doublet, the decays of b-flavored hadrons occur via generation-changing processes through CKM matrix. Because of this, and the fact that the CKM matrix is close to a 3×3 unit matrix, many interesting features such as loop and box diagrams, flavor oscillations, as well as large CP asymmetries, can be observed in the weak decays of b-flavored hadrons.

The CKM matrix is parameterized by three real parameters and one complex phase. This complex phase is the source of CP violation in B meson decays in the Standard Model. A crucial milestone was the first observation of CP violation in the B meson system in 2001, by the BaBar [3] and Belle [4] collaborations. They measured a large value for the parameter $\sin 2\beta$ $(= \sin 2\phi_1)$ [5], almost four decades after the discovery of a small CP asymmetry in neutral kaons. A more detailed discussion of the CKM matrix and CP violation can be found elsewhere in this *Review* [6, 7].

The structure of this mini-review is organized as follows. After a discussion of b-quark production and current results on spectroscopy, we discuss lifetimes of b-flavored hadrons. We then discuss some basic properties of B-meson decays, followed by summaries of dominant hadronic, rare hadronic, and electroweak penguin decays of B-mesons. There are separate mini-reviews for B^0–$\overline{B}^0$ mixing [8] and the extraction of the CKM matrix elements V_{cb} and V_{ub} from B-meson decays [9] in this *Review*.

73.1 Production and spectroscopy

The bound states of a $\bar{b}$ antiquark and a u, d, s, or c quark are referred to as the B_u (B^+), B_d (B^0), B_s (B_s^0), and B_c (B_c^+) mesons, respectively. The B_c^+ is the heaviest of the ground–state b-flavored mesons, and the most difficult to produce: it was observed for the first time in the semileptonic mode by CDF in 1998 [10], but its mass was accurately determined only in 2006, from the fully reconstructed mode $B_c^+ \to J/\psi\pi^+$ [11]. Many exclusive decay channels can now be used for the accurate mass measurements, given the large statistics available at the LHC. Currently the most precise measurement is made by LHCb and yields $m(B_c^+) = 6274.47 \pm 0.27 \pm 0.17$ MeV/c^2 [12], combining $B_c^+ \to J/\psi\pi^+$, $B_c^+ \to J/\psi\pi^+\pi^-\pi^+$, $B_c^+ \to J/\psi p\bar{p}\pi^+$, $B_c^+ \to J/\psi D_s^+$, $B_c^+ \to J/\psi D^0 K^+$ and $B_c^+ \to B_s^0\pi^+$ decay modes.

The first excited meson is called the B^* meson, while B^{**} is the generic name for the four orbitally excited $(L = 1)$ B-meson states that correspond to the P-wave mesons in the charm system, D^{**}. Excited states of the B_s^0 meson are similarly named B_s^* and B_s^{**}.

Of the possible bound $\bar{b}b$ states, the $\Upsilon(nS)$ and $\chi_{bJ}(nP)$ states are well studied. The pseudoscalar ground state η_b has been observed for the first time by BaBar [13] indirectly through the decay $\Upsilon(3S) \to \gamma\eta_b$, and then confirmed by Babar in $\Upsilon(2S)$ decays [14] and CLEO in $\Upsilon(3S)$ decays [15]. The most accurate mass and width measurements come now from Belle, using decays $\Upsilon(5S) \to h_b(1P)\pi^+\pi^-$, $h_b(1P) \to \gamma\eta_b(1S)$ [16] and $\Upsilon(4S) \to \eta h_b(1P)$, $h_b(1P) \to \gamma\eta_b(1S)$ [17]. Belle has also reported first evidence for the $\eta_b(2S)$ in the $h_b(2P) \to \eta_b(2S)\gamma$ transition [16]. In addition, Belle has observed $Z_b(10610)$ and $Z_b(10650)$ states in the processes $\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-$ $(n = 1, 2, 3)$ and $\Upsilon(5S) \to h_b(mP)\pi^+\pi^-$ $(m = 1, 2)$ [18]. These Z_b states are observed to decay to $\Upsilon(nS)\pi^\pm$ and $h_b(mP)\pi^\pm$, hence electrically charged and do not belong to ordinary $q\bar{q}$ mesons. For classification and naming of these and other states, see Ref. [19].

Experimental studies of b decays have been performed in e^+e^- collisions at the $\Upsilon(4S)$ (ARGUS, CLEO, Belle, BaBar) and $\Upsilon(5S)$ (CLEO, Belle) resonances. The $e^+e^- \to b\bar{b}$ production cross-section at the $\Upsilon(4S)$ $(\Upsilon(5S))$ resonance is about 1.1 nb (0.3 nb). The full data samples of BaBar and Belle are 560 fb^{-1} and 1020 fb^{-1}, respectively, of which 433 fb^{-1} and 710 fb^{-1} are at the $\Upsilon(4S)$ resonance. Since the $\Upsilon(4S)$ decays dominantly to a pair of B mesons (either B^+B^- or $B^0\overline{B}^0$), a precise knowledge of the energy-momentum of one B meson (the 'tagging B') enables deducing the properties of the other B (the 'signal B'). This property has been exploited by both BaBar and Belle, in particular, to measure inclusive decay modes as well as final states with missing neutrinos. The Belle II experiment at SuperKEKB has started recording data in 2019, and the experiment has so far collected about 210 fb^{-1} of data by summer 2021. At the Z resonance (SLC, LEP) all species of b-flavored hadrons could be studied for the first time. The $e^+e^- \to b\bar{b}$ production cross-section at the Z resonance is about 6.6 nb.

High-energy $p\bar{p}$ (Tevatron) and pp collisions (LHC) produce b-flavored hadrons of all species with large cross-sections. At the Tevatron ($\sqrt{s} = 1.96$ TeV) the visible cross section $\sigma(p\bar{p} \to bX, |\eta| < 1)$ is about 30 μb. CDF and D0 experiments at the Tevatron have accumulated by the end of their running about 10 fb^{-1} each.

At the LHC pp collider at $\sqrt{s} = 7 - 13$ TeV, the visible b-hadron cross section at the LHCb experiment with pseudorapidity acceptance $2 < \eta < 5$ has been measured to be ~ 72 μb at 7 TeV and ~ 144 μb at 13 TeV [20] (cross section at 13 TeV corrected in Erratum). LHCb has collected about 1 fb^{-1} at 7 TeV, 2 fb^{-1} at 8 TeV, and close to 5.9 fb^{-1} at 13 TeV during LHC Runs 1 and 2. CMS and ATLAS have collected each about 5 fb^{-1} of data at $\sqrt{s} = 7$, 20 fb^{-1} at 8 TeV and about 150 fb^{-1} at 13 TeV during LHC Runs 1 and 2. The LHCb experiment is undergoing currently major upgrade. The LHC operation is planned to resume in 2022.

In hadron collisions, production happens as $b\bar{b}$ pairs via leading order flavor creation or higher order processes such as gluon–splitting. Single b-quarks can be produced by flavor excitation. The total b-production cross section is an interesting test of our understanding of leading and higher order QCD processes. With a wealth of measurements at LHC and at Tevatron (see Ref. [20] and references therein), and improved calculations [21], there is a reasonable agreement between measurements and predictions.

Each quark of a $b\bar{b}$ pair produced in hadron collisions hadronizes separately and incoherently from the other, but it is still possible to obtain a statistical indication of the charge of a produced $b/\bar{b}$ quark ("flavor tag" or "charge tag") from the accompanying particles produced in the hadronization process, or from the decay products of the other quark. The momentum spectrum of produced b-quarks typically peaks near the b-quark mass, and extends to much higher momenta, dropping by about a decade for every ten GeV. Typical decay lengths are of the order of a centimeter at 13 TeV pp collisions; the resolution for the decay vertex must be more precise than this to resolve the fast oscillations of B_s^0 mesons.

In e^+e^- colliders, since the B mesons are very slow in the $\Upsilon(4S)$ rest frame, asymmetric beam energies are used to boost the decay products to allow time-dependent measurements that are crucial for the study of CP violation. At KEKB, the boost was $\beta\gamma = 0.43$, while PEP-II used a slightly larger boost, $\beta\gamma = 0.55$. The typical B-meson decay length is dilated from ≈ 20 μm to ≈ 200 μm. At SuperKEKB the boost is lower, $\beta\gamma = 0.28$, which puts more demanding requirements on the track reconstruction precision at Belle II to reach a resolution in decay time measurements similar to Belle. The two B mesons produced in $\Upsilon(4S)$ decay are in a coherent quantum state, which makes it easier than in hadron collisions to infer the charge state of one B meson from observation of the other; however, the coherence also requires determination of the decay time of both mesons, rather than just one, in order to perform time–dependent CP–violation measurements. For B_s^0, which can be produced at $\Upsilon(5S)$ the situation is less favourable,

as boost is not high enough to provide sufficient time resolution to resolve the fast B_s^0 oscillations.

For the measurement of branching fractions, the initial composition of the data sample must be known. The $\Upsilon(4S)$ resonance decays predominantly to $B^0\overline{B}^0$ and B^+B^-; the current experimental upper limit for non-$B\overline{B}$ decays of the $\Upsilon(4S)$ is less than 4% at the 95% confidence level (CL) [22]. The observed modes of this category are decays to lower Υ states and a pion pair, η, or η', measured branching fractions being of order $10^{-4} - 10^{-5}$ [23], and decays to $h_b(1P)\eta$ with branching fraction of order 10^{-3} [17].

The ratio f_+/f_0 of the fractions of charged to neutral B productions from $\Upsilon(4S)$ decays has been measured by CLEO, BaBar, and Belle in various ways. They typically use pairs of isospin-related decays of B^+ and B^0, such that it can be assumed that $\Gamma(B^+ \to x^+) = \Gamma(B^0 \to x^0)$. In this way, the ratio of the number of events observed in these modes is proportional to $(f_+\tau_+)/(f_0\tau_0)$ [24,25]. BaBar has also performed an independent measurement of f_0 with a different method that does not require isospin symmetry or the value of the lifetime ratio, based on the number of events with one or two reconstructed $B^0 \to D^{*-}\ell^+\nu$ decays [26]. The combined result, from the current average of τ_+/τ_0, is $f_+/f_0 = 1.058 \pm 0.024$ [27]. The result is consistent within 2.4σ with equal production of B^+B^- and $B^0\overline{B}^0$ pairs, and we assume $f_+/f_0 = 1$ in this mini-review except where explicitly stated otherwise. This assumption is also supported by the near equality of the B^+ and B^0 masses: our fit yields $m(B^0) = 5279.65 \pm 0.12$ MeV/c^2, $m(B^+) = 5279.34 \pm 0.12$ MeV/c^2, and $m(B^0) - m(B^+) = 0.31 \pm 0.05$ MeV/c^2.

Data collected at the $\Upsilon(5S)$ resonance gave CLEO, Belle and BaBar access to B_s^0 decays. In $\Upsilon(5S)$ decays there are seven possible final states including a pair of non-strange B mesons and 0, 1 or 2 pions, and three with a pair of strange B mesons ($B_s^{*0}\overline{B}_s^{*0}$, $B_s^{*0}\overline{B}_s^0$, and $B_s^0\overline{B}_s^0$). The fraction of events with a pair of B_s^0 mesons over the total number of events with a pair of b-flavored hadrons has been measured to be $f_s[\Upsilon(5S)] = 0.199^{+0.030}_{-0.029}$ [28], of which 88% is $B_s^{*0}\bar{B}_s^{*0}$ events. However, the small boost of B_s^0 mesons produced in this way prevents resolution of their fast oscillations for time-dependent measurements; these are only accessible in hadron collisions (or at the Z peak).

In high-energy collisions, the produced b or $\bar{b}$ quarks can hadronize with different probabilities into the full spectrum of b-hadrons, either in their ground or excited states. The hadronization does not have to be identical in $p\overline{p}$ or pp collisions and in Z decay, because of the different momentum distributions of the b-quark in these processes; the sample used in the $p\overline{p}$ measurements has momenta close to the b mass, rather than $m_Z/2$ in Z decay. The available data from Tevatron and LHC show that the production fractions f_d, f_u, f_s, and $f_{\rm baryon}$ of B^0, B^+, B_s^0, and b baryons, respectively, of weakly decaying b hadrons depend on the kinematics of the produced b hadron. The production fractions of b hadrons are discussed in more detail in the $B^0 - \overline{B}^0$ mixing section in this *Review* [8].

Excited B-meson states have been thoroughly studied by CLEO, LEP, CUSB, D0 and CDF (an admixture of B mesons) and LHCb (B^{*+}-meson). The current world average of the B^*–B mass difference is 45.21 ± 0.21 MeV/c^2. Excited B_s^*-meson states have observed in $\Upsilon(5S)$ decays by CUSB, CLEO and Belle.

For orbitally excited $B_{(s)}$ meson states, with relative angular momentum L=1 of the two quarks, there exist four states $(J, j_q) = (0, 1/2), (1, 1/2), (1, 3/2), (2, 3/2)$, where j_q is the total angular momentum of the light u, d or s quark and J is the total angular momentum of the B meson. These states are collectively called as $B_{(s)}^{**}$ mesons. The $j_q = 1/2$ states are named $B^*_{(s)0}$ ($J = 0$) and $B_{(s)1}$ ($J = 1$) mesons, while the states with $j_q = 3/2$ are named $B_{(s)1}$ ($J = 1$) and $B^*_{(s)2}$ ($J = 2$) mesons. The states with $j_q = 1/2$ can decay through an S-wave transition and are expected to have a large width, but the $j_q = 3/2$ states are narrow D-wave decays. Evidence for B^{**} production has been initially obtained at LEP as a broad $B\pi$ resonance [29] or a B^+K^- enhancement [30]. Detailed results have been obtained for the narrow states $B_1(5721)^{0,+}$ and $B_2(5747)^{0,+}$ at the Tevatron and by LHCb, and clear enhancements compatible with the higher mass states $B_J(5840)^{0,+}$ and $B_J(5970)^{0,+}$ have been observed [31,32]. Also the narrow B_s^{**} states $B_{s1}(5830)^0$ and $B_{s2}(5840)^0$ have been measured at the CDF [31], LHCb [33], and CMS [34].

Excited states of B_c^+ mesons will provide important information about the strong potential. A $B_c^+\pi^+\pi^-$ resonance has been observed for the first time by ATLAS [35]. The mass of the resonance has been measured precisely by CMS and LHCb as 6871.6 ± 1.1 MeV/c^2 [36,37]. The resonance may be interpreted as the second S-wave state of the B_c^+ meson, $B_c^+(2S)$, but the quantum numbers are to be confirmed.

Baryon states containing a b quark are labeled according to the same scheme used for non-b baryons, with the addition of a b subscript [19]. The first observed b baryon was the Λ_b^0 (quark composition udb). Thanks to the large samples accumulated at the Tevatron and specially at the LHC many new b baryons have been found. The masses of all these new baryons have been measured to a precision of a few MeV/c^2, and found to be in agreement with predictions from Heavy Quark Effective Theory (HQET).

Clear signals of four strongly–decaying baryon states, Σ_b^+, Σ_b^{*+} (uub), Σ_b^-, Σ_b^{*-} (ddb) have been obtained by CDF [38] and LHCb [39]. LHCb has also observed two new mass peaks in the $\Lambda_b^0\pi^\pm$ systems, consistent with single resonances and named as $\Sigma_b^\pm(6097)$ [39]. The nature of these resonances is, however, not yet clear. The isodublet of strange b baryons Ξ_b^0 (usb) and $\Xi_b^\pm$ (dsb) has been observed by CDF and D0 [40]. Masses, lifetimes, and branching ratios have been accurately measured by LHCb [41] and CDF [42]. LHCb has also measured several parameters sensitive to P and CP violation [43]. Other observed Ξ_b baryons are spin-3/2 states $\Xi_b(5945)^0$ (Ξ_b^{*0}) [44,45] and $\Xi_b^*(5955)^-$ [46], a spin-1/2 state $\Xi_b'(5935)^-$ [46], and a resonance state $\Xi_b^-(6227)$ [47]. The doubly–strange bottom baryon Ω_b^- has been observed first by D0 and CDF [48]. Mass and mean life have been measured precisely by LHCb [49] and CDF [42].

The so-called exotic states have raised a lot of interest recently. While many exotic states were seen in the charm sector, in bottom sector there are fewer seen. The D0 Collaboration claimed a narrow state $X(5568)$ decaying into a $B_s^0\pi^\pm$ final state [50]. While this would be an interesting addition to the observed states as the first exotic state with constituent quarks with four different flavours (b, s, u, d), analysis by LHCb yields negative result [51]. Also CMS finds no such a state [52].

73.2 Lifetimes

Precise lifetimes are key in extracting the weak parameters that are important for understanding the role of the CKM matrix in CP violation, such as the determination of V_{cb} and B_s^0–$\overline{B}_s^0$ mixing parameters. In the naive spectator model, the heavy quark can decay only via the external spectator mechanism, and thus, the lifetimes of all mesons and baryons containing b quarks would be equal. Non–spectator effects, such as the interference between contributing amplitudes, modify this simple picture and give rise to a lifetime hierarchy for b-flavored hadrons similar to the one in the charm sector. However, since the lifetime differences are expected to scale as $1/m_Q^2$, where m_Q is the mass of the heavy quark, the variations in the b system are expected to be only 10% or less [53,54]. We expect:

$$\tau(B^+) \geq \tau(B^0) \approx \tau(B_s^0) > \tau(\Lambda_b^0) \gg \tau(B_c^+)\,. \qquad (73.1)$$

For the B_c^+, both quarks decay weakly, so the lifetime is much shorter.

Measurements of the lifetimes of the different b-flavored hadrons thus provide a means to determine the importance of non-spectator mechanisms in the b sector. Availability of large samples of fully–reconstructed decays of different b-hadron species has resulted in precise measurements with small statistical and systematic uncertainties (∼1%). The world averages given in Table 73.1 have been determined by the Heavy Flavor Averaging Group (HFLAV) [28].

The B_s^0 lifetime in Table 73.1 is defined as $1/\Gamma_s$, where Γ_s is the average width of the light (L) and heavy (H) mass eigenstates, $(\Gamma_L + \Gamma_H)/2$. In the absence of CP violation, the light (heavy) B_s^0

Table 73.1: Summary of the world-average b-hadron lifetime measurements. For the B_s^0 lifetimes, see text below.

Particle	Lifetime [ps]
B^+	1.638 ± 0.004
B^0	1.519 ± 0.004
B_s^0	1.520 ± 0.005
B_{sL}^0	1.429 ± 0.007
B_{sH}^0	1.624 ± 0.009
B_c^+	0.510 ± 0.009
Λ_b^0	1.471 ± 0.009
Ξ_b^-	1.572 ± 0.040
Ξ_b^0	1.480 ± 0.030
Ω_b^-	$1.64^{+0.18}_{-0.17}$

mass eigenstate is the CP-even (CP-odd) eigenstate. Thus, the lifetime of the light (heavy) mass eigenstate can be measured from CP-even (odd) final states. The lifetimes can also be obtained from time-dependent angular analysis of $B_s^0 \to J/\psi\phi$ decays.

The short B_c^+ lifetime is in good agreement with predictions [55]. With large samples of B_c^+ mesons at the LHC precision on the lifetimes can still improve. The measurement using semileptonic decays gives $\tau_{B_c^+} = 0.509 \pm 0.008 \pm 0.012$ ps [56] while using decays $B_c^+ \to J/\psi\pi^+$ yields $\tau_{B_c^+} = 0.5134 \pm 0.0110 \pm 0.0057$ ps [57]. Each of these is more precise than the combination of all previous experiments.

The recent Λ_b^0 lifetime measurements from LHC experiments and CDF are precise and favour lifetime close to the lifetime of B^0 meson, in agreement with theory.

For precision comparisons with theory, lifetime ratios are more sensitive. Experimentally it is found [28]:

$$\frac{\tau_{B^+}}{\tau_{B^0}} = 1.076 \pm 0.004\,, \quad \frac{\tau_{B_s^0}}{\tau_{B^0}} = 1.001 \pm 0.004\,,$$

$$\frac{\tau_{\Lambda_b^0}}{\tau_{B^0}} = 0.969 \pm 0.006\,,$$

while recent Heavy Quark Expansion (HQE) predictions give [54]:

$$\frac{\tau_{B^+}}{\tau_{B^0}} = 1.04^{+0.05}_{-0.01} \pm 0.02 \pm 0.01\ , \quad \frac{\tau_{B_s^0}}{\tau_{B^0}} = 1.001 \pm 0.002\ ,$$

$$\frac{\tau_{\Lambda_b^0}}{\tau_{B^0}} = 0.935 \pm 0.054.$$

The ratio of B^+ to B^0 lifetimes has a precision of better than 1%, and is significantly different from 1.0, in agreement with predictions [53]. The ratio of B_s^0 to B^0 lifetimes is expected to be very close to 1.0.

For a detailed discussion on neutral B^0 and B_s^0 oscillation and relevant CP violation measurements see Ref. [8].

73.3 Features of decays

The ground states of b-flavored hadrons decay via weak interactions. In most decays of the b-flavored hadrons, where the b-quark is accompanied by lighter partner quarks (d, u, s, or c), the decay modes are well described by the decay of the b quark (spectator model) [58]. The dominant decay mode of a b quark is $b \to cW^{*-}$ (referred to as a "tree" or "spectator" decay), where the virtual W materializes either into a pair of leptons $\ell\bar{\nu}$ ("semileptonic decay"), or into a pair of quarks which then hadronizes. The transition $b \to u$ is suppressed by $|V_{ub}/V_{cb}|^2 \sim (0.1)^2$ relative to $b \to c$ transitions. The decays in which the spectator quark combines with one of the quarks from W^* to form one of the final state hadrons are suppressed by a factor $\sim (1/3)^2$, because the colors of the two quarks from different sources must match ("color–suppression").

Semileptonic B decays $B \to X_c\ell\nu$ and $B \to X_u\ell\nu$ provide an excellent way to measure the magnitude of the CKM elements $|V_{cb}|$ and $|V_{ub}|$ respectively, because the strong interaction effects are much simplified due to the two leptons in the final state. Both exclusive and inclusive decays can be used with dominant uncertainties being complementary. For exclusive decay analysis, knowledge of the form factors for the exclusive hadronic system $X_{c(u)}$ is required. For inclusive analysis, it is usually necessary to restrict the available phase-space of the decay products to suppress backgrounds; subsequently uncertainties are introduced in the extrapolation to the full phase-space. Moreover, restriction to a small corner of the phase-space may result in breakdown of the operator-product expansion scheme, thus making theoretical calculations unreliable. A more detailed discussion of B semileptonic decays and the extraction of $|V_{cb}|$ and $|V_{ub}|$ is given elsewhere in this *Review* [9]. While traditionally B^0 and B^+ decays were used, over time also other B hadron studies became available. Most notably, determination of of $|V_{ub}|$ using $\Lambda_b^0 \to p\mu^-\bar{\nu}_\mu$ decays by LHCb [59] was more precise than expected. Besides, there have been measurements of inclusive semileptonic decay rates of B_s^0 [60] and B_c^+ [61] mesons. One of the latest additions in this area is the observation of the $B_s^0 \to K^-\mu^+\nu_\mu$ decays by LHCb using only a fraction of their available data [62].

On the other hand, hadronic B decays are complicated because of strong interaction effects caused by the surrounding cloud of light quarks and gluons. While this complicates the extraction of CKM matrix elements, it also provides a great opportunity to study perturbative and non-perturbative QCD, hadronization, and Final State Interaction (FSI) effects.

Many aspects of B decays can be understood through the Heavy Quark Effective Theory (HQET) [63]. This has been particularly successful for semileptonic decays. For further discussion of HQET, see for instance Ref. [64]. For hadronic decays, one typically uses effective Hamiltonian calculations that rely on a perturbative expansion with Wilson coefficients. In addition, some form of the factorization hypothesis is commonly used, where, in analogy with semileptonic decays, two-body hadronic decays of B mesons are expressed as the product of two independent hadronic currents, one describing the formation of a charm meson (in case of the dominant $b \to cW^{*-}$ decays), and the other the hadronization of the remaining $\overline{u}d$ (or $\overline{c}s$) system from the virtual W^-. Qualitatively, for B decays with a large energy release, e.g. $b \to uW^{*-}$ transitions, the $\overline{u}d$ pair (produced as a color singlet) travels fast enough to leave the interaction region without influencing the charm meson. This is known to work well for the dominant spectator decays [65]. There are several common implementations of these ideas for hadronic B decays, the most common of which are QCD factorization (QCDF) [66–69], perturbative QCD (pQCD) [70–74], and soft collinear effective theory (SCET) [75–77].

The transitions $b \to s$ and $b \to d$ are flavor-changing neutral-current (FCNC) processes. Although they are not allowed in the SM as a tree-process, they can occur via loop diagrams (denoted "penguin" decays). The rates for $b \to s$ penguin decays are comparable to the CKM-suppressed $b \to u$ tree processes. Pure-penguin decays were first established by the observation of $B \to K^*(892)\gamma$ [78]. Penguin processes involving $b \to d$ transitions are further suppressed by CKM, and have been observed for $B \to (\rho/\omega)\gamma$ decays [79, 80]. LHCb has observed a $b \to d$ penguin transition in the $B^+ \to \pi^+\mu^+\mu^-$ mode and measured its branching fraction to be $(1.83 \pm 0.24 \pm 0.05) \times 10^{-8}$ [81].

Other decay processes discussed in this *Review* include W–exchange (a W is exchanged between initial–state quarks), penguin annihilation (the gluon from a penguin loop attaches to the spectator quark, similar to an exchange diagram), and pure–annihilation (the initial quarks annihilate to a virtual W, which then decays). Some observed decay modes such as $B^0 \to D_s^- K^+$, may be interpreted as evidence of a W-exchange process [82]. The evidence for the purely leptonic decay $B^+ \to \tau^+\nu$ from Belle [83] and BaBar [84] is the first sign of a pure annihilation decay. The average branching fraction is $(1.09 \pm 0.24) \times 10^{-4}$, which is somewhat larger than, though consistent with, the value expected in the SM. A substantial region of parameter space of charged Higgs mass vs. $\tan\beta$ is excluded by the measurements of this mode. A dedicated discussion of purely leptonic decays of charged pseudoscalar mesons is given elsewhere in this *Review* [85].

73.4 Dominant hadronic decays

Most of the hadronic B decays involve $b \to c$ transition at the quark level, resulting in a charmed hadron or charmonium in the final state. Other types of hadronic decays are very rare and will be discussed separately in the next section. The experimental results on hadronic B decays have steadily improved over the years, and the measurements have reached sufficient precision to challenge our understanding of the dynamics of these decays. With good particle detection and hadron identification capabilities of B-factory detectors, a substantial fraction (roughly on the order of a few per mill) of hadronic B decay events can be fully reconstructed. In particular, good performances for detecting π^0 and other neutral particles helped Belle and BaBar to make comprehensive measurements of the decays $\overline{B}^0 \to D^{(*)0}h^0$ [86], where h^0 stands for light neutral mesons such as $\pi^0, \eta^{(\prime)}, \rho^0, \omega$. The measurements are being complemented by LHCb, in decays like $\overline{B^0} \to D^0\pi^+\pi^-$ [87], where no neutral particles reconstruction is needed. These decays proceed through color-suppressed diagrams, hence they provide useful tests on the factorization models.

Because of the kinematic constraint of $\Upsilon(4S) \to B\bar{B}$, the energy sum of the final-state particles of a B meson decay is always equal to one half of the total energy in the center of mass frame. As a result, the two variables, ΔE (energy difference) and M_B (B candidate mass with a beam-energy constraint) are very effective for reducing combinatorial background both from $\Upsilon(4S)$ and $e^+e^- \to q\bar{q}$ continuum events. In particular, the energy-constraint in M_B improves the signal resolution by almost an order of magnitude.

The kinematically clean environment of B meson decays provides an excellent opportunity to search for new states. For instance, quark-level $b \to c\bar{c}s$ decays have been used to search for new charmonium and charm-strange mesons and study their properties in detail. While narrow charm-strange states $D^*_{s0}(2317)$ [88] and $D_{s1}(2460)$ [89] were discovered by BaBar and CLEO, respectively, the properties of these new states were revealed by studying the B meson decays, $B \to DD^*_{s0}(2317)$ and $B \to DD_{s1}(2460)$ by Belle [90] and BaBar [91]. Another example is Dalitz plot analysis of decay $B^0_s \to \bar{D}^0K^-\pi^+$ in which the decay to spin-3 resonance was observed for the first time [92].

Information on B^0_s, B^+_c and Λ^0_b decays have been remarkably improved with recent studies of large samples from LHCb. Noticeable additions in B_s include decay modes to $D^{(*)+}_s D^{(*)-}_s$, $\bar{D}^0\bar{K}^0$, and $J/\psi\bar{K}^*(892)^0$. The $B^0_s \to D^{(*)+}_s D^{(*)-}_s$ decays were first observed by CDF [93], followed by Belle [94]. LHCb has improved the precision with $\mathcal{B}(B^0_s \to D^{(*)+}_s D^{(*)-}_s) = (3.07 \pm 0.22 \pm 0.33)\%$ [95], which suggests that $B^0_s \to D^{(*)+}_s D^{(*)-}_s$ decays do not saturate the CP-even modes of the B_s decays. The $B^0_s \to \bar{D}^0\bar{K}^0$ decay occurs mostly via a color-suppressed tree diagram, and has a small theoretical uncertaintiy in the SM, thus this mode can significantly improve the determination of the CP-violation angle ϕ_s. LHCb has observed this decay and the branching fraction is $(4.3 \pm 0.5 \pm 0.7) \times 10^{-4}$ [96]. The $B^0_s \to J/\psi\bar{K}^*(892)^0$ decay can be used to constrain the penguin pollution in determing ϕ_s. LHCb has updated the branching fraction and measured the CP asymmetries of this decay, thereby constraining the penguin pollution in ϕ_s [97], although a much more stringent constraint on penguin polltion can come from $B^0 \to J/\psi\rho^0$ which has been observed by BaBar [98] and LHCb [99]. The $B^+_c \to B^0_s\pi^+$ decay is unique as the only observed mode of b-flavored hadron decays where the partner quark decays (c in this case) while the b quark remains a spectator. LHCb has observed this mode and measured $[\sigma(B^+_c)/\sigma(B^0_s)] \times \mathcal{B}(B^+_c \to B^0_s\pi^+) = (2.37 \pm 0.31 \pm 0.11^{+0.17}_{-0.13}) \times 10^{-3}$ [100]. In addition, LHCb [101] and ATLAS [102] have measured $B^+_c \to J/\psi D^{(*)+}_s$, which, by comparing with $B^+_c \to B^0_s\pi^+$, provides a ratio of exclusive $b \to c$ and $c \to s$ decays of B^+_c. For $\Lambda^0_b \to \Lambda^+_c\pi^+\pi^-\pi^-$ [103], not only the total rate is measured, but also structure involving decays through excited Λ_c and Σ_c baryons.

In addition, a variety of exotic particles that do not fit the conventional meson spectroscopy have been discovered in B decays. Belle found the $X(3872)$ state by studying $B^+ \to J/\psi\pi^+\pi^-K^+$ [104], which was confirmed by CDF [105], D0 [106] and BaBar [107]. Production of $X(3872)$ has been studied by the LHC experiments, LHCb [108], CMS [109] and ATLAS [110].

A charged charmonium-like state $X(4430)^\pm$ that decays to $\psi(2S)\pi^\pm$ was observed by Belle in $B \to \psi(2S)K\pi^\pm$ [111]. Since it is charged, it could not be an ordinary charmonium state. A high-statistics study by LHCb confirmed the existence of the $X(4430)^\pm$ in decays $B \to \psi(2S)K\pi^\pm$ [112], demonstrated its resonance character by studying the phase motion, unambiguously determined its spin-parity, and saw evidence for another state. In a Dalitz plot analysis of $\bar{B}^0 \to J/\psi K^-\pi^+$ [113], Belle has found another state, labeled as $X(4200)^+$ in this *Review*, adding to the list of exotic charged charmonium-like states. In an amplitude analysis of the decay $\Lambda^0_b \to J/\psi pK^-$, LHCb observed exotic structures, labeled as $P_c(4380)^+$ and $P_c(4450)^+$ in this *Review*, in the $J/\psi p$ channel [114]. The subsequent analysis with significantly increased statistics observed additional state and resolved the peak at 4450 MeV/c^2 as being due to the two states close in the mass [115]. They are referred to as charmonium-pentaquark states. More detailed discussions of exotic meson-like states and pentaquarks are given elsewhere in this *Review* [116].

73.5 Rare hadronic decays

All B-meson decays that do not occur through the $b \to c$ transition are usually called rare B decays. These include both semileptonic and hadronic $b \to u$ decays that are suppressed at leading order by the small CKM matrix element V_{ub}, as well as higher-order $b \to s(d)$ processes such as electroweak and gluonic penguin decays. In this section, we review hadronic rare B decays, while electroweak penguin decays and others are discussed in the next.

Charmless B meson decays into two-body hadronic final states such as $B \to \pi\pi$ and $K\pi$ are experimentally clean, and provide good opportunities to probe new physics and search for indirect and direct CP violations. Since the final state particles in these decays tend to have larger momenta than average B decay products, the event environment is cleaner than for $b \to c$ decays. Branching fractions are typically around 10^{-5}. Over the past decade, many such modes have been observed not only by e^+e^- collider experiments such as BaBar and Belle, but also by hadron collider experiments such as CDF ($p\bar{p}$) and LHCb (pp). In the latter cases, huge data samples of the modes with all charged final-state particles have been reconstructed by triggering on the impact parameter of the charged tracks. This has also allowed observation of charmless decays of the B_s, in final states such as $\phi\phi$ [117, 118], K^+K^- [119, 120], and $K^-\pi^+$ [120, 121], and of charmless decays of the Λ^0_b baryon [121]. The large samples available at LHCb experiment allow to perform also time-dependent CP violation measurements [122, 123]. Charmless B_s modes are related to corresponding B^0 modes by U-spin symmetry, and are determined by similar amplitudes. Combining the observables from B^0_s and B^0 modes is a further way of eliminating hadronic uncertainties and extracting relevant CKM information [124].

Because of relatively high-momenta for final state particles, the dominant source of background in e^+e^- collisions is $q\bar{q}$ continuum events; sophisticated background suppression techniques exploiting event shape variables are essential for these analyses. In hadron collisions, the dominant background comes from QCD or partially reconstructed heavy flavors, and is similarly suppressed by a combination of kinematic and isolation requirements. The results are in general consistent among the experiments.

Most rare decay modes including $B^0 \to K^+\pi^-$ have contributions from both $b \to u$ tree and $b \to sg$ penguin processes. If the size of the two contributions are comparable, the interference between them may result in direct CP violation, seen experimentally as a charge asymmetry in the decay rate measurement. BaBar [125], Belle [126], CDF [119], and LHCb [122] have measured the direct CP violating asymmetry in $B^0 \to K^+\pi^-$ decays. Direct CP violation has been observed in this decay with a significance of more than 5σ. The world average value of the asymmetry is now rather precise, $A_{CP}(K^+\pi^-) = -0.083 \pm 0.004$. The CP asymmetry in $B^+ \to K^+\pi^0$ mode has been measured by BaBar [127], Belle [126] and LHCb [128] with the average value $A_{CP}(K^+\pi^0) = 0.017 \pm 0.016$. These two asymmetries differ signif-

icantly, in constrast to a naive expectation based on simplified picture in the SM. For more detailed tests, there are sum rules [129] that relate the decay rates and decay-rate asymmetries between the four $K\pi$ charge states. A crucial ingredient of the sum rule test is $A_{CP}(K^0\pi^0)$. Currently, measured values are reported by both BaBar [130] and Belle [131]. Using the $A_{CP}(K^0\pi^0)$ value of Ref. [131], Belle reports the sum rule test result that is consistent with zero within 1.9σ [126]. With the future improvements via Belle II and upgraded LHCb, the measurements are expected to become precise enough to shape a definite conclusion. The CP asymmetry in the π^+K^- mode has also been measured in B_s^0 decays, by CDF [119] and LHCb [122]. The combined value is $A_{CP}(B_s^0 \to \pi^+K^-) = 0.221 \pm 0.015$.

In addition to $B_{(s)} \to K\pi$ modes, significant ($> 3\sigma$) non-zero CP asymmetries have been measured in several other rare decay modes: $A_{CP}(B^+ \to \rho^0K^+) = 0.37 \pm 0.10$ [132], $A_{CP}(B^+ \to \eta K^+) = -0.37 \pm 0.08$ [133], $A_{CP}(B^0 \to \eta K^{*0}) = 0.19 \pm 0.05$ [134], and $A_{CP}(B^+ \to f_2(1270)K^+) = -0.68^{+0.19}_{-0.17}$ [132]. In at least the first two cases, a large direct CP violation might be expected since the penguin amplitude is suppressed so the tree and penguin amplitudes may have comparable magnitudes. There are also measurements by LHCb of CP asymmetries in several 3-body modes: $A_{CP}(B^+ \to \pi^+\pi^-\pi^+) = 0.057 \pm 0.013$, $A_{CP}(B^+ \to K^+\pi^-\pi^+) = 0.027 \pm 0.008$, $A_{CP}(B^+ \to K^+K^-\pi^+) = -0.122 \pm 0.0021$, and $A_{CP}(B^+ \to K^+K^-K^+) = -0.033 \pm 0.008$ [135,136]. Many of these analyses now include Dalitz plot treatments with many intermediate resonances.

BaBar [137] and Belle [126, 138] have observed the decays $B^+ \to \overline{K}^0K^+$ and $B^0 \to K^0\overline{K}^0$. The world-average branching fractions are $\mathcal{B}(B^0 \to K^0\overline{K}^0) = (1.21 \pm 0.16) \times 10^{-6}$ and $\mathcal{B}(B^+ \to \overline{K}^0K^+) = (1.31 \pm 0.17) \times 10^{-6}$. These are the first observations of hadronic $b \to d$ transitions, with significance bigger than 5σ for all four measurements. CP asymmetries have been measured for these modes, but with large errors. LHCb has observed $B^0 \to K^+K^-$ mode which occurs via a weak-annihilation process and is the rarest hadronic B-meson decay thus far observed, with $\mathcal{B}(B^0 \to K^+K^-) = (7.80 \pm 1.52) \times 10^{-8}$ [139]. $B_s^0 \to K^+K^-$ decay mode, which occurs mostly via $b \to s$ penguin process, has been observed by Belle [140], CDF [141] and LHCb [120]. The average branching fraction is $\mathcal{B}(B_s^0 \to K^+K^-) = (26.6 \pm 2.2) \times 10^{-6}$. Belle has also observed $B_s^0 \to K^0\overline{K}^0$ [142] which also occurs via $b \to s$ penguin transition in the SM. This was recently confirmed by LHCb [143]. The average branching fraction is $(1.76 \pm 0.31) \times 10^{-5}$.

The decay $B^0 \to \pi^+\pi^-$ can be used to extract the CKM angle α (for details see elsewhere in this *Review* [144]). This is complicated by the presence of significant contributions from penguin diagrams. An isospin analysis [145] can be used to untangle the penguin complications. The decay $B^0 \to \pi^0\pi^0$ is crucial in this analysis. Both BaBar and Belle have observed $B^0 \to \pi^0\pi^0$, with a mild tension in the measured branching fractions: $(1.83 \pm 0.25) \times 10^{-6}$ for BaBar [125] and $(1.31 \pm 0.26) \times 10^{-6}$ for Belle [146]. It turns out that the amount of penguin pollution in the $B \to \pi\pi$ system is rather large. In the past few years, measurements in the $B^0 \to \rho\rho$ system have produced more precise values of α, since penguin amplitudes are generally smaller for decays with vector mesons. An important ingredient in the analysis is the $B^0 \to \rho^0\rho^0$ branching fraction. The average of measurements from BaBar [147] and Belle [148] yields a branching fraction of $(0.96 \pm 0.15) \times 10^{-6}$. This is only 3% of the $\rho^+\rho^-$ branching fraction, much smaller than the corresponding ratio ($\gtrsim 20\%$) in the $\pi\pi$ system.

Since $B \to \rho\rho$ has two vector mesons in the final state, the CP eigenvalue of the final state depends on the longitudinal polarization fraction f_L for the decay. Therefore, a measurement of f_L is needed to extract the CKM angle α. Both BaBar and Belle have measured f_L for the decays $\rho^+\rho^-$ [149] and $\rho^+\rho^0$ [150] and in both cases the measurements show $f_L > 0.9$, making a complete angular analysis unnecessary. In $B^0 \to \rho^0\rho^0$, f_L is measured by BaBar [147], Belle [148] and LHCb [151], with the average value being $0.71^{+0.08}_{-0.09}$.

By analyzing the angular distributions of the B decays to two vector mesons, we can learn a lot about both weak- and strong-interaction dynamics in B decays. Decays that are penguin-dominated surprisingly have values of f_L near 0.5. The list of such decays has now grown to include $B \to \phi K^*(892)$, $B \to \rho K^*(892)$, and $B \to \omega K^*(892)$. The reasons for this "polarization puzzle" are not fully understood. A detailed description of the angular analysis of B decays to two vector mesons can be found in a separate mini-review [152] in this *Review* .

73.6 Electroweak penguin decays

Electroweak decays are one-loop FCNC decays proceeding through penguin or box Feynman diagrams with final state including real photon or pair of leptons. Such decays were first observed by CLEO experiment when it observed decay $B \to K^*(892)\gamma$ [78]. Since then significant amount of experimental information was obtained. Branching fractions for these decays are 10^{-5} or less, which makes them excellent candidates for searches for new physics beyond SM. Often several observables are available, which allows for stringent tests of the SM.

Starting with radiative decays, experimentally easiest to study are exclusive decays with a fully reconstructed final state. The best studied decay in this class is $B \to K^*(892)\gamma$ seen by CLEO, Belle, BaBar experiments [153–155] with world average branching fraction $\mathcal{B}(B^0 \to K^*(892)^0\gamma) = (41.8 \pm 2.5) \times 10^{-6}$. Decays through several other kaon resonances such as $B \to K_1(1270)\gamma$, $K_2^*(1430)\gamma$, *etc.* were studied at B-factories [156–159]. It is worth to mention decay $B^+ \to K^+\pi^+\pi^-\gamma$ for which besides measurements of the branching fraction [157,160,161] one can also use the angular distribution to access photon polarization. Such a measurement was done by the LHCb experiment, which was able to clearly demonstrate that the photon in $B^+ \to K^+\pi^+\pi^-\gamma$ decay is polarized [162]. Unfortunately given non-trivial hadronic structure, more work is needed before turning this into test of the SM. The exclusive radiative decays $B_s^0 \to \phi\gamma$ was seen by the Belle and LHCb experiments [163, 164] with an average branching fraction of $(3.4 \pm 0.4) \times 10^{-5}$ and more recently also decay $\Lambda_b \to \Lambda\gamma$ was observed by LHCb [165].

Compared to $b \to s\gamma$, the $b \to d\gamma$ transitions such as $B \to \rho\gamma$, are suppressed by the CKM elements ratio $|V_{td}/V_{ts}|^2$. Both Belle and BaBar have observed these decays [79,80]. The world average $\mathcal{B}(B \to (\rho,\omega)\gamma) = (1.30 \pm 0.23) \times 10^{-6}$. This can be used to calculate $|V_{td}/V_{ts}|$ [166]; the measured values are $0.195^{+0.025}_{-0.024}$ from Belle [79] and $0.233^{+0.033}_{-0.032}$ from BaBar [80].

The observed radiative penguin branching fractions can constrain a large class of SM extensions [167]. However, due to the uncertainties in the hadronization, only the inclusive $b \to s\gamma$ rate can be reliably compared with theoretical calculations. This rate can be measured from the endpoint of the inclusive photon spectrum in B decay. By combining the measurements of $B \to X_s\gamma$ from the CLEO, BaBar, and Belle experiments [168–170], HFLAV obtains the average: $\mathcal{B}(B \to X_s\gamma) = (3.32 \pm 0.15) \times 10^{-4}$ [28] for $E_\gamma \geq 1.6$ GeV, averaging over B^+ and B^0. Consistent but less precise results have been reported by ALEPH for inclusive b–hadrons produced at the Z, which includes also contribution from B_s^0 and Λ_b^0 hadrons. Using the sum of seven exclusive final states, the BaBar experiment measured the branching fraction of inclusive $b \to d\gamma$ decays to be $(9.2 \pm 2.0 \pm 2.3) \times 10^{-6}$ [171]. The measured branching fraction can be compared to theoretical calculations. Recent calculations of $\mathcal{B}(b \to s\gamma)$ at NNLO level predict for the $E_\gamma \geq 1.6$ GeV values of $(3.36 \pm 0.23) \times 10^{-4}$ for $b \to s\gamma$ and $(1.73^{+0.12}_{-0.22}) \times 10^{-5}$ for $b \to d\gamma$ decays [172].

The CP asymmetry in $b \to s\gamma$ is extensively studied theoretically both in the SM and beyond [173]. According to the SM, the CP asymmetry in $b \to s\gamma$ is smaller than 1%, but some non-SM models allow significantly larger CP asymmetry ($\sim 10\%$) without altering the branching fraction. The current world average is $A_{CP} = 0.015 \pm 0.011$, again dominated by BaBar and Belle [174]. In addition to the CP asymmetry, BaBar and Belle also measured the isospin asymmetry $\Delta_{0-} = -0.006 \pm 0.020$ in $b \to s\gamma$ measured using sum of exclusive decays [174, 175]. An alternative measurement using full reconstruction of the companion B in the hadronic decay modes yields a consistent, but less precise result [176]. Both Belle and BaBar experiments measured the isospin asymmetry in exclusive $B \to K^*(892)\gamma$ decay with aver-

age of $6.3 \pm 1.7\%$ [154, 155] and therefore providing evidence for the non-zero isospin asymmetry.

In addition, experiments have measured the inclusive photon energy spectrum for $b \to s\gamma$, and by analyzing the shape of the spectrum they obtain the first and second moments for photon energies. Belle has measured these moments covering the widest range in the photon energy ($1.7 < E_\gamma < 2.8$ GeV) [170]. The measurement by BaBar has slightly smaller range with lower limit at 1.8 GeV [177]. These results can be used to extract non-perturbative HQET parameters that are needed for precise determination of the CKM matrix element V_{ub} (see further discussion elsewhere in this *Review* [178]).

Additional information on FCNC processes can be obtained from $b \to s\ell^+\ell^-$ decays. These processes are studied as a function of dilepton invariant mass squared, q^2. Different q^2 regions are sensitive to different physics. Starting at the very low q^2 decays exhibit sensitivity to the same physics as the radiative decays. Then for the q^2 in region 1.1 to 6.0 GeV$^2/c^4$ the SM and new physics have best chance to compete. At the high q^2 above the $\psi(2S)$ mass, the interference of SM and new physics is to some extend complementary to that in lower q^2. Regions around J/ψ and $\psi(2S)$ is normally excluded from measurements as these are dominated by the $b \to c$ transitions to charmonia. For exclusive decays, theory predictions require calculations of hadronic form factors. With current theory predictions, the most useful are measurements within the q^2 regions 1.1 to 6.0 GeV$^2/c^4$ and from 16.0 GeV$^2/c^4$ up to the kinematic limit. From this reason in the listing we provide results mainly in those two regions.

Similar as for radiative decays, also for the $b \to s\ell^+\ell^-$ decays the inclusive measurements provide some benefits. Both Belle and BaBar performed such measurement without reconstructing hadronic part exclusively and measure a branching fraction of $(5.8 \pm 1.3) \times 10^{-6}$ [179]. Unfortunately this measurement is not trivially possible at hadron colliders and also does not easily allow the angular distributions of the decay products to be exploited. One alternative is to extract information on the inclusive decay as sum of exclusive decays. Such a measurement was performed by Belle [180], but in this case the difficulty lies in extrapolation for the missing hadronic states.

Turning to the exclusive decays, the initial measurements performed by B-factories typically averaged between charged and neutral B mesons as well as between e^+e^- and $\mu^+\mu^-$ finals states. The experiments CDF, LHCb, ATLAS and CMS are much better suited for the $\mu^+\mu^-$ finals states compared to the e^+e^- final states. As such most measurements at hadron colliders are done only with $\mu^+\mu^-$ pairs and by separating charged and neutral B mesons. The best studied decays are $B^+ \to K^+\ell^+\ell^-$ and $B^0 \to K^*(892)^0\ell^+\ell^-$. At hadron colliders other b hadrons are produced and as such CDF and LHCb experiments did observe also $B_s^0 \to \phi\mu^+\mu^-$ [181, 182], $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ [181, 183] and $\Lambda_b^0 \to pK^-\mu^+\mu^-$ decays [184]. The averages of the total branching fractions integrated over whole q^2 regions are $(5.6 \pm 0.6) \times 10^{-7}$ for $B^+ \to K^+e^+e^-$, $(4.53 \pm 0.35) \times 10^{-7}$ for $B^+ \to K^+\mu^+\mu^-$, $(1.03^{+0.19}_{-0.17}) \times 10^{-6}$ for $B^0 \to K^*(892)^0e^+e^-$ and $(0.94 \pm 0.05) \times 10^{-6}$ for $B^0 \to K^*(892)^0\mu^+\mu^-$ decays [185–189]. The total branching fractions for $B_s^0 \to \phi\mu^+\mu^-$ and $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ decays are $(8.2 \pm 1.2) \times 10^{-7}$ [181,182] and $(1.08 \pm 0.28) \times 10^{-6}$ [181,183] respectively. With increased precision of $B^0 \to K^*(892)^0\ell^+\ell^-$ decay, there is a question on what fraction of the seen branching fraction is due to the $K^*(892)^0$ resonance and what fraction is due to the $K\pi$ in s-wave. This has been studied by LHCb which found that the $K\pi$ in s-wave fraction varies between 1% and about 10% depending on the q^2 region [189]. It should be noted, that for all relevant B meson decays the branching fractions so far studied are consistently below the SM expectation.

In the $b \to s\ell^+\ell^-$ decays angular distributions offer rich source of information. The full angular analysis was performed for decays $B^+ \to K^+\ell^+\ell^-$, $B^0 \to K^0\ell^+\ell^-$, $B^+ \to K^*(892)^+\ell^+\ell^-$, $B^0 \to K^*(892)^0\ell^+\ell^-$, $B_s^0 \to \phi\mu^+\mu^-$ and $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ decays [190–198]. An attempt to increase sensitivity to the NP was made by constructing observables, which have reduced theory uncertainties and measurements of these are done. Most notably the observable called P_5' [199] shows a discrepancy with the SM in the q^2 region which is highly sensitive to new physics [192–194]. Measurements of the CP asymmetries [184,185,188,200,201], the isospin asymmetry [186–188, 200] were also performed. All these measurements are well consistent with the small A_{CP} and small isospin asymmetry expected in the SM [202]. With statistics available at the LHC, the measurement of phase difference between long- and short-distance contribution in $B^+ \to K^+\mu^+\mu^-$ decays became possible [203].

With the data samples available at LHC, the lepton universality in $b \to s\ell^+\ell^-$ can be tested. While in the SM decays to electron-positron and muon pairs are expected to be same up to small corrections due to the different masses of leptons, in extensions of the SM this does not have to hold. The angular analysis of $B^0 \to K^*(892)^0e^+e^-$ decays was performed by LHCb at low dilepton invariant masses [204] and Belle in several regions over whole q^2 range [194]. The LHCb measurement yields the most stringent constraint on the photon polarization. The most notable result on lepton universality test is the ratio of branching fractions between $B^+ \to K^+\mu^+\mu^-$ and $B^+ \to K^+e^+e^-$ and between $B^0 \to K^*(892)^0\mu^+\mu^-$ and $B^0 \to K^*(892)^0e^+e^-$ decays [186, 205–208]. In both cases, the measurements by LHCb show mild discrepancy from the SM, with significance of $3.1\,\sigma$ for $B^+ \to K^+\ell^+\ell^-$ and about $2.4\,\sigma$ for $B^0 \to K^*(892)^0\ell^+\ell^-$. LHCb experiment performed similar test with $\Lambda_b^0 \to pK^-\ell^+\ell^-$ decays [209].

While $b \to d\ell^+\ell^-$ decays are further suppressed, they recently became accessible. Signals were observed for $B^+ \to \pi^+\mu^+\mu^-$ [81], $B^0 \to \pi^+\pi^-\mu^+\mu^-$ [210] and $\Lambda_b^0 \to p\pi^-\mu^+\mu^-$ [211] decays. The total branching fractions are only quantities measured and these are about 2×10^{-8} for the meson decays and about 7×10^{-8} for the Λ_b^0 decay.

A closely related process is $B \to X_s\nu\overline{\nu}$. Since the neutrinos are not detected, the final state is a strange hadron system X_s plus missing energy-momentum. Depending on X_s, the SM branching fraction is $\mathcal{O}(10^{-6})$. New physics effects beyond SM, e.g. those from dark sector models can greatly enhance the yield of X_s plus missing energy. Both BaBar [212] and Belle [213] have searched for these decays and determined the upper limits in the range $\mathcal{O}(10^{-5})$.

Finally the decays $B_{(s)}^0 \to e^+e^-$ and $\mu^+\mu^-$ are interesting since they only proceed at second order in weak interactions in the SM, but may have large contributions from supersymmetric loops, proportional to $(\tan\beta)^6$. First limits were published 30 years ago and since then experiments at Tevatron, B-factories and LHC gradually improved those and effectively excluded whole models of new physics and significantly constrained allowed parameter space of others. For the decays to $\mu^+\mu^-$, Tevatron experiments pushed the limits down to roughly factor of 5-10 above the SM expectation [214, 215]. The long journey in the search for these decays culminated in 2012, when first evidence for $B_s^0 \to \mu^+\mu^-$ decay was seen [216]. Subsequently, LHC experiments ATLAS [217], CMS [218] and LHCb [219] observed statitically significant signal for $B_s^0 \to \mu^+\mu^-$ decay. The average branching fraction is found to be $(2.9 \pm 0.4) \times 10^{-9}$. In experiments at hadron colliders searches for $B^0 \to \mu^+\mu^-$ decays are performed at the same time. The best limit on $B(B^0 \to \mu^+\mu^-) < 2.1 \times 10^{-10}$ at 95% C.L. [217]. The limits for the e^+e^- modes are: $< 9.4 \times 10^{-9}$ and $< 2.5 \times 10^{-9}$, respectively, for B_s^0 and B^0 [220]. The searches for decays to $\tau^+\tau^-$ are more challenging with current best limits of $B(B^0 \to \tau^+\tau^-) < 2.1 \times 10^{-3}$ and $B(B_s^0 \to \tau^+\tau^-) < 6.8 \times 10^{-3}$ at 95% C.L. [221]. All existing measurements of B^0 and B_s^0 decays to same flavour dilepton pair is consistent with SM expectation [222]. With $B_s^0 \to \mu^+\mu^-$ decay observed, it was suggested that the effective lifetime is useful further test of the decay [223]. Attempt was made by LHCb and CMS experiments, but its precision is not yet sufficient to provide test of the SM [218, 219]. It will take couple of years until interesting precision is reached. The searches were also performed for lepton flavour violating decays to two leptons with best limits in $e^\pm\mu^\mp$ channel, where limits are $< 1.3 \times 10^{-9}$ for B^0 and $< 6.3 \times 10^{-9}$ for B_s^0, at 95% confidence level [224].

Several theory groups performed global analysis of electroweak decays concluding that significant tension between data and SM is

present [225]. The tension can be relieved by new physics beyond SM. For more detailed reviews see e.g. Ref. [226].

73.7 Summary and Outlook

The study of B mesons continues to be one of the most productive fields in particle physics. With the two asymmetric B-factory experiments Belle and BaBar, we now have a combined data sample of well over 1 ab^{-1}. CP violation has been firmly established in many decays of B mesons. Evidence for direct CP violation has been observed. Many rare decays resulting from hadronic $b \to u$ transitions and $b \to s(d)$ penguin decays have been observed, and the emerging pattern is still full of surprises. Despite the remarkable successes of the B-factory experiments, many fundamental questions in the flavor sector remain unanswered.

At Fermilab, CDF and D0 each has accumulated about 10 fb^{-1}, which is the equivalent of about 10^{12} b-hadrons produced. In spite of the low trigger efficiency of hadronic experiments, a selection of modes have been reconstructed in large quantities, giving a start to a program of studies on B_s and b-flavored baryons, in which a first major step has been the determination of the B_s oscillation frequency.

As Tevatron and B-factories finished their data taking few year ago, the experiments at the LHC have become very active. LHCb has collected about 1 fb^{-1} at 7 TeV, 2 fb^{-1} at 8 TeV, and close to 5.9 fb^{-1} at 13 TeV during LHC Runs 1 and 2. CMS and ATLAS have collected each about 5 fb^{-1} of data at $\sqrt{s} = 7$ TeV, 20 fb^{-1} at 8 TeV and about 150 fb^{-1} at 13 TeV during LHC Runs 1 and 2. LHCb, which is dedicated to the studies of b- and c-hadrons, has a data sample that is for many decays larger than the sum of all previous experiments. With it, we are entering to regime of precision physics even for many rare decays, which allows much more detailed measurements.

The Belle II experiment at the SuperKEKB has started recording data in 2019 and has so far collected about 200 fb^{-1} of data (August 2021). The aim to increase sample to $\sim$ 50 ab^{-1} will make it possible to explore the indirect evidence of new physics beyond the SM in the heavy-flavor particles (b, c, and τ), in a way that is complementary to the LHC. In the same time period, LHCb Collaboration is working on the upgrade of its detector, installation of which is ongoing. The aim of the upgrade is to increase flexibility of the trigger, which will allow about a factor of five increase in instantaneous luminosity and of about a factor of two in efficiencies on triggering on purely hadronic decays. The plan is to integrate about 50 fb^{-1} of data starting from 2022.

These experiments promise a rich spectrum of rare and precise measurements that have the potential to fundamentally affecting our understanding of the SM and CP-violating phenomena.

74. Polarization in B Decays

Revised February 2022 by A.V. Gritsan (Johns Hopkins U.).

We review the notation used in polarization measurements in particle production and decay, with a particular emphasis on the B decays and the CP-violating observables in polarization measurements. We look at several examples of vector-vector and vector-tensor B meson decays, while more details about the theory and experimental results in B decays can be found in a separate mini-review [1] in this *Review*.

Figure 74.1 illustrates angular observables in an example of the sequential process $ab \to X \to P_1P_2 \to (p_{11}p_{12})(p_{21}p_{22})$ [2]. The angular distributions are of particular interest because they are sensitive to spin correlations and reveal properties of particles and their interactions, such as quantum numbers and couplings. In the case of a spin-zero particle X, such as B meson or a Higgs boson, there are no spin correlations in the production mechanism and the decay chain is to be analyzed. The angular distribution of decay products can be expressed as a function of three helicity angles which describe the alignment of the particles in the decay chain. The analyzer of the B-daughter polarization is normally chosen for two-body decays, as the direction of the daughters in the center-of-mass of the parent (*e.g.*, $\rho \to 2\pi$) [3], and for three-body decays as the normal to the decay plane (*e.g.*, $\omega \to 3\pi$) [4]. An equivalent set of transversity angles is sometimes used in polarization analyses [5]. The differential decay width depends on complex amplitudes $A_{\lambda_1\lambda_2}$, corresponding to the X-daughter helicity states λ_i.

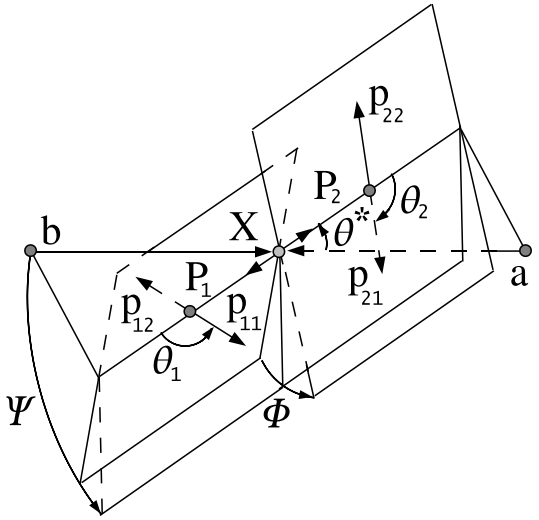

Figure 74.1: Definition of the production and helicity angles in the sequential process $ab \to X \to P_1P_2 \to (p_{11}p_{12})(p_{21}p_{22})$. The three helicity angles include θ_1 and θ_2, defined in the rest frame of the two daughters P_1 and P_2, and Φ, defined in the X frame as the angle between the two decay planes. The two production angles θ^* and Ψ are defined in the X frame, where Ψ is the angle between the production plane and the average of the two decay planes.

In the case of a spin-zero B-meson decay, its daughter helicities are constrained to $\lambda_1 = \lambda_2 = \lambda$. Therefore we simplify amplitude notation as A_λ. Moreover, most B-decay polarization analyses are limited to the case when the spin of one of the B-meson daughters is 1. In that case, there are only three independent amplitudes corresponding to $\lambda = 0$ or ±1 [6], where the last two can be expressed in terms of parity-even and parity-odd amplitudes $A_{\parallel,\perp} = (A_{+1} \pm A_{-1})/\sqrt{2}$. The overall decay amplitude involves three complex terms proportional to the above amplitudes and the Wigner d functions of helicity angles. The exact angular dependence would depend on the quantum numbers of the B-meson daughters and of their decay products, and can be found in the literature [6,7]. When both B-meson daughters are tensor mesons and the smaller of the two daughter spins is $J_1 > 1$, this formalism can be easily extended by introducing the parity-even and parity-odd amplitudes of higher order $A_{\parallel n,\perp n} = (A_{+n} \pm A_{-n})/\sqrt{2}$, with $1 < n \leq J_1$, while the general angular parameterization may be found in Ref. [7]. However, we limit the following discussion to $J_1 = 1$. The differential decay rate would involve six real quantities α_i, including interference terms,

$$\frac{d\Gamma}{\Gamma\, d\cos\theta_1\, d\cos\theta_2\, d\Phi} = \sum_i \alpha_i\ f_i\,(\cos\theta_1,\, \cos\theta_2,\, \Phi)\,, \qquad (74.1)$$

where each $f_i\,(\cos\theta_1, \cos\theta_2, \Phi)$ has unique angular dependence specific to particle quantum numbers, and the α_i parameters are defined as:

$$\alpha_1 = \frac{|A_0|^2}{\Sigma|A_\lambda|^2} = f_L\,, \qquad (74.2)$$

$$\alpha_2 = \frac{|A_\parallel|^2 + |A_\perp|^2}{\Sigma|A_\lambda|^2} = (1 - f_L)\,, \qquad (74.3)$$

$$\alpha_3 = \frac{|A_\parallel|^2 - |A_\perp|^2}{\Sigma|A_\lambda|^2} = (1 - f_L - 2\,f_\perp)\,, \qquad (74.4)$$

$$\alpha_4 = \frac{\Im m(A_\perp A_\parallel^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_\perp(1-f_L-f_\perp)}\,\sin(\phi_\perp - \phi_\parallel)\,, \qquad (74.5)$$

$$\alpha_5 = \frac{\Re e(A_\parallel A_0^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_L\,(1-f_L-f_\perp)}\,\cos(\phi_\parallel)\,, \qquad (74.6)$$

$$\alpha_6 = \frac{\Im m(A_\perp A_0^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_\perp\, f_L}\,\sin(\phi_\perp)\,, \qquad (74.7)$$

where the amplitudes have been expressed with the help of polarization parameters f_L, $f_\perp$, $\phi_\parallel$, and $\phi_\perp$ defined in Table 74.1. Note that the terms proportional to $\Re e(A_\perp A_\parallel^*)$, $\Im m(A_\parallel A_0^*)$, and $\Re e(A_\perp A_0^*)$ are absent in Eqs. (2-7). However, these terms may appear for some three-body decays of a B-meson daughter, see Ref. [7].

Table 74.1: Rate, polarization, and CP-asymmetry parameters defined for the B-meson decays to mesons with non-zero spin. Numerical examples are shown for the average of the $B^0 \to \varphi K^*(892)^0$ decay measurements obtained from BABAR [8], Belle [9], and LHCb [10]. The first six parameters are defined under the assumption of no CP violation in decay, while they are averaged between the $\overline{B}$ and B parameters in general. The last six parameters involve differences between the $\overline{B}$ and B meson decay parameters. The phase convention δ_0 is chosen with respect to a single A_{00} amplitude from a reference B decay mode, which is $B^0 \to \varphi K_0^*(1430)^0$ for numerical results.

parameter	definition	average
$\mathcal{B}$	$\Gamma/\Gamma_{\rm total}$	$(10.1^{+0.6}_{-0.5}) \times 10^{-6}$
f_L	$\lvert A_0\rvert^2/\Sigma\lvert A_\lambda\rvert^2$	0.497 ± 0.017
$f_\perp$	$\lvert A_\perp\rvert^2/\Sigma\lvert A_\lambda\rvert^2$	0.225 ± 0.015
$\phi_\parallel - \pi$	$\arg(A_\parallel/A_0) - \pi$	-0.712 ± 0.058
$\phi_\perp - \pi$	$\arg(A_\perp/A_0) - \pi$	-0.615 ± 0.056
$\delta_0 - \pi$	$\arg(A_{00}/A_0) - \pi$	-0.26 ± 0.10
A_{CP}	$(\bar{\Gamma} - \Gamma)/(\bar{\Gamma} + \Gamma)$	-0.003 ± 0.038
A_{CP}^0	$(\bar{f_L} - f_L)/(\bar{f_L} + f_L)$	-0.007 ± 0.030
$A_{CP}^\perp$	$(\bar{f_\perp} - f_\perp)/(\bar{f_\perp} + f_\perp)$	-0.014 ± 0.057
$\Delta\phi_\parallel$	$(\bar{\phi_\parallel} - \phi_\parallel)/2$	$+0.051 \pm 0.053$
$\Delta\phi_\perp$	$(\bar{\phi_\perp} - \phi_\perp - \pi)/2$	$+0.075 \pm 0.050$
$\Delta\delta_0$	$(\bar{\delta_0} - \delta_0)/2$	$+0.13 \pm 0.08$

Overall, six real parameters describe three complex amplitudes A_0, $A_\parallel$, and $A_\perp$. These could be chosen to be the four polarization

parameters f_L, $f_\perp$, $\phi_\parallel$, and $\phi_\perp$, one overall size normalization, such as decay rate Γ, or branching fraction $\mathcal{B}$, and one overall phase δ_0. The phase convention is arbitrary for an isolated B decay mode. However, for several B decays, the relative phase could produce meaningful and observable effects through interference with other B decays with the same final states, such as for $B \to VK_J^*$ with $J = 0, 1, 2, 3, 4, ...$ The phase could be referenced to the single $B \to VK_0^*$ amplitude A_{00} in such a case, as shown in Table 74.1. Here V stands for any spin-one vector meson.

Moreover, *CP* violation can be tested in the angular distribution of the decay as the difference between the B and $\overline{B}$. Each of the six real parameters describing the three complex amplitudes would have a counterpart *CP*-asymmetry term, corresponding to three direct-*CP* asymmetries in three amplitudes, and three *CP*-violating phase differences, equivalent to the phase measurements from the mixing-induced *CP* asymmetries in the time evolution of B-decays [1]. In Table 74.1 and Ref. [11], these are chosen to be the direct-*CP* asymmetries in the overall decay rate $\mathcal{A}_{CP}$, in the f_L fraction $\mathcal{A}_{CP}^0$, and in the $f_\perp$ fraction $\mathcal{A}_{CP}^\perp$, and three weak phase differences:

$$\Delta\phi_\parallel = \frac{1}{2}\arg(\bar{A}_\parallel A_0 / A_\parallel \bar{A}_0)\,, \tag{74.8}$$

$$\Delta\phi_\perp = \frac{1}{2}\arg(\bar{A}_\perp A_0 / A_\perp \bar{A}_0) - \frac{\pi}{2}\,, \tag{74.9}$$

$$\Delta\delta_0 = \frac{1}{2}\arg(\bar{A}_{00} A_0 / A_{00} \bar{A}_0)\,. \tag{74.10}$$

The $\frac{\pi}{2}$ term in Eq. (74.8) reflects the fact that $A_\perp$ and $\bar{A}_\perp$ differ in phase by π if *CP* is conserved. The two parameters $\Delta\phi_\parallel$ and $\Delta\phi_\perp$ are equivalent to triple-product asymmetries constructed from the vectors describing the decay angular distribution [12]. The *CP*-violating phase difference in the reference decay mode [11] is, in the Wolfenstein CKM quark-mixing phase convention,

$$\Delta\phi_{00} = \frac{1}{2}\arg(A_{00} / \bar{A}_{00})\,. \tag{74.11}$$

This can be measured only together with the mixing-induced phase difference for some of the neutral B-meson decays similar to other mixing-induced *CP* asymmetry measurements [1].

It may not always be possible to have a phase-reference decay mode which would define δ_0 and $\Delta\delta_0$ parameters. In that case, it may be possible to define the phase difference directly similarly to Eq. (74.11):

$$\Delta\phi_0 = \frac{1}{2}\arg(A_0 / \bar{A}_0)\,. \tag{74.12}$$

One can measure the angles of the CKM unitarity triangle, assuming Standard Model contributions to the $\Delta\phi_0$ and B-mixing phases. Examples include measurements of $\beta = \phi_1$ with $B \to J/\psi K^*$ and $\alpha = \phi_2$ with $B \to \rho\rho$.

Most of the B decays that arise from tree-level $b \to c$ transitions have the amplitude hierarchy $|A_0| > |A_+| > |A_-|$ which is expected from analyses based on quark-helicity conservation [13]. The larger the mass of the vector-meson daughters, the weaker the inequality. The B meson decays to heavy vector particles with charm, such as $B \to J/\psi K^*$, $\psi(2S)K^*$, $\chi_{c1}K^*$, $D^*\rho$, D^*K^*, D^*D^*, and $D^*D_s^*$, show a substantial fraction of the amplitudes corresponding to transverse polarization of the vector mesons ($A_{\pm 1}$), in agreement with the factorization prediction. The detailed amplitude analysis of the $B \to J/\psi K^*$ decays has been performed by the BABAR [14], Belle [15], CDF [16], CLEO [17], D0 [18], and LHCb [19] collaborations. Most analyses are performed under the assumption of the absence of direct *CP* violation. The parameter values are given in the particle listing of this *Review*. The difference between the strong phases $\phi_\parallel$ and $\phi_\perp$ deviates significantly from zero. The measurements [14, 15] of *CP*-violating terms similar to those in $B \to \varphi K^*$ [8] shown in Table 74.1 are consistent with zero.

In addition, the mixing-induced *CP*-violating asymmetry is measured in the $B^0 \to J/\psi K^{*0}$ decay [1, 14, 15] where angular analysis allows one to separate *CP*-eigenstate amplitudes. This allows one to resolve the sign ambiguity of the $\cos 2\beta$ ($\cos 2\phi_1$) term that appears in the time-dependent angular distribution due to interference of parity-even and parity-odd terms. This analysis relies on the knowledge of discrete ambiguities in the strong phases $\phi_\parallel$ and $\phi_\perp$, as discussed below. The BABAR experiment used a method based on the dependence on the $K\pi$ invariant mass of the interference between the S- and P-waves to resolve the discrete ambiguity in the determination of the strong phases $(\phi_\parallel, \phi_\perp)$ in $B \to J/\psi K^*$ decays [14]. The result is in agreement with the amplitude hierarchy expectation [13]. The CDF [20], D0 [21], and LHCb [22] experiments have studied the $B_s^0 \to J/\psi(K^+K^-)$, $J/\psi(\pi^+\pi^-)$, $\psi(K^+\pi^-)$ decays and provided the lifetime, polarization, and phase measurements.

The amplitude hierarchy $|A_0| \gg |A_+| \gg |A_-|$ was expected in B decays to light vector particles in both penguin transitions [23, 24] and tree-level transitions [13]. There is confirmation by the BABAR and Belle experiments of predominantly longitudinal polarization in the tree-level $b \to u$ transition, such as $B^0 \to \rho^+\rho^-$ [25], $B^+ \to \rho^0\rho^+$ [26], and $B^+ \to \omega\rho^+$ [27]; this is consistent with the analysis of the quark helicity conservation [13]. Because the longitudinal amplitude dominates the decay, a detailed amplitude analysis is not possible with current B samples, and limits on the transverse amplitude fraction are obtained. The small branching fractions of $B^0 \to \rho^0\rho^0, \omega\rho^0, \omega\omega$ [27–30] indicate that $b \to d$ penguin pollution is small in the charmless, strangeless vector-vector B decays. There is a measurement of large longitudinal polarization in $B^0 \to \rho^0\rho^0$ [28–30] decays. The fraction of transverse polarization is large in decays to heavier mesons such as $B^0 \to a_1(1260)^+ a_1(1260)^-$ [31].

The interest in the polarization and *CP*-asymmetry measurements in penguin transition, such as $b \to s$ decays $B \to \varphi K^*$, ρK^*, ωK^*, or $B_s^0 \to \varphi\varphi$, K^*K^*, and $b \to d$ decay $B \to K^*\bar{K}^*$, is motivated by their potential sensitivity to physics beyond the Standard Model. The decay amplitudes for $B \to \varphi K^*$ have been measured by the BABAR, Belle, and LHCb experiments [9–11, 32, 33]. The fractions of longitudinal polarization are $f_L = 0.50 \pm 0.05$ for the $B^+ \to \varphi K^{*+}$ decay and $f_L = 0.497 \pm 0.017$ for the $B^0 \to \varphi K^{*0}$ decay. These indicate significant departure from the naive expectation of predominant longitudinal polarization, suggesting other contributions to the decay amplitude, previously neglected, either within the Standard Model, such as penguin annihilation [34] or QCD rescattering [35], or from physics beyond the Standard Model [36]. The complete set of twelve amplitude parameters measured in the $B^0 \to \varphi K^{*0}$ decay is given in Table 74.1. Several other parameters could be constructed from the above twelve parameters, as suggested in Ref. [37].

The discrete ambiguity in the phase $(\phi_\parallel, \phi_\perp, \Delta\phi_\parallel, \Delta\phi_\perp)$ measurements has been resolved by BABAR in favor of $|A_+| \gg |A_-|$ through interference between the S- and P-waves of $K\pi$. The search for vector-tensor and vector-axialvector $B \to \varphi K_J^{(*)}$ decays with $J = 1, 2, 3, 4$ revealed a large fraction of longitudinal polarization in the decay $B \to \varphi K_2^*(1430)$ with $f_L = 0.90^{+0.06}_{-0.07}$ [11, 38], but large contribution of transverse amplitude in $B \to \varphi K_1(1270)$ with $f_L = 0.46^{+0.13}_{-0.15}$ [39].

Like $B \to \varphi K^*$, the decays $B \to \rho K^*$ and $B \to \omega K^*$ may be sensitive to New Physics. Measurements of the longitudinal polarization fraction in $B \to \rho K^*$ [40] and in both vector-vector and vector-tensor final states of $B \to \omega K_J^*$ [27] by BABAR and Belle reveal a large fraction of transverse polarization, indicating an anomaly similar to $B \to \varphi K^*$ except for a different pattern in vector-tensor final states. An angular analysis of the $B^0 \to \rho^0 K^{*0}$ decay mode by LHCb [41] provides much higher precision and indicates remarkably small longitudinal polarization fraction and a significant direct CP asymmetry observed in angular distributions of $B \to VV$ decays for the first time. A large transverse polarization is also observed in the $B_s^0 \to \varphi\varphi$ decay by CDF [42] and LHCb [43], $B_s^0 \to K^{*0}\bar{K}^{*0}$ decays by LHCb [44], and $B_s^0 \to \varphi K^{*0}$ decays by LHCb [45]. At the same time, measurement of the polarization in the $b \to d$ penguin decays $B \to K^*\bar{K}^*$ indicates a large fraction of longitudinal polarization [44, 46]. The LHCb experiment has also provided the very first polarization results on the tensor-tensor, as well as vector-tensor, decays of the B_s^0 meson in the $(K\pi)(K\pi)$ final state [44]. The polarization pattern in penguin-dominated B-meson decays is not fully understood [34–36].

The three-body semileptonic B-meson decays, such as $B \to V\ell_1\ell_2$, share many features with the two-body $B \to VV$ decays. Their differential decay width can be parameterized with the two helicity angles defined in the V and $(\ell_1\ell_2)$ frames and with the azimuthal angle, as defined in Fig. 74.1. However, since the $(\ell_1\ell_2)$ pair does not come from an on-shell particle, the angular distribution is unique to each point in the dilepton mass $m_{\ell\ell}$ spectrum. The polarization measurements as a function of $m_{\ell\ell}$ provide complementary information on physics beyond the Standard Model, as discussed for $B \to K^*\ell^+\ell^-$ and $B_s \to \phi\ell^+\ell^-$ decays in Ref. [47]. The data in these modes have been analyzed by the BABAR, Belle, CDF, CMS, and LHCb experiments [48–53].

The examples of the angular distributions and observables in $B \to K^*\ell^+\ell^-$ are discussed in Ref. [47]. Two angular observables have been measured in this decay in certain ranges of the dilepton mass $m_{\ell\ell}$. One parameter is the fraction of longitudinal polarization F_L, which is determined by the K^* angular distribution and is similar to f_L defined for exclusive two-body decays. The other parameter is the forward-backward asymmetry of the lepton pair A_{FB}, which is the asymmetry of the decay rate with positive and negative values of $\cos\theta_1$. A complete set of observables and angular terms has been adopted by the LHCb collaboration [52] following Ref. [47] with the F_L, A_{FB}, and $S_3 - S_9$ coefficients in the angular distributions. Additional set of optimized observables $P_i^{(\prime)}$ is derived from those, for example $P_2 = 2A_{FB}/(3-3F_L)$ and $P_5' = S_5/\sqrt{F_L(1-F_L)}$. These observables have the advantage that the leading form-factor uncertainties cancel. There have been hints of deviations from SM in the measurement of P_5' and lepton flavor universality [48–53].

In summary, there has been considerable interest in the polarization measurements of B-meson decays because they reveal both weak- and strong-interaction dynamics [34–36, 54]. New measurements will further elucidate the pattern of spin alignment measurements in rare B decays, and further test the Standard Model and strong interaction dynamics, including the non-factorizable contributions to the B-decay amplitudes.

75. B^0–$\overline{B}^0$ Mixing

Revised March 2022 by O. Schneider (EPFL).

There are two neutral B^0–$\overline{B}^0$ meson systems, B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ (generically denoted B_q^0–$\overline{B}_q^0$, $q = s, d$), which exhibit particle-antiparticle mixing [1]. This mixing phenomenon is described in Ref. [2]. In the following, we adopt the notation introduced in Ref. [2], and assume CPT conservation throughout. In each system, the light (L) and heavy (H) mass eigenstates,

$$|B_{\rm L,H}\rangle = p|B_q^0\rangle \pm q|\overline{B}_q^0\rangle, \tag{75.1}$$

have a mass difference $\Delta m_q = m_{\rm H} - m_{\rm L} > 0$, a total decay width difference $\Delta\Gamma_q = \Gamma_{\rm L} - \Gamma_{\rm H}$ and an average decay width $\Gamma_q = (\Gamma_{\rm L} + \Gamma_{\rm H})/2$. In the absence of CP violation in the mixing, $|q/p| = 1$, the differences are given by $\Delta m_q = 2|M_{12}|$ and $|\Delta\Gamma_q| = 2|\Gamma_{12}|$, where M_{12} and Γ_{12} are the off-diagonal elements of the mass and decay matrices [2]. The evolution of a pure $|B_q^0\rangle$ or $|\overline{B}_q^0\rangle$ state at $t = 0$ is given by

$$|B_q^0(t)\rangle = g_+(t)\,|B_q^0\rangle + \frac{q}{p}\,g_-(t)\,|\overline{B}_q^0\rangle, \tag{75.2}$$

$$|\overline{B}_q^0(t)\rangle = g_+(t)\,|\overline{B}_q^0\rangle + \frac{p}{q}g_-(t)\,|B_q^0\rangle, \tag{75.3}$$

which means that the flavor states remain unchanged (+) or oscillate into each other (−) with time-dependent probabilities proportional to

$$|g_\pm(t)|^2 = \frac{e^{-\Gamma_q t}}{2}\left[\cosh\left(\frac{\Delta\Gamma_q}{2}\,t\right) \pm \cos(\Delta m_q\, t)\right]. \tag{75.4}$$

In the absence of CP violation, the time-integrated mixing probability $\int |g_-(t)|^2\,dt/(\int |g_-(t)|^2\,dt + \int |g_+(t)|^2\,dt)$ is given by

$$\chi_q = \frac{x_q^2 + y_q^2}{2(x_q^2+1)}\,, \quad \text{where} \quad x_q = \frac{\Delta m_q}{\Gamma_q}\,, \quad y_q = \frac{\Delta\Gamma_q}{2\Gamma_q}\,. \tag{75.5}$$

75.1 Standard Model predictions and phenomenology

In the Standard Model, the transitions $B_q^0 \to \overline{B}_q^0$ and $\overline{B}_q^0 \to B_q^0$ are due to the weak interaction. They are described, at the lowest order, by box diagrams involving two W bosons and two up-type quarks (see Fig. 75.1), as is the case for $K^0 - \overline{K}^0$ mixing. However, the long range interactions arising from intermediate virtual states are negligible for the neutral B meson systems, because the large B mass is off the region of hadronic resonances. The calculation of the dispersive and absorptive parts of the box diagrams yields the following predictions for the off-diagonal element of the mass and decay matrices [3],

$$M_{12} = -\frac{G_F^2 m_W^2 \eta_B m_{B_q} B_{B_q} f_{B_q}^2}{12\pi^2}\, S_0(m_t^2/m_W^2)\,(V_{tq}^* V_{tb})^2\,, \tag{75.6}$$

$$\Gamma_{12} = \frac{G_F^2 m_b^2 \eta'_B m_{B_q} B_{B_q} f_{B_q}^2}{8\pi} \times \left[(V_{tq}^* V_{tb})^2 + V_{tq}^* V_{tb} V_{cq}^* V_{cb}\,\mathcal{O}\left(\frac{m_c^2}{m_b^2}\right) + (V_{cq}^* V_{cb})^2\,\mathcal{O}\left(\frac{m_c^4}{m_b^4}\right)\right], \tag{75.7}$$

where G_F is the Fermi constant, m_W the W boson mass, and m_i the mass of quark i; m_{B_q}, f_{B_q} and B_{B_q} are the B_q^0 mass, weak decay constant and bag parameter, respectively. The known function $S_0(x_t)$ can be approximated very well by $0.784\,x_t^{0.76}$ [4], and V_{ij} are the elements of the CKM matrix [5]. The QCD corrections η_B and η'_B are of order unity. The only non-negligible contributions to M_{12} are from box diagrams involving two top quarks. The phases of M_{12} and Γ_{12} satisfy

$$\phi_M - \phi_\Gamma = \pi + \mathcal{O}\left(\frac{m_c^2}{m_b^2}\right), \tag{75.8}$$

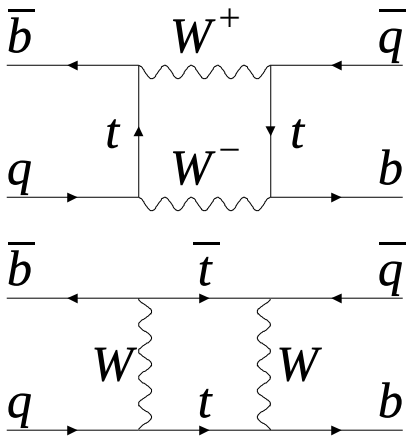

Figure 75.1: Dominant box diagrams for the $B_q^0 \to \overline{B_q}^0$ transitions ($q = d$ or s). Similar diagrams exist where one or both t quarks are replaced with c or u quarks.

implying that the mass eigenstates have mass and width differences of opposite signs. This means that, like in the K^0–$\overline{K}^0$ system, the heavy state is expected to have a smaller decay width than that of the light state: $\Gamma_{\rm H} < \Gamma_{\rm L}$. Hence, $\Delta\Gamma_q = \Gamma_{\rm L} - \Gamma_{\rm H}$ is expected to be positive in the Standard Model.

Furthermore, the quantity

$$\left|\frac{\Gamma_{12}}{M_{12}}\right| \simeq \frac{3\pi}{2}\,\frac{m_b^2}{m_W^2}\,\frac{1}{S_0(m_t^2/m_W^2)} \sim \mathcal{O}\left(\frac{m_b^2}{m_t^2}\right) \tag{75.9}$$

is small, and a power expansion of $|q/p|^2$ yields

$$\left|\frac{q}{p}\right|^2 = 1 + \left|\frac{\Gamma_{12}}{M_{12}}\right| \sin(\phi_M - \phi_\Gamma) + \mathcal{O}\left(\left|\frac{\Gamma_{12}}{M_{12}}\right|^2\right). \tag{75.10}$$

Therefore, considering both Eqs. (75.8) and (75.9), the CP-violating parameter

$$1 - \left|\frac{q}{p}\right|^2 \simeq \mathrm{Im}\left(\frac{\Gamma_{12}}{M_{12}}\right) \tag{75.11}$$

is expected to be very small: $\sim \mathcal{O}(10^{-3})$ for the B_d^0–$\overline{B}_d^0$ system and $\lesssim \mathcal{O}(10^{-4})$ for the B_s^0–$\overline{B}_s^0$ system [6].

In the approximation of negligible CP violation in mixing, the ratio $\Delta\Gamma_q/\Delta m_q$ is equal to the small quantity $|\Gamma_{12}/M_{12}|$ of Eq. (75.9); it is hence independent of CKM matrix elements, *i.e.*, the same for the B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ systems. Calculations [7] yield $\sim 5 \times 10^{-3}$ with a $\sim 20\%$ uncertainty. Given the published experimental knowledge [8] on the mixing parameter x_q

$$\begin{cases} x_d = 0.769 \pm 0.004 & (B_d^0\text{–}\overline{B}_d^0 \text{ system}) \\ x_s = 27.01 \pm 0.10 & (B_s^0\text{–}\overline{B}_s^0 \text{ system}) \end{cases}, \tag{75.12}$$

the Standard Model thus predicts that $\Delta\Gamma_d/\Gamma_d$ is very small (below 1%), but $\Delta\Gamma_s/\Gamma_s$ considerably larger ($\sim 10\%$). These width differences are caused by the existence of final states to which both the B_q^0 and $\overline{B}_q^0$ mesons can decay. Such decays involve $b \to c\bar{c}q$ quark-level transitions, which are Cabibbo-suppressed if $q = d$ and Cabibbo-allowed if $q = s$.

A complete set of Standard Model predictions for all mixing parameters in both the B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ systems can be found in Refs. [9–11].

75.2 Experimental issues and methods for oscillation analyses

Time-integrated measurements of B^0–$\overline{B}^0$ mixing were published for the first time in 1987 by UA1 [12] and ARGUS [13], and

since then by many other experiments. These measurements are typically based on counting same-sign and opposite-sign lepton pairs from the semileptonic decay of the produced $b\bar{b}$ pairs. Such analyses cannot easily separate the contributions from the different b-hadron species, therefore, the clean environment of $\Upsilon(4S)$ machines (where only B^0_d and charged B_u mesons are produced) is in principle best suited to measure χ_d.

However, better sensitivity is obtained from time-dependent analyses aiming at the direct measurement of the oscillation frequencies Δm_d and Δm_s, from the proper time distributions of B^0_d or B^0_s candidates identified through their decay in (mostly) flavor-specific modes, and suitably tagged as mixed or unmixed. This is particularly true for the B^0_s–$\overline{B}^0_s$ system, where the large value of x_s implies maximal mixing, *i.e.*, $\chi_s \simeq 1/2$. In such analyses, the B^0_d or B^0_s mesons are either fully reconstructed, partially reconstructed from a charm meson, selected from a lepton with the characteristics of a $b \to \ell^-$ decay, or selected from a reconstructed displaced vertex. At high-energy colliders (LEP, SLC, Tevatron, LHC), the proper time $t = \frac{m_B}{p} L$ is measured from the distance L between the production vertex and the B decay vertex, and from an estimate of the B momentum p. At asymmetric B factories (KEKB, PEP-II), producing $e^+e^- \to \Upsilon(4S) \to B^0_d\,\overline{B_d}{}^0$ events with a boost $\beta\gamma$ ($= 0.425$, 0.55), the proper time difference between the two B candidates is estimated as $\Delta t \simeq \frac{\Delta z}{\beta\gamma c}$, where Δz is the spatial separation between the two B decay vertices along the boost direction. In all cases, the good resolution needed on the vertex positions is obtained with silicon detectors.

The average statistical significance $\mathcal{S}$ of a B^0_q oscillation signal can be approximated as [14]

$$\mathcal{S} \approx \sqrt{N/2}\, f_{\rm sig}\,(1-2\eta)\, e^{-(\Delta m_q\, \sigma_t)^2/2}\,, \qquad (75.13)$$

where N is the number of selected and tagged candidates, $f_{\rm sig}$ is the fraction of signal in that sample, η is the total mistag probability, and σ_t is the resolution on proper time (or proper time difference). The quantity $\mathcal{S}$ decreases very quickly as Δm_q increases; this dependence is controlled by σ_t, which is therefore a critical parameter for Δm_s analyses. At high-energy colliders, the proper time resolution $\sigma_t \sim \frac{m_B}{\langle p\rangle}\sigma_L \oplus t\frac{\sigma_p}{p}$ includes a constant contribution due to the decay length resolution σ_L (typically 0.04–0.3 ps), and a term due to the relative momentum resolution σ_p/p (typically 10–20% for partially reconstructed decays), which increases with proper time. At B factories, the boost of the B mesons is estimated from the known beam energies, and the term due to the spatial resolution dominates (typically 1–1.5 ps because of the much smaller B boost).

In order to tag a B^0_q candidate as mixed or unmixed, it is necessary to determine its flavor both in the initial state and in the final state. The initial and final state mistag probabilities, η_i and η_f, degrade $\mathcal{S}$ by a total factor $(1-2\eta) = (1-2\eta_i)(1-2\eta_f)$. In lepton-based analyses, the final state is tagged by the charge of the lepton from $b \to \ell^-$ decays; the largest contribution to η_f is then due to $\bar{b} \to \bar{c} \to \ell^-$ decays. Alternatively, the charge of a reconstructed charm meson (D^{*-} from B^0_d or D^-_s from B^0_s), or that of a kaon hypothesized to come from a $b \to c \to s$ decay [15], can be used. For fully-inclusive analyses based on topological vertexing, final-state tagging techniques include jet-charge [16] and charge-dipole [17, 18] methods. At high-energy colliders, the methods to tag the initial state (*i.e.*, the state at production), can be divided into two groups: the ones that tag the initial charge of the $\bar{b}$ quark contained in the B^0_q candidate itself (same-side tag), and the ones that tag the initial charge of the other b quark produced in the event (opposite-side tag). On the same side, the sign of a charged pion, kaon or proton from the primary vertex is correlated with the production state of the B^0_q meson if that particle is a decay product of a B^{**} state or the first in the fragmentation chain [19, 20]. Jet- and vertex-charge techniques work on both sides and on the opposite side, respectively. Finally, the charge of a lepton from $b \to \ell^-$, of a kaon from $b \to c \to s$ or of a charm hadron from $b \to c$ [21] can be used as an opposite-side tag, keeping in mind that its performance is degraded due to integrated mixing. At SLC, the beam polarization produced a sizeable forward-backward asymmetry in the $Z \to b\bar{b}$ decays, and provided another very interesting and effective initial state tag based on the polar angle of the B^0_q candidate [17]. Initial state tags have also been combined to reach $\eta_i \sim 26\%$ at LEP [20, 22] or 22% at SLD [17] with full efficiency. In the case $\eta_f = 0$, this corresponds to an effective tagging efficiency $Q = \epsilon D^2 = \epsilon(1-2\eta)^2$, where ϵ is the tagging efficiency, in the range $23 - 31\%$. The equivalent figure achieved by CDF during Tevatron Run I was $\sim 3.5\%$ (see tagging summary on page 160 of Ref. [23]), reflecting the fact that tagging is more difficult at hadron colliders. The CDF and DØ analyses of Tevatron Run II data reached $\epsilon D^2 = (1.8 \pm 0.1)\%$ [24] and $(2.5 \pm 0.2)\%$ [25] for opposite-side tagging, while same-side kaon tagging (for B^0_s analyses) contributed an additional $3.7-4.8\%$ at CDF [24], and pushed the combined performance to $(4.7 \pm 0.5)\%$ at DØ [26]. LHCb, operating in the forward region at the LHC where the environment is different in terms of track multiplicity and b-hadron production kinematics, has reported $\epsilon D^2 = (2.10 \pm 0.25)\%$ [27] for opposite-side tagging, $(1.80 \pm 0.26)\%$ [28] for same-side kaon tagging, and $(2.11 \pm 0.11)\%$ [29] for same-side pion and proton tagging: the combined figure ranges typically between $(3.73 \pm 0.15)\%$ [30] and $(5.33 \pm 0.25)\%$ [31] depending on the mode in which the tagged B^0_s meson is reconstructed, and reaches up to $(8.1 \pm 0.6)\%$ [32] for hadronic B^0_d modes. CMS has recently reported $\epsilon D^2 \sim 10\%$ using opposite-side muon tagging of $B^0_s \to J/\psi\phi$ decays [33].

At B factories, the flavor of a B^0_d meson at production cannot be determined, since the two neutral B mesons produced in a $\Upsilon(4S)$ decay evolve in a coherent P-wave state where they keep opposite flavors at any time. However, as soon as one of them decays, the other follows a time-evolution given by Eqs. (75.2) or (75.3), where t is replaced with Δt (which will take negative values half of the time). Hence, the "initial state" tag of a B can be taken as the final-state tag of the other B. Effective tagging efficiencies of 30% are achieved by BaBar and Belle [34], using different techniques including $b \to \ell^-$ and $b \to c \to s$ tags. It is worth noting that, in this case, mixing of the other B (*i.e.*, the coherent mixing occurring before the first B decay) does not contribute to the mistag probability.

Before the experimental observation of a decay-width difference, oscillation analyses typically neglected $\Delta\Gamma_q$ in Eq. (75.4), and described the time dependence with the functions $\Gamma_q e^{-\Gamma_q t}(1 \pm \cos(\Delta m_q t))/2$ (high-energy colliders) or $\Gamma_d e^{-\Gamma_d|\Delta t|}(1 \pm \cos(\Delta m_d \Delta t))/4$ (asymmetric $\Upsilon(4S)$ machines). As can be seen from Eq. (75.4), a non-zero value of $\Delta\Gamma_q$ would effectively reduce the oscillation amplitude with a small time-dependent factor that would be very difficult to distinguish from time resolution effects. Measurements of Δm_q are usually extracted from the data using a maximum likelihood fit.

75.3 Δm_d and $\Delta\Gamma_d$ measurements

Many B^0_d–$\overline{B}^0_d$ oscillations analyses have been published [35] by the ALEPH [36], DELPHI [18, 37], L3 [38], OPAL [39, 40], BaBar [41], Belle [42], CDF [19], DØ [25], and LHCb [43–46] collaborations. Although a variety of different techniques have been used, the individual Δm_d results obtained at LEP and Tevatron have remarkably similar precision. Their average is compatible with the more precise measurements at the asymmetric B factories and the LHC. The systematic uncertainties are not negligible; they are often dominated by sample composition, mistag probability, or b-hadron lifetime contributions. Before being combined, the measurements are adjusted on the basis of a common set of input values, including the b-hadron lifetimes and fractions published in this *Review*. Some measurements are statistically correlated. Systematic correlations arise both from common physics sources (fragmentation fractions, lifetimes, branching ratios of b hadrons), and from purely experimental or algorithmic effects (efficiency, resolution, tagging, background description). Combining all measurements [18, 19, 25, 36–46] and accounting for all identified correlations yields $\Delta m_d = 0.5065 \pm 0.0016(\text{stat}) \pm 0.0011(\text{syst})\ \text{ps}^{-1}$ [8], a result dominated by the latest LHCb measurement with $B^0 \to D^{(*)-}\mu^+\nu_\mu X$ decays [46].

On the other hand, ARGUS and CLEO have published time-integrated measurements [47–49], which average to $\chi_d = 0.182 \pm 0.015$. Following Ref. [49], the width difference $\Delta\Gamma_d$ could in

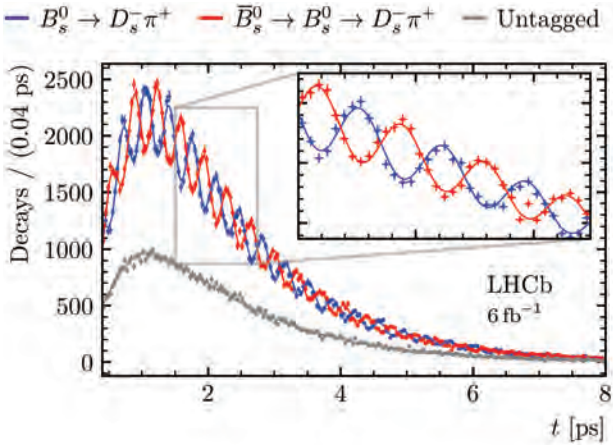

Figure 75.2: Proper time distribution of $B_s^0 \to D_s^- \pi^+$ candidates tagged as unmixed (blue), tagged as mixed (red) or untagged (grey) in the LHCb experiment, displaying B_s^0–$\overline{B}_s^0$ oscillations (from Ref. [59]).

principle be extracted from the measured value of $1/\Gamma_d$ and the above averages for Δm_d and χ_d (see Eq. (75.5)), provided that $\Delta\Gamma_d$ has a negligible impact on the Δm_d and $1/\Gamma_d$ analyses that have assumed $\Delta\Gamma_d = 0$. However, $\Delta\Gamma_d/\Gamma_d$ is too small and the knowledge of χ_d too imprecise to provide useful sensitivity on $\Delta\Gamma_d/\Gamma_d$. Direct time-dependent studies published by DELPHI [18], BaBar [50], Belle [51], LHCb [52], ATLAS [53] and CMS [54] provide stronger constraints, which can be combined to yield [8]

$$\Delta\Gamma_d/\Gamma_d = +0.001 \pm 0.010\,. \tag{75.14}$$

This determination is compatible both with zero and with the Standard Model prediction of $(3.97 \pm 0.90) \times 10^{-3}$ [11].

Assuming $\Delta\Gamma_d = 0$ and no CP violation in mixing, and using the B_d^0 lifetime average of 1.519 ± 0.004 ps [8], the Δm_d and χ_d results are combined to yield the world average

$$\Delta m_d = 0.5065 \pm 0.0019 \text{ ps}^{-1} \tag{75.15}$$

or, equivalently,

$$\chi_d = 0.1858 \pm 0.0011\,. \tag{75.16}$$

This Δm_d value provides an estimate of $2|M_{12}|$, and can be used with Eq. (75.6) to extract $|V_{td}|$ within the Standard Model [55]. The main experimental uncertainties on the result come from m_t and Δm_d, but are still completely negligible with respect to the uncertainty due to the hadronic matrix element $f_{B_d}\sqrt{B_{B_d}} = 225 \pm 9$ MeV [56] obtained from three-flavor lattice QCD calculations.

75.4 Δm_s and $\Delta\Gamma_s$ measurements

After many years of intense search at LEP and SLC, B_s^0–$\overline{B}_s^0$ oscillations were first observed in 2006 by CDF using 1 fb^{-1} of Tevatron Run II data [24]. LHCb then observed B_s^0–$\overline{B}_s^0$ oscillations independently with $B_s^0 \to D_s^- \pi^+$ [43, 57], $B_s^0 \to D_s^- \mu^+ \nu X$ [45] and $B_s^0 \to J/\psi K^+ K^-$ [30] decays, using between 1 and 4.9 fb^{-1} of data collected at the LHC until 2016. More recently measurements based on the full LHC Run 2 data have been published by CMS with $B_s^0 \to J/\psi\phi$ decays [33], and by LHCb with $B_s^0 \to D_s^- \pi^+\pi^-\pi^+$ [58] and $B_s^0 \to D_s^- \pi^+$ [59] decays. Taking systematic correlations into account, the average [8] of all published measurements of Δm_s [24, 30, 33, 43, 45, 57–59] is

$$\Delta m_s = 17.765 \pm 0.004(\text{stat}) \pm 0.004(\text{syst}) \text{ ps}^{-1}\,, \tag{75.17}$$

with an impressive precision dominated by the most recent LHCb result (see Fig. 75.2).

The information on $|V_{ts}|$ obtained in the framework of the Standard Model is hampered by the hadronic uncertainty, as in the B_d^0 case. However, several uncertainties cancel in the frequency ratio

$$\frac{\Delta m_s}{\Delta m_d} = \frac{m_{B_s}}{m_{B_d}}\,\xi^2 \left|\frac{V_{ts}}{V_{td}}\right|^2\,, \tag{75.18}$$

where the SU(3) flavor-symmetry breaking factor $\xi = (f_{B_s}\sqrt{B_{B_s}})/(f_{B_d}\sqrt{B_{B_d}})$ is obtained as 1.206 ± 0.017 from a combination of three-flavor lattice QCD calculations [56] dominated by the results of Ref. [60], or as $1.2014^{+0.0065}_{-0.0072}$ from QCD sum rules [61]. Using the measurements of Eqs. (75.15) and (75.17), one can extract

$$\left|\frac{V_{td}}{V_{ts}}\right| = \begin{cases} 0.2053 \pm 0.0004 \pm 0.0029 \text{ (lattice QCD)} \\ 0.2045 \pm 0.0004^{+0.0011}_{-0.0012} \text{ (QCD sum rules)} \end{cases}\,, \tag{75.19}$$

in good agreement with (but much more precise than) the value obtained from the ratio of the $b \to d\gamma$ and $b \to s\gamma$ transition rates observed at the B factories [55].

The CKM matrix can be constrained using experimental results on observables such as Δm_d, Δm_s, $|V_{ub}/V_{cb}|$, ϵ_K, and $\sin(2\beta)$ together with theoretical inputs and unitarity conditions [55,62,63]. The constraint from our knowledge on the ratio $\Delta m_s/\Delta m_d$ is more effective in limiting the position of the apex of the CKM unitarity triangle than the one obtained from the Δm_d measurements alone, due to the reduced hadronic uncertainty in Eq. (75.18). We also note that the measured value of Δm_s is consistent with the Standard Model prediction obtained from CKM fits where no experimental information on Δm_s is used, *e.g.*, 17.25 ± 0.85 ps^{-1} [62] or $16.54^{+0.50}_{-0.30}$ ps^{-1} [63].

Information on $\Delta\Gamma_s$ can be obtained from the study of the proper time distribution of untagged B_s^0 samples [64]. In the case of an inclusive B_s^0 selection [65], or a flavor-specific (semileptonic or hadronic) B_s^0 decay selection [22, 66–68], both the short- and long-lived components are present, and the proper time distribution is a superposition of two exponentials with decay constants $\Gamma_{\rm L,H} = \Gamma_s \pm \Delta\Gamma_s/2$. In principle, this provides sensitivity to both Γ_s and $(\Delta\Gamma_s/\Gamma_s)^2$. Ignoring $\Delta\Gamma_s$ and fitting for a single exponential leads to an estimate of $1/\Gamma_s$ (called effective lifetime) with a relative bias proportional to $(\Delta\Gamma_s/\Gamma_s)^2$. An alternative approach, sensitive to first order in $\Delta\Gamma_s/\Gamma_s$, is to determine the effective lifetime of untagged B_s^0 decays to pure CP eigenstates; measurements exist for $B_s^0 \to D_s^+ D_s^-$ [67], $B_s^0 \to K^+K^-$ [68,69], $B_s^0 \to J/\psi\eta$ [70], $B_s^0 \to J/\psi f_0(980)$ [71], $B_s^0 \to J/\psi\pi^+\pi^-$ [54,72,73], $B_s^0 \to J/\psi K_S^0$ [74], and $B_s^0 \to \mu^+\mu^-$ [75]. The extraction of $1/\Gamma_s$ and $\Delta\Gamma_s$ from such measurements, discussed in detail in Ref. [76], requires additional information in the form of theoretical assumptions or external inputs on weak phases and hadronic parameters. In what follows, we only use the effective lifetimes of decays to CP-even ($D_s^+ D_s^-$, $J/\psi\eta$) and CP-odd ($J/\psi f_0(980)$, $J/\psi\pi^+\pi^-$) final states where CP conservation can be assumed.

The best sensitivity to $1/\Gamma_s$ and $\Delta\Gamma_s$ is achieved by the time-dependent measurements of the $B_s^0 \to J/\psi K^+K^-$ (including $B_s^0 \to J/\psi\phi$) and $B_s^0 \to \psi(2S)\phi$ decay rates performed at CDF [77], DØ [78], ATLAS [79], CMS [33, 80] and LHCb [30, 81–83], where the CP-even and CP-odd amplitudes are separated statistically through a full angular analysis. The LHCb collaboration analyzes the $B_s^0 \to J/\psi K^+K^-$ decay considering that the K^+K^- system can be in a P-wave or S-wave state, and measures the dependence of the strong phase difference between the P-wave and S-wave amplitudes as a function of the K^+K^- invariant mass [30, 84]; this allows the unambiguous determination of the sign of $\Delta\Gamma_s$, which is found to be positive. All these studies use both untagged and tagged B_s^0 candidates and are optimized for the measurement of the phase $\phi_s^{c\bar{c}s}$ that describes CP violation in the interference between B_s^0–$\overline{B}_s^0$ mixing and decay in $b \to c\bar{c}s$ transitions. The published $B_s^0 \to J/\psi K^+K^-$, $J/\psi\phi$ and $\psi(2S)\phi$ analyses [30, 33, 77–83] are combined in a multi-dimensional fit including all measured parameters and their correlations. To account for a tension in the time and angular parameters, scale factors are applied on the combined uncertainty of each parameter where a discrepancy arise. For example, the scale factors on the uncertainties of $\Delta\Gamma_s$, Γ_s and $\phi_s^{c\bar{c}s}$ are 1.72, 2.56 and 1.00, respectively. The averages are then further refined by applying

Table 75.1: $\overline{\chi}$ and b-hadron fractions (see text).

	Z decays [96]	Tevatron [96]	LHC ($\sqrt{s}$) [97,98]
$\overline{\chi}$	0.1259 ± 0.0042	0.147 ± 0.011	
$f_u = f_d$	0.408 ± 0.007	0.344 ± 0.021	
f_s	0.100 ± 0.008	0.115 ± 0.013	
$f_{\rm baryon}$	0.084 ± 0.011	0.198 ± 0.046	
f_s/f_d	0.246 ± 0.023	0.333 ± 0.040	0.239 ± 0.007 (7 TeV)
			0.239 ± 0.008 (8 TeV)
			0.254 ± 0.008 (13 TeV)

constraints from the effective lifetime measurements with flavor-specific [22,66–68] and pure CP [54,67,70–73] final states, to yield

$$\Delta\Gamma_s = +0.084 \pm 0.005 \text{ ps}^{-1} \text{ and } 1/\Gamma_s = 1.520 \pm 0.005 \text{ ps}\,, \quad (75.20)$$

or, equivalently,

$$1/\Gamma_{\rm L} = 1.429 \pm 0.007 \text{ ps} \quad \text{and} \quad 1/\Gamma_{\rm H} = 1.624 \pm 0.009 \text{ ps}\,, \quad (75.21)$$

in good agreement with the Standard Model prediction $\Delta\Gamma_s = +0.091 \pm 0.013$ ps^{-1} [9].

Estimates of $\Delta\Gamma_s/\Gamma_s$ obtained from measurements of the $B_s^0 \to D_s^{(*)+} D_s^{(*)-}$ branching fractions are not included in the average, since they are based on the questionable [7] assumption that these decays account for all CP-even final states.

75.5 Average b-hadron mixing probability and b-hadron production fractions at high energy

Mixing measurements can significantly improve our knowledge on the fractions f_u, f_d, f_s, and $f_{\rm baryon}$, defined as the fractions of B_u, B_d^0, B_s^0, and b-baryons in an unbiased sample of weakly-decaying b hadrons produced in high-energy collisions. Indeed, time-integrated mixing analyses using lepton pairs from $b\overline{b}$ events at high energy measure the quantity

$$\overline{\chi} = f'_d\,\chi_d + f'_s\,\chi_s\,, \quad (75.22)$$
