Abstract. The broad physics reach of the LUX-ZEPLIN (LZ) experiment covers rare phenomena beyond the direct detection of dark matter. We report precise measurements of the extremely rare decay of ^{124}Xe through the process of two-neutrino double electron capture ($2\nu 2\text{EC}$), utilizing a $1.39\text{ kg} \times \text{yr}$ isotopic exposure from the first LZ science run. A half-life of $T_{1/2}^{2\nu 2\text{EC}} = (1.09 \pm 0.14_{\text{stat}} \pm 0.05_{\text{sys}}) \times 10^{22}\text{ yr}$ is observed with a statistical significance of 8.3σ , in agreement with literature. First empirical measurements of the KK capture fraction relative to other K-shell modes were conducted, and demonstrate consistency with respect to recent signal models at the 1.4σ level.

1. Introduction

Alongside a world-leading sensitivity to keV-scale scatters from weakly interacting massive particles (WIMPs), dual-phase xenon time projection chambers (TPCs) are also capable of searching for rare phenomena beyond dark matter interactions. Most notably, this encompasses experimental probes for the fundamental nature of the neutrino mass such as neutrinoless double beta decay ($0\nu\beta\beta$), the observation of which would indicate that neutrinos are Majorana particles [1]. Neutrinoless double electron capture ($0\nu 2\text{EC}$) is an analogous process that would be associated with the proton-rich side of the binding energy parabola for even-even isobars [2–4]; $0\nu 2\text{EC}$ decays have yet to be observed, with extremely long expected half-lives in excess of 10^{29} yr [5]. Models and predictions for this process may be developed through measurements of the adjacent process of two-neutrino double electron capture ($2\nu 2\text{EC}$) [6], which involves the absorption of two atomic electrons and the subsequent conversion of a pair of protons into neutrons, along with the simultaneous emission of two neutrinos. Measured half-lives for this decay inform the underlying nuclear matrix element $M^{(2\nu)}$ through the relation

$$(T_{1/2}^{2\nu 2\text{EC}})^{-1} = G_{2\nu}^{2\text{EC}} g_A^4 |m_e c^2 M^{(2\nu)}|^2, \quad (1)$$

where g_A denotes the weak axial-vector coupling strength, m_e is the electron mass, and the phase space factor $G_{2\nu}^{2\text{EC}}$ is proportional to the reaction Q-value taken to the fifth power [7]. Thus far, $2\nu 2\text{EC}$ has only been observed for ^{130}Ba [8, 9], ^{78}Kr [10, 11], and ^{124}Xe [12, 13].

In this work, the extensive physics program of the LUX-ZEPLIN (LZ) experiment is highlighted with a precise measurement of the ^{124}Xe decay half-life through $2\nu 2\text{EC}$. This result is extended with the first measurement of the relative capture fractions between atomic shell combinations. A brief description of the LZ experiment and its first exposure is provided in section 2. This is followed by a detailed overview of the analysis given in section 3, which covers the employed signal model, construction of the background model with an emphasis on the dominant ^{125}I background, and an outline of the fit procedure. Finally, results of the analysis, including the measured relative capture fractions, are discussed in section 4.

2. The LUX-ZEPLIN experiment

The LZ experiment [14, 15] is situated 1480 m underground within the Davis Cavern at the Sanford Underground Research Facility in Lead, South Dakota. With a 1100 m (4300 m.w.e) rock overburden, the flux of cosmic muons in the cavern is attenuated by a factor of 3×10^6 with respect to that at the surface [16, 17]. The detector is housed within a tank holding 238 t of ultra-pure water for additional shielding from ambient radiation. Combined with an extensive radioassay campaign and strict cleanliness protocols in assembly, this establishes an ultra-low background environment [18].

At the core of the LZ detector is a dual-phase xenon TPC with an active volume containing 7 t of liquid xenon (LXe). Energy depositions in the LXe generate vacuum ultraviolet scintillation photons (S1), as well as ionization electrons. The electrons drift to the liquid surface under a vertical electric field and are subsequently extracted into the gas phase by a stronger field, where they produce a secondary scintillation signal (S2). Light is detected by two arrays of 3-inch photomultiplier tubes (PMTs), with 253 at the top and 241 at the bottom. To enhance background rejection, the detector features two anti-coincidence veto systems: an optically isolated LXe skin surrounding the TPC, which is instrumented with 93 1-inch and 38 2-inch PMTs; and a near-hermetic outer detector (OD) comprised of acrylic tanks filled with gadolinium-loaded liquid scintillator, viewed by 120 8-inch PMTs in the water tank. These detectors enable the rejection of events with coincident gamma rays or neutrons.

The detector response is calibrated with a variety of dedicated sources [19]. In particular, dispersed mono-energetic sources such as $^{83\text{m}}\text{Kr}$ and $^{131\text{m}}\text{Xe}$ are used to correct the S1 and S2 observables for position-dependent effects; the corrected versions are denoted as S1c and S2c, and are measured in units of photons detected (phd) [20]. These quantities are combined to reconstruct the energy of an event according to

$$E = W \left(\frac{\text{S1c}}{g_1} + \frac{\text{S2c}}{g_2} \right), \quad (2)$$

where $g_1 = (0.114 \pm 0.002)$ phd/photon and $g_2 = (47.1 \pm 1.1)$ phd/electron respectively describe the photon detection efficiency and the effective charge gain, and $W = 13.5$ eV is the assumed work function [21].

Of the calibration sources deployed during the first exposure of LZ, a 4.5 d calibration campaign partway through the run is of particular relevance to this work. This utilized neutrons generated by deuterium-deuterium (DD) fusion to characterize the nuclear recoil response of the detector [22, 23]. The deployment of neutron calibrations introduces additional transient backgrounds from activation of xenon isotopes. Treatment of these sources for the background model is detailed in section 3.2.

3. Analysis overview

The data analyzed here are from Science Run 1 (SR1), acquired between December 23rd, 2021, and May 11th, 2022. For the first LZ WIMP search (WS) result [20], a suite of data quality cuts were developed to target accidental coincidence backgrounds, which originate from false pairings of uncorrelated S1s and S2s, as well as other unique detector pathologies such as photon pileup and delayed electron emission. A number of these cuts involved the exclusion of periods with elevated detector activity, and hence posed a substantial impact on the accrued live time. For the purpose of this analysis, the contribution of such effects is not significant as the focus is at a higher energy regime, and hence only a minimal set of cuts need be applied: a fiducial volume (FV) cut to reject external backgrounds near the TPC boundaries; pulse area thresholds of ($S1c > 100$ phd) and ($S2 > 600$ phd) to mitigate for tails of accidental backgrounds; and vetoes from the skin and OD to tackle events with multiple interaction vertices. This results in an overall exposure of (96.4 ± 1.0) live days. The same (5.5 ± 0.2) t FV definition was maintained as the SR1 WS analysis. Constraints on various background rates in the FV were informed by dedicated measurements from several studies [24].

3.1. Signal model

For ^{124}Xe , $2\nu 2\text{EC}$ proceeds as

with a reaction Q-value of (2856.73 ± 0.12) keV [25]. Most of this energy is carried away by the neutrinos, whilst the nuclear recoil energy is only $\mathcal{O}(10)$ eV [26], and hence the only detectable signal consists entirely of deposits from the X-rays and Auger cascade in the subsequent atomic de-excitation of the ^{124}Te daughter. The energy of the experimental signature is determined by the combination of atomic shells from which electrons were captured. Here we assume the same relative shell capture fractions and energies as the XENON collaboration [13]; these are summarized in table 1. All capture combinations are expected to manifest as single-scatter (SS) interactions due to the sub-millimeter reach in LXe at the energy scale of the emitted X-rays and Auger electrons.

The half-life $T_{1/2}^{2\nu 2\text{EC}}$ is related to the activity $A_{2\nu 2\text{EC}}$ by

$$T_{1/2}^{2\nu 2\text{EC}} = \frac{\eta N_A}{A_{2\nu 2\text{EC}} M_A} \ln 2, \quad (4)$$

where N_A is Avogadro's constant, $M_A = (131.293 \pm 0.006)$ g/mol is the molar mass of xenon [27], and η is the isotopic abundance of ^{124}Xe . It is assumed that the isotopic composition of xenon in LZ is consistent with that of atmospheric xenon. At the natural ^{124}Xe abundance $\eta = (0.0952 \pm 0.0003)\%$ [28], the isotopic exposure is $1.39 \text{ kg} \times \text{yr}$. Out of ~ 400 decays over the course of this exposure (for $T_{1/2}^{2\nu 2\text{EC}} = 1.1 \times 10^{22} \text{ yr}$ [13]), < 10 events are expected to occur from double L-shell (LL) and higher-shell electron captures.

Therefore, a 20–100 keV interval was set as the region of interest (ROI) for this search; the lower bound reflects the lack of sensitivity to these modes, whereas the upper bound encapsulates the energies of flat backgrounds extending beyond the signal peaks.

Table 1. Energies and relative capture fractions for different shell combinations in the ^{124}Xe $2\nu 2\text{EC}$ signal model, as adopted in [13]. Decay modes are labeled by the combination of shells from which electrons were captured.

Decay mode	Capture fraction [%]	Energy [keV]
KK	72.4	64.3
KL	20.0	36.7–37.3
KM	4.3	32.9–33.3
KN	1.0	32.3–32.4
LL	1.4	8.8–10.0
Other	0.9	< 10

3.2. Background model

The majority of backgrounds within the 20–100 keV $2\nu 2\text{EC}$ ROI, listed in table 2, exhibit flat and continuous energy spectra, enabling straightforward modeling. Furthermore, their rates in SR1 have been well-constrained by a variety of sideband studies, as reported in reference [24]. A subset of these backgrounds is comprised of unstable xenon isotopes, which were produced via cosmogenic activation during transport, as well as through neutron activation as a result of deploying neutron sources to calibrate the detector response to nuclear recoils. Aside from ^{133}Xe , which features as a beta spectrum with a shoulder starting at the 81.0 keV gamma-ray line [29], these can deposit energies within close proximity to the secondary (KL + KM + KN) ^{124}Xe signal peak, denoted here as KX. Isotopes with decays involving a single electron capture, namely ^{125}Xe and ^{127}Xe , involve cascades with a total deposited energy of 33.2 keV for K-shell captures [30]. However, these decays are accompanied by a gamma ray, which often gives rise to a multiple-scatter (MS) topology or is tagged by the veto detectors, with an efficiency of $(78.0 \pm 5.0)\%$, and hence they are suppressed by the SS and veto cuts. Similarly, $^{129\text{m}}\text{Xe}$ emits a pair of coincident 196.6 keV and 39.6 keV internal conversion electrons in its transitions to the ground state [31], with a very low probability of detecting the lower energy gamma ray in isolation.

An especially problematic background is ^{125}I , which is produced by the neutron activation of ^{124}Xe according to the following steps

and decays to an excited state of ^{125}Te via electron capture as

Table 2. Summary of backgrounds to the ^{124}Xe $2\nu 2\text{EC}$ measurement. Reported rate estimates are for SS events within the ROI, after the application of area thresholds, vetoes, and the FV cut. Solar neutrino and detector material backgrounds consist of a sum over all relevant sources. K-shell EC and single gamma-ray rates are for cases where the skin veto fails to tag an outgoing associated gamma ray; ^{125}Xe is excluded as its average rate is effectively zero in this context. Half-lives are quoted from nuclear data sheets [29–32], and otherwise omitted in cases where they exceed the lifetime of the experiment, or for sources that are continually produced.

Source	ROI signature	Half-life	Average rate [mHz]
^{125}I	Multiple EC peaks	59.4 d	$(1.75 \pm 0.38) \times 10^{-1}$
^{127}Xe	K-shell EC (33.2 keV)	36.3 d	$(3.98 \pm 0.25) \times 10^{-3}$
$^{129\text{m}}\text{Xe}$	γ (39.6 keV)	8.9 d	$(7.31 \pm 0.52) \times 10^{-4}$
^{133}Xe	$\beta + \gamma$ (81.0 keV)	5.2 d	$(7.36 \pm 0.75) \times 10^{-1}$
^{136}Xe $2\nu\beta\beta$	continuous	-	$(1.34 \pm 0.32) \times 10^{-1}$
^{212}Pb	continuous	-	$(5.70 \pm 0.03) \times 10^{-3}$
^{214}Pb	continuous	-	$(2.16 \pm 0.05) \times 10^{-1}$
^{85}Kr	continuous	-	$(3.83 \pm 0.92) \times 10^{-2}$
Solar neutrinos	continuous	-	$(2.71 \pm 0.07) \times 10^{-2}$
Materials	continuous	-	$(8.25 \pm 0.03) \times 10^{-4}$

The combination of the subsequent de-excitation cascades and the 35.5 keV nuclear transition of the ^{125}Te daughter generates peaks that significantly overlap with the ^{124}Xe signals. For instance, the K-shell capture mode of ^{125}I has an associated total energy of 67.3 keV; with a measured energy resolution of $(4.5 \pm 0.4)\%$, this peak is 1σ from the 64.3 keV KK peak ^{124}Xe . This is similarly the case for the other ^{125}I decay modes, as shown in table 3.

Table 3. Energies and capture fractions for ^{125}I background peaks. The capture fractions are quoted from [33], and the binding energies are taken from [34, 35] with uncertainties excluded as they are of $\mathcal{O}(1)$ eV.

Decay mode	Capture fraction [%]	Energy [keV]
$\gamma + \text{K}$	80.11 ± 0.17	67.3 (35.5 + 31.8)
$\gamma + \text{L}$	15.61 ± 0.13	40.4 (35.5 + 4.9)
$\gamma + \text{M}$	3.49 ± 0.07	36.5 (35.5 + 1.0)

In SR1, ^{125}I was predominantly produced during the DD calibration campaign. Whilst it has a natural half-life of 59.4 d [32], it is efficiently removed by the LZ online purification system, which employs a hot zirconium getter [14]. To quantify the removal rate during SR1, the 67.3 keV peak associated with K-shell ECs in ^{125}I was selected in data immediately following the DD calibration using the 2σ contour of a two-dimensional Gaussian fit of the corresponding population in (S1c, S2c) space. Events passing this selection along with the specified minimal set of cuts were divided into one-day bins according to their registered trigger timestamps, with the rate calculated

in each bin adjusted for the experimental dead time.

The observed time profile of ^{125}I rates over the course of SR1 is visualized in figure 1, with a pronounced growth due to neutron activation following the DD calibrations. To model the behavior of its rate in the post-DD period, the number of ^{125}I nuclei at a given time, $N_{125\text{I}}(t)$, was described by a differential equation

$$\frac{dN_{125\text{I}}(t)}{dt} = \lambda_{125\text{Xe}} N_{125\text{Xe}}(t) - (\lambda_{125\text{I}} + \lambda_g) N_{125\text{I}}(t), \quad (8)$$

in which the positive term represents the production of ^{125}I from the decay of ^{125}Xe , and the effective decay constant $\lambda_{\text{eff}} = (\lambda_{125\text{I}} + \lambda_g)$ consists of a getter removal component λ_g and a natural decay component $\lambda_{125\text{I}}$. A fit to the post-DD exponential decay in figure 1 yields a getter removal half-life of $t_{1/2}^g = (3.8 \pm 0.2) \text{ d}$, which translates into an effective ^{125}I half-life of $t_{1/2}^{\text{eff}} = (3.6 \pm 0.2) \text{ d}$ with the natural decay component included. For reference, the values reported for $t_{1/2}^g$ by LUX and XENON1T are $(3.7 \pm 0.3) \text{ d}$ and $(4.6 \pm 1.6) \text{ d}$, respectively [13, 26]. In each case, the corresponding getter removal time constant was consistent with the interval for xenon to flow through one cycle of the circulation system.

Figure 1. Rate of events in the FV over SR1 for a selection dominated by ^{125}I . Along with skin and OD vetoes, a 2σ elliptical contour was applied from a two-dimensional Gaussian fit to the ^{125}I K-shell EC population in (S1c, S2c) space. The overlaid profile represents a combination of the neutron activation model and a fit to the post-DD decay trend. The additional intermission window beyond the DD calibration period was caused by a circulation event, over which the detector purity temporarily decreased.

In addition, the expected amount of ^{125}I was also constrained by an activation model. The activation rate was characterized using DD calibration data by profiling the rates of both ^{125}I and ^{125}Xe within the vicinity of the neutron conduit at the top of the TPC. This subsequently informed the predicted ^{125}I rate through the DD period given the measured getter removal time constant. The projected rate within the post-DD

period is in very close agreement with the direct fit of the decay trend, and hence the latter is adopted for the combined model curve overlaid in figure 1.

In general, the baseline rate was expected to consist of continuous backgrounds, some contamination from the $2\nu\text{KK}$ mode of ^{124}Xe , and a flat rate of ^{125}I from thermal neutron activation. However, a shift was observed between the pre-DD and post-DD baseline rates, from (16.1 ± 3.2) counts/d down to (10.0 ± 0.5) counts/d. This was attributed to a residual ^{125}I population in the pre-DD window from activation during longer neutron calibrations performed a month prior to the start of SR1. With different circulation settings used in the physics commissioning period leading up to SR1, such as a higher flow rate through the getter, the ^{125}I removal efficiency was slightly lower and hence extended the pre-DD decay curve. Nevertheless, the low pre-DD ^{125}I rate is sufficiently well-approximated as flat over time.

3.3. Fit procedure

Since the signals and backgrounds both produce electron recoils (ERs), reconstructed energy was adopted as the main observable. Furthermore, rather than excluding a post-DD window with elevated background rates, the full exposure can be preserved by leveraging the temporal variation of the primary ^{125}I background, which motivates the use of calendar time as an additional observable. Given the substantial overlap in energy between ^{125}I and the signal, incorporating this temporal information leads to a boost in sensitivity.

Two-dimensional fits in energy and time were performed according to a binned extended maximum likelihood approach, using a likelihood function of the form

$$\ln \mathcal{L}(\mathbf{d}|\boldsymbol{\theta}, \boldsymbol{\mu}, \boldsymbol{\sigma}) = \sum_i^{N_E} \sum_j^{N_t} d_{ij} \ln f_{ij}(\boldsymbol{\theta}) - \nu(\boldsymbol{\theta}) - \sum_k^{N_c} \frac{1}{2} \left(\frac{\theta_k - \mu_k}{\sigma_k} \right)^2, \quad (9)$$

where observed counts d_{ij} and expected counts $f_{ij}(\boldsymbol{\theta})$ are divided into N_E 1 keV energy bins and N_t 1 d time bins. For each of the N_c signal plus background components, there is an associated energy PDF p_k and time PDF t_k , both of which are scaled by the corresponding rate parameter θ_k such that $f_{ij}(\boldsymbol{\theta}) = \sum_k^{N_c} \theta_k p_{ik} t_{jk}$. Energy spectra produced by the LZ parametric simulations chain were normalized to produce p_k [36], whereas t_k represents the live time distribution over calendar time scaled by rate profile of the k th component, which is either constant or an exponential decay. The extended Poisson term $\nu(\boldsymbol{\theta}) = \sum_i^{N_E} \sum_j^{N_t} f_{ij}(\boldsymbol{\theta})$ serves to include information from the total sample size.

To simplify the fit procedure, the SR1 dataset was split into pre-DD and post-DD subsets consisting of 23.1 and 73.3 live days each, and evaluated with a simultaneous likelihood fit. The model contains a total of 10 parameters: 6 are shared between the two likelihoods, and a pair of unique pre-DD and post-DD rates is associated with each of ^{125}I and ^{133}Xe as they are impacted by the DD calibrations. Rates for ^{212}Pb and detector materials were fixed as they were comparatively subdominant.

The model parameters θ are regularized by a Gaussian constraint term, which penalizes significant deviations from the expected rates μ as a fraction of their uncertainties σ . Whereas the signal term was left unconstrained, initial estimates for background rates and their constraints were derived from the results of sideband analyses [24]. In particular, tight constraints on ^{125}I were enabled by the activation model outlined in section 3.2. Goodness of fit is quantified in terms of the χ^2_λ metric, which is constructed by means of a Poisson likelihood ratio test [37].

4. Results and discussion

The outcome of the fit is presented in figure 2 as separate projections in energy and time, with a best-fit activity of $A_{2\nu 2\text{EC}} = (0.28 \pm 0.04)$ counts/kg/yr. Evaluation of a likelihood ratio test statistic with respect to the background-only case yields a significance of 8.3σ for the presence of a $2\nu 2\text{EC}$ signal. The half-life inferred using equation 4 is

$$T_{1/2}^{2\nu 2\text{EC}} = (1.09 \pm 0.14_{\text{stat}} \pm 0.05_{\text{sys}}) \times 10^{22} \text{ yr}, \quad (10)$$

which is in excellent agreement with the previously reported measurement by XENON1T at $T_{1/2}^{2\nu 2\text{EC}} = (1.1 \pm 0.2_{\text{stat}} \pm 0.1_{\text{sys}}) \times 10^{22} \text{ yr}$ [13]. A breakdown of the systematic uncertainties is given in table 4. The dominant contribution is formed by the uncertainty on the FV mass. Secondary sources of uncertainty stem from the energy reconstruction parameters g_1 and g_2 as calibrated for the WS, as well as the live time estimate.

Table 4. Summary of systematic uncertainties on the ^{124}Xe $2\nu 2\text{EC}$ half-life, with the total calculated by summing the individual contributions in quadrature.

Contribution	Uncertainty [10^{22} yr]	Relative uncertainty [%]
Fiducial mass	0.04	3.7
Energy reconstruction	0.02	1.8
Live time	0.01	0.9
Total	0.05	4.6

A first measurement of the relative capture fractions is performed by introducing an additional parameter for the KK fraction, allowing the two signal peaks to float separately. Relative ratios of modes comprising the KX peak were kept fixed. Bounds at $[0, 0.977]$ were imposed on this value, such that the 2.3% proportion of ^{124}Xe signal below the ROI is preserved, and the KX fraction can be inferred directly; the KK fraction was otherwise left unconstrained. The fitted KK and KX fractions are $(64.8 \pm 5.3)\%$ and $(32.9 \pm 5.3)\%$, with an associated overall $\chi^2_\lambda/N_{\text{dof}} = 4843.42/4461 = 1.09$. At 1.4σ away from the values in table 1, these fit results are reasonably consistent with the assumed model. Future LZ runs will enable more precise measurements of these fractions, and may provide sensitivity towards the substructure of the KX peak.

Figure 2. Simultaneous fit of pre-DD and post-DD subsets of SR1 projected into energy and time. Both ^{212}Pb and the detector material components were fixed as they are subdominant. The top panel is displayed with rates averaged over the pre-DD and post-DD time windows, whereas rates in the bottom panel were integrated over the entire ROI. Although ^{133}Xe appears to dominate in the time projection plot, it is well-separated from the signal peaks in energy. The residual plots show fractional differences between the best-fit model $\mathbf{m}$ and the data $\mathbf{d}$ to illustrate the fit quality, with the most significant differences occurring in the low-statistics regions between features. The overall $\chi^2_{\lambda}/N_{\text{dof}} = 4451.22/4462 = 1.00$ is indicative of a high quality fit. The energy-only goodness of fit, calculated by marginalizing over time, is $\chi^2_{\lambda}/N_{\text{dof}} = 197.34/150 = 1.32$.

The measured half-life is compared with recent predictions from various theoretical frameworks, as well as measurements and lower limits set by other experiments, in figure 3. The result obtained here is compatible with effective theory (ET) and large-scale nuclear shell model (NSM) calculations [38], and is in agreement with those from the quasiparticle random-phase approximation (QRPA) [39,40] approach at the 2σ level. Moreover, this measurement is also consistent with the 90% confidence level lower limits set by XENON100 [41] and LUX [26], though a discrepancy is observed with respect to the limit produced by XMASS [42].

Figure 3. Comparison of the measured half-life with theoretical predictions represented by black bars and experimental lower limits indicated by dashed lines.

5. Conclusion and outlook

In this paper, we reported on the search for $2\nu 2EC$ of ^{124}Xe in the first science run of the LZ experiment. With an isotopic exposure of $1.39 \text{ kg} \times \text{yr}$, we observed a half-life of $T_{1/2}^{2\nu 2EC} = (1.09 \pm 0.14_{\text{stat}} \pm 0.05_{\text{sys}}) \times 10^{22} \text{ yr}$ at a significance of 8.3σ , demonstrating the versatility of LZ in exploring physics beyond its primary goal of searching for dark matter. We also report on the first measurement of the relative capture fractions for this decay, at $(64.8 \pm 5.3)\%$ and $(32.9 \pm 5.3)\%$ for the KK and summed (KL + KM + KN) modes respectively, which are relatively consistent with the adopted signal model [13]. Additional data from upcoming LZ exposures will allow for these capture fractions to be measured with higher precision, and will ultimately enable searches for rarer variants of ^{124}Xe decay, namely $2\nu EC\beta^+$ and $2\nu 2\beta^+$, along with their neutrinoless counterparts [5]. Moreover, it may be of interest to also probe for enhancements to recombination in ^{124}Xe decays in future work, as has been observed for single electron captures [43].

Acknowledgments
